The paramedic should obtain a baseline set of vital signs for every patient. Vital functions to be assessed include pulse rate, respiratory rate, and blood pressure. Other assessments may be indicated as well. These include monitoring the patient's oxygen saturation using pulse oximetry, and electrocardiogram (ECG) monitoring. Like the brief neuro exam, baseline measurements of vital functions help to identify positive and negative trends in the course of the patient's care. They also help to identify priority patients. As a rule, vital signs should be measured and recorded every 15 minutes for stable patients, and at least every 5 minutes for patients who are unstable or potentially unstable.

IDENTIFYING PATIENTS WHO NEED PRIORITY CARE AND TRANSPORT

The paramedic uses the findings from the primary survey to identify life threats and priority patients. These are unstable patients or potentially unstable patients who need stabilization and rapid transport to an emergency facility. Examples of priority patients include those who have the following:

- Poor general impression
- Decreased level of consciousness (depressed or absent gag or cough reflex)
- No response to commands (unresponsiveness)
- Difficulty breathing
- Shock (hypoperfusion)
- Complicated childbirth
- Chest pain with a systolic pressure less than 100 mm Hg
- Uncontrolled bleeding
- Severe pain anywhere
- Multiple injuries

Integration of Treatment/Procedures Needed to Preserve Life

In some cases, definitive care for medical patients can be initiated in the prehospital setting. For example, patients who have altered consciousness related to hypoglycemia or narcotic overdose should receive immediate interventions that may completely reverse their life-threatening signs and symptoms. In the case of severe respiratory emergencies, prehospital care can relieve severe hypoxic signs and symptoms before arrival at the hospital. Because of this, the time spent on-scene with medical patients may be slightly longer.

NOTE

For patients with stroke or myocardial infarction, life-saving care can begin at the scene, but simultaneous and rapid transport is also needed. The combination of initial on-scene care and rapid transport allows for time-sensitive and definitive treatment to be delivered at the hospital.

In contrast, most seriously injured trauma patients require short scene times and rapid transport. These patients should be taken to an appropriate trauma center or other medical facility for definitive care. Patients with internal bleeding, major fractures, head injury, and multiple-system trauma need life-saving care. This care can be provided only by specially trained physicians and support staff. Minimal time should be spent at the scene with these patients. Most trauma life-support training programs (e.g., basic trauma life support, prehospital trauma life support, and advanced trauma life support) recommend that patients needing immediate transport be stabilized and prepared for transport ("packaged") within 10 minutes after arrival of EMS.[5] Field management should be limited to airway control and ventilatory support, spinal immobilization, and major fracture stabilization. Intravenous fluid therapy should be initiated en route to the hospital. (Trauma management is addressed further in Part 9: Trauma.)

SUMMARY

- Sizing-up the scene consists of the initial steps performed on every emergency medical services response. These steps help to ensure scene safety. They also provide valuable information to the paramedic.
- Paramedics should ensure they have access to and wear appropriate personal protective equipment to protect against injury or illness related to an unsafe scene or infectious diseases.
- The primary assessment includes the paramedic's general impression of the patient, the assessment for life-threatening conditions, and the identification of priority patients requiring immediate care and transport.
- Assessment of life-threatening conditions entails a systematic evaluation of the patient's level of consciousness, airway, breathing, circulation, and disability. The patient should also be appropriately exposed during the primary assessment to detect life threats.
- Information from the primary survey is used to identify life threats and prioritize patients.
- The paramedic begins resuscitative measures such as airway maintenance, ventilatory assistance, and cardiopulmonary resuscitation immediately after recognizing the life-threatening condition that necessitates each respective maneuver.

CHAPTER

20 Secondary Assessment

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Define the purpose of the secondary assessment.
2. Describe physical examination techniques commonly used in the prehospital setting.
3. Describe the examination equipment commonly used in the prehospital setting.
4. Describe the general approach to physical examination.
5. Outline the steps of a comprehensive physical examination.
6. Detail the components of the mental status examination.
7. Distinguish between normal and abnormal findings in the mental status examination.
8. Outline the steps in the general patient survey.
9. Distinguish between normal and abnormal findings in the general patient survey.
10. Describe physical examination techniques used for assessment of specific body regions.
11. Distinguish between normal and abnormal findings when assessing specific body regions.
12. Outline the process of patient reassessment.
13. State modifications to the physical examination that are necessary when assessing children.
14. State modifications to the physical examination that are necessary when assessing the older adult.

KEY TERMS

anisocoria Normal or congenital unequal pupil size.

aphasia Loss of the power of speech.

apical impulse A pulsation of the left ventricle of the heart, palpable and sometimes visible at the fifth intercostal space to the left of the midline.

ataxia Failure of muscle coordination.

auscultation A technique that requires the use of a stethoscope and is used to assess body sounds produced by the movement of various fluids or gases in organs or tissues.

bronchial breath sounds Breath sounds heard only over the trachea and are the highest in pitch.

bronchovesicular breath sounds Normal breath sounds heard over the major bronchi and over the upper right posterior lung field.

bruit An abnormal sound or murmur heard while auscultating an artery, organ, or gland.

crackle A fine, bubbling sound heard on auscultation of the lung; it is produced by air entering distal airways and alveoli that contain serous secretions.

crepitus A grating sound associated with rubbing of bone fragments.

deep tendon reflexes Reflexes elicited by sensory afferents from muscle rather than bone.

diastolic blood pressure The minimum level of blood pressure measured between contractions of the heart.

dysconjugate gaze Deviation of the eyes to opposite sides.

dysarthria Difficult and poorly articulated speech resulting from poor control over the muscles of speech.

dysphonia An abnormality in the speaking voice, such as hoarseness.

epistaxis Bleeding from the nose.

heart murmur An abnormal heart sound caused by altered blood flow into a chamber or through a valve.

inspection A visual assessment of the patient and surroundings.

nystagmus Involuntary jerking movements of the eyes.

palpation A technique in which an examiner uses the hands and fingers to gather information from a patient by touch.

percussion A technique used to evaluate the presence of air or fluid in body tissues.

pericardial friction rub A dry, grating sound heard with a stethoscope during auscultation; suggestive of pericarditis.

PERRL Acronym for pupils that are equal, round, and react to light.

physical examination An assessment of a patient that includes examination techniques, measurement of vital signs, an assessment of height and weight, and the skillful use of examination equipment.

pleural friction rub A rubbing or grating sound that occurs as one layer of the pleural membrane slides over the other during breathing.

pronator drift test A test to evaluate balance and upper extremity weakness; performed by having the patient close the eyes and hold both arms out from the body.

pulse deficit A condition that exists when the radial pulse is less than the ventricular rate; it indicates a lack of peripheral perfusion.

reassessment The ongoing assessment that follows the paramedic's initial evaluation of the patient.

rhonchi Abnormal sounds heard on auscultation of a respiratory airway obstructed by thick secretions, muscular spasm, neoplasm, or external pressure.

Romberg's test A test to evaluate stance and balance; performed by having the patient stand erect with the feet together and arms at the sides.

secondary assessment Consists of physical examination techniques, measurement of vital signs, an assessment of body systems, and the skillful use of examination equipment.

six cardinal fields of gaze A test to evaluate extraocular muscle function; performed by having the patient visually track an object in six visual fields in an H pattern.

stridor An abnormal, high-pitched musical sound caused by obstruction in the trachea or larynx.

subcutaneous emphysema The presence of air in the subcutaneous tissues.

superficial reflexes Reflexes elicited by sensory afferents from skin.

systolic blood pressure The blood pressure measured during the period of ventricular contraction.

temporomandibular joint dysfunction Acute or chronic inflammation in the temporomandibular joint.

thrill A fine vibration felt by an examiner's hands over the site of an aneurysm or on the pericardium.

tidal volume The volume of gas inhaled or exhaled during a normal breath.

tympany A hollow drum-like sound produced when a gas-containing cavity is percussed.

vesicular breath sounds Breath sounds heard over most of the lung fields; the major normal breath sound.

wheeze A form of rhonchus characterized by a high-pitched, musical quality; it is caused by high-velocity airflow through narrowed airways.

The paramedic must have a wide range of knowledge and skills to perform a comprehensive physical examination and to make effective clinical care decisions. This chapter presents the techniques of the basic physical examination. Some of the techniques presented will have application to examinations more likely to be performed in the expanded scope of practice activities. The goal of this chapter is to prepare the paramedic with the tools and skills needed to perform a thorough physical examination in any patient care setting.

(Courtesy Monroe Yancie, St. Louis, Mo.)

NOTE

Chapter 19 addressed the components of the primary survey. That chapter focused on recognizing and managing life-threatening conditions in the initial patient care encounter. This chapter is devoted to the techniques of the detailed physical examination—the examination performed in the secondary assessment. Like the primary survey, the secondary assessment integrates patient assessment findings with knowledge of pathophysiology. This helps to form a final impression and to identify an appropriate treatment plan.

SECONDARY ASSESSMENT: APPROACH AND OVERVIEW

The **secondary assessment** consists of physical examination techniques, measurement of vital signs, an assessment of body systems, and the skillful use of examination equipment (Box 20-1). Physical examination techniques will vary by patient, depending on the chief complaint, present illness, and history. The appropriate assessment of the patient depends on:

- The stability of the patient
- The complaint and history

- The patient's ability to communicate
- The potential for unrecognized illness

NOTE

Some aspects of the physical assessment may not be appropriate for all patients. For example, if the patient has a life-threatening injury or illness, a primary survey and rapid transport may be all that is provided in the prehospital phase of care. If the patient is stable, however, and has a significant history, a more thorough secondary assessment may be indicated. The order of care for this group of patients is:

1. Scene size-up
2. Primary survey
3. Secondary assessment
4. Reassessment

Examination Techniques

Four techniques commonly are used in the physical examination. These are inspection, palpation, percussion, and auscultation. These terms are referred to often in this text because they relate to the evaluation of specific body systems. Depending on the situation, these techniques may be the sole method for evaluating a patient. For example, this may be the case with an unconscious trauma patient. In other cases, these techniques may be integrated with history taking and other care procedures. If time permits, the paramedic should explain each technique that requires touch to the patient before performing it.

CRITICAL THINKING

You arrive at the scene of a motor vehicle crash. What will you look for during your initial patient inspection?

INSPECTION

Inspection is the visual assessment of the patient and the surroundings. This technique can alert the paramedic to the patient's mental status. Inspection also can alert the paramedic to possible injury or underlying illness. Patient hygiene, clothing, eye gaze, body language and position, skin color, and odor are significant inspection findings. The EMS response may be to the patient's home. In this case, the paramedic should make a visual inspection for cleanliness, prescription medicines, illegal drug paraphernalia, weapons, and signs of alcohol use. These and other items seen by EMS personnel can play a key role in determining patient care activities.

PALPATION

Palpation is a technique in which the paramedic uses the hands and fingers to gather information by touch. Generally, the paramedic uses the palmar surface of the fingers and the finger pads to palpate for texture, masses, fluid, and **crepitus** and to assess skin temperature (Figure 20-1). The dorsal and ulnar hand surfaces may also be used. Palpation may be either superficial or deep; *the applications for each are addressed throughout this chapter*. Examining a patient by palpation is a form of invasion of the patient's body. Therefore the approach should be gentle and should be initiated with respect.

PERCUSSION

Percussion is used to evaluate the presence of air or fluid in body tissues. This technique is performed by the paramedic striking one finger against another to produce vibrations and sound waves of underlying tissue. Sound waves are heard as percussion tones (resonance). They are determined by the density of the tissue being examined. The

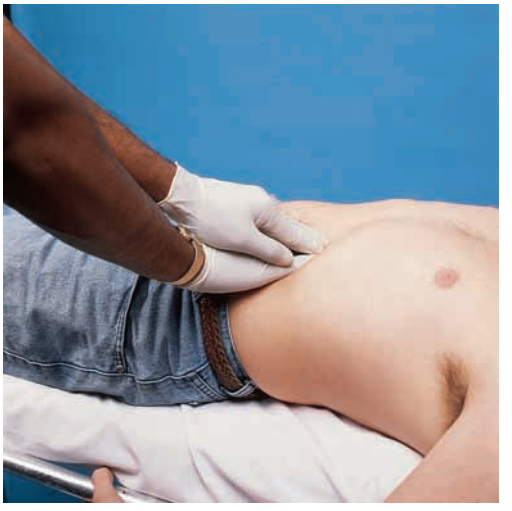

FIGURE 20-1 Deep bimanual palpation.

denser the body area, the lower the pitch of the percussion tone. To percuss, the paramedic places the first joint of the middle finger of the nondominant hand on the patient, keeping the rest of the hand poised above the skin. The fingers of the other hand should be flexed and the wrist action loose. The paramedic then snaps the wrist of the dominant hand downward with the tip of the middle finger tapping the joint of the finger that is on the body surface. The tap should be sharp and rigid, percussing the same area several times to interpret the tone (Figure 20-2). Box 20-2 describes percussion tones and examples of each. As with any other examination technique, percussion requires practice to obtain the skill needed for the physical examination.

FIGURE 20-2 Percussion technique.

AUSCULTATION

Auscultation calls for the use of a stethoscope. This technique is used to assess body sounds made by the movement of various fluids or gases in the patient's organs or tissues. Auscultation is best performed in a quiet environment to focus on each body sound being assessed. The paramedic should isolate a particular area to note characteristics of intensity, pitch, duration, and quality. In the prehospital setting, auscultation most often is used to assess blood pressure and to evaluate breath sounds, heart sounds, and bowel sounds. To auscultate, the paramedic should place the diaphragm of the stethoscope firmly against the patient's skin for stabilization (Figure 20-3). If a bell end piece is used, it should be positioned lightly on the body surface. This prevents the damping of vibrations.

BOX 20-2 Percussion Tones and Examples

Percussion Tone	Example
Tympany (the loudest)	Gastric bubble
Hyperresonance	Air-filled lungs (e.g., chronic obstructive pulmonary disease and pneumothorax)
Resonance	Healthy lungs
Dullness	Liver
Flat (the quietest)	Muscle

NOTE

The bell and diaphragm end pieces of a stethoscope selectively emphasize sounds of different frequencies. The bell is central for listening to low-pitched sounds (e.g., certain heart sounds). In contrast, the diaphragm filters out low-pitched sounds and therefore emphasizes high-pitched ones. Examples of high-pitched sounds include breath sounds and bowel sounds.

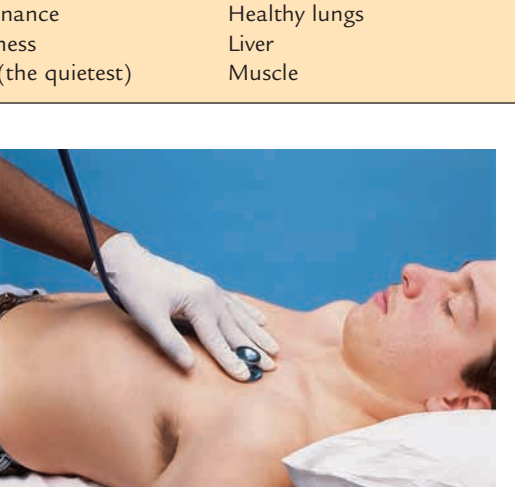

FIGURE 20-3 Position of the stethoscope between the index and middle fingers.

Examination Equipment

Basic equipment used during the comprehensive physical examination includes the stethoscope, ophthalmoscope, otoscope, and blood pressure cuff. The ophthalmoscope and otoscope are nontraditional EMS tools. They are being introduced to the paramedic with expanded scope of practice. These devices will not be used routinely with patients in the prehospital setting.

NOTE

Monitoring devices such as capnography, electrocardiography, and devices used to test blood chemistry are also frequently used in the prehospital setting. These devices will be described throughout this text by subject matter.

STETHOSCOPE

The stethoscope is used to evaluate sounds created by the cardiovascular, respiratory, and gastrointestinal systems. The three major types of stethoscopes are acoustic stethoscopes, magnetic stethoscopes, and electronic stethoscopes (Figure 20-4).

FIGURE 20-4 Stethoscope types. **A,** Acoustic. **B,** Electronic. (Courtesy 3M Healthcare, St Paul, Minn.)

Acoustic stethoscopes transmit sound waves from the source to the paramedic's ears. Most have a rigid diaphragm. This diaphragm transmits high-pitched sounds. The bell end piece transmits low-pitched sounds.

Magnetic stethoscopes have a single diaphragm end piece. The end piece contains an iron disk and a permanent magnet. The air column of the diaphragm is activated as magnetic attraction is established between the iron disk and the magnet. A frequency dial adjusts for high-, low-, and full-frequency sounds.

Electronic stethoscopes convert sound vibrations into electrical impulses that are amplified. The impulses are transmitted to a speaker where they are converted to sound. These devices can compensate for environmental noise. Thus they may be beneficial for use in the prehospital setting.

OPHTHALMOSCOPE

The ophthalmoscope is used to inspect structures of the eye, including the retina, choroid, optic nerve disk, macula (an oval, yellow spot at the center of the retina), and retinal vessels. This device has a battery light source, two dials, and a viewer (Figure 20-5). The dial at the top of the battery changes the light image. The dial at the top of the viewer allows for the selection of lenses. (Five lenses are available, but the large white light generally is used.)

OTOSCOPE

The otoscope is used to examine deep structures of the external and middle ear. This device is basically an ophthalmoscope with a special ear speculum attached to the battery tube (Figure 20-6). Ear specula are available in a number of sizes to conform to various ear canals. (The paramedic should choose the largest one that fits comfortably in the patient's ear.) The light from the otoscope allows one to visualize the tympanic membrane.

FIGURE 20-5 Ophthalmoscope.

BLOOD PRESSURE CUFF

The blood pressure cuff (sphygmomanometer) most commonly is used along with the stethoscope to measure systolic and diastolic blood pressure. The common blood pressure cuff used in the prehospital setting consists of a pressure gauge that registers millimeter calibrations, a synthetic cuff with Velcro closures that encloses an inflatable rubber bladder, and a pressure bulb with a release valve. Blood pressure cuffs are available in a number of sizes.

FIGURE 20-6 Otoscope.

Adult widths should be one third to one half the circumference of the limb. For children, the width should cover about two thirds of the upper arm or thigh. (Blood pressure cuffs that are too large give a falsely low reading; cuffs that are too small give a falsely high reading.)

Electronic devices that automatically measure a patient's vital signs are used by hospitals and EMS agencies to monitor the patient's blood pressure, pulse rate, body temperature, end-tidal carbon dioxide concentration, and oxygen saturation level at regular intervals (Figure 20-7).

General Approach to the Physical Examination

The physical examination is performed as a step-by-step process. Special emphasis is placed on the patient's present illness and chief complaint. The paramedic should know that most patients view a physical exam with some anxiety. They often feel vulnerable and exposed. Therefore it is important to establish a professional trust early in the encounter. In addition, ensuring the patient's privacy and comfort when possible is very important.

Overview of a Comprehensive Physical Examination

The physical examination is a systematic assessment of the body that includes the following components:

- Mental status
- General survey
- Vital signs
- Skin
- Head, eyes, ears, nose, and throat
- Chest
- Abdomen
- Posterior body
- Extremities (peripheral vascular and musculoskeletal)
- Neurological exam

FIGURE 20-7 Electronic blood pressure device.

NOTE

The Centers for Disease Control and Prevention and the Occupational Safety and Health Administration have recommended that health care workers wear gloves "when handling blood-soiled items, body fluids, excretions and secretions, as well as surfaces, materials, and objects exposed to them."[1] This text assumes that all paramedics are appropriately gloved for patient care procedures. Personal protective measures are addressed in Chapter 14 and 28.

MENTAL STATUS

The first step in any encounter with a patient is to note the patient's appearance and behavior. With this step, one also should assess for level of consciousness. A healthy patient is expected to be alert and responsive to touch, verbal instruction, and painful stimuli.

Appearance and Behavior

As mentioned before, a visual assessment of the patient can yield key information. Abnormal findings may include drowsiness or the inability to respond to unpleasant or painful stimuli. Terms that are sometimes used to describe abnormal findings include *obtundation, stupor,* or *coma*. A patient who is obtunded has a decreased level of consciousness usually produced by anesthetics or analgesics. Stupor is a state of lethargy and unresponsiveness. Stuporous patients usually are unaware of their surroundings. Coma is a state of profound unconsciousness. A patient in coma has no spontaneous eye movements. These patients do not respond to verbal or painful stimuli and cannot be aroused.

NOTE

Most medical direction agencies discourage the use of these terms to describe a patient's mental status. Because these terms are vague, they may be open to interpretation. Therefore it is best to describe the patient's reactions and verbal and motor responses with indexes such as the AVPU scale or Glasgow Coma Scale (described in Chapter 19 and Chapter 40). These measurements often are considered better patient information.

POSTURE, GAIT, AND MOTOR ACTIVITY

The paramedic should observe the patient's posture, gait, and motor activity. This involves assessing pace, range, character, and appropriateness of movement. For example, most patients without physical disabilities can walk with good balance and without a limp, discomfort, or fear of falling. Abnormal findings may include **ataxia** (uncoordinated movement), paralysis, restlessness, agitation, bizarre body posture, immobility, and involuntary movements.

DRESS, GROOMING, PERSONAL HYGIENE, AND BREATH OR BODY ODORS

Dress, grooming, and personal hygiene should be appropriate for the patient's age, lifestyle, and occupation. A person's dress should be appropriate for environmental temperature and weather conditions. (Older adults and children who are improperly dressed for temperatures or who have poor hygiene may be victims of neglect.) Medical jewelry (e.g., copper bracelets for arthritis, medical insignias) should be noted. Hair, fingernails, and cosmetics may reflect the patient's lifestyle, mood, and personality. These findings can point to a decreased interest in appearance (e.g., grown-out hair or faded nail polish). This may help to estimate the length of an illness.

Breath or body odors can point to underlying conditions or illness. Examples of breath odors include alcohol, acetone (seen with some diabetic conditions), feces (seen with bowel obstruction), and halitosis from throat infections and poor dental and oral hygiene. Renal and liver disease and poor hygiene also may result in body odor.

FACIAL EXPRESSION

Facial expressions may reveal anxiety, depression, elation, anger, or withdrawal. They may also show fear, sadness, or pain. The paramedic should be alert to changes in facial expression while the patient is at rest, during conversation, during the examination, and when asking questions. Facial expressions should be appropriate to the situation.

MOOD, AFFECT, AND RELATION TO PERSONS AND THINGS

Like facial expression, the patient's mood and affect also should be appropriate to the event. Mood and affect describe the patient's emotional state and the outward display of feelings and emotions; they are expressed verbally and nonverbally. Examples of abnormal findings include an unusual happiness in the presence of major illness, indifference, thoughts of suicide, responses to imaginary persons or objects, and unpredictable mood swings.

CRITICAL THINKING

What physical clues do you look for in your friends or your partner that tell you about their mood?

Speech and Language

The patient's speech should be understandable and of a moderate pace. The paramedic should assess the quantity, rate, loudness, and fluency of the patient's speech patterns. Abnormal findings include **aphasia** (loss of speech), **dysphonia** (abnormal speaking voice), **dysarthria** (poorly articulated speech), and speech and language that changes with mood.

Thoughts and Perceptions

A healthy person's thoughts and perceptions are logical, relevant, organized, and coherent. Patients should have an insight into their illness or injury. They also should be able to show a level of judgment in making decisions or plans about their situation and their care. Although accurately assessing a person's thoughts and perceptions is difficult, the following usually are considered abnormal findings:

- Abnormal thought processes
  - Flight of ideas
  - Incoherence
  - Confabulation
  - Blocking
  - Transference
- Abnormal thought content
  - Obsessions
  - Compulsions
  - Delusions
  - Suicidal ideations
  - Homicidal thoughts
  - Feelings of unreality
- Abnormal perceptions
  - Illusions
  - Visual/auditory hallucinations

Memory and Attention

Healthy persons normally are oriented to person, place, and date ("oriented times 3"). They also are usually aware of the event that initiated the EMS response ("oriented × 4"). The paramedic can use several other methods to assess a patient's memory and attention. One method is to ask the patient to count from 1 to 10 using only even or odd numbers (digit span). Another is to multiply by sevens (serial sevens). A third method is to spell simple words backward (e.g., "world"). The paramedic also should assess the patient's remote memory (e.g., birthdays) and recent memory (e.g., events of the day), and the patient's new learning ability. New learning ability can be evaluated by giving the patient new information (e.g., your name; the year and model of the ambulance). Later the paramedic would ask the patient to recall that information.

GENERAL SURVEY

After assessing a patient's level of consciousness and mental status, the paramedic performs a general survey of the patient. In addition to the assessments described previously, the patient should be evaluated for signs of distress,

apparent state of health, skin color and obvious lesions, height and build, sexual development, and weight. Vital signs also are assessed during the general survey.

Signs of Distress

Obvious signs of distress include those that result from cardiorespiratory insufficiency, pain, and anxiety. Examples of these signs and symptoms are as follows:

- Cardiorespiratory insufficiency
  - Labored breathing
  - Wheezing
  - Cough
- Pain
  - Wincing
  - Sweating
  - Protectiveness of a painful body part or area
- Anxiety
  - Restlessness
  - Anxious expression
  - Fidgety movement
  - Cold, moist palms

CRITICAL THINKING

Combine one symptom from each of the groups of distress, and imagine how a patient with these symptoms might look and act.

Apparent State of Health

A patient's apparent state of health can be assessed by observation. The paramedic should note the patient's basic appearance as being acutely or chronically ill, frail, feeble, robust, or vigorous. Although these are subjective assessments, *frail* usually means impaired mental judgment with a dependence on others; *feeble* usually means weakness or a lack of strength; *robust* means strong and healthy; and *vigorous* means full of energy.

Skin Color and Obvious Lesions

Skin color can vary by body part and from person to person. A patient's normal skin color depends of course on race and can range from pink or ivory to deep brown, yellow, or olive. Skin color is best assessed by evaluating skin that usually is not exposed to the sun (e.g., the palms) or skin that has less pigmentation (e.g., lips and nail beds). Box 20-3 describes abnormal skin colors and their possible causes. Obvious skin lesions that can indicate illness or injury include rashes, bruises, scars, and discoloration (Figure 20-8; Tables 20-1 and 20-2).

BOX 20-3 Abnormal Skin Color and Possible Causes

Color	Possible Causes
Pallor (decrease in color)	Shock, dehydration, fright
Cyanosis (bluish color)	Cardiorespiratory insufficiency, cold environment
Jaundice (yellow-orange color)	Liver disease, red blood cell destruction
Red	Fever, inflammation, carbon monoxide poisoning

NOTE

Skin color, texture, and appearance can be affected by a person's age. For example, the skin color of a pediatric patient with light skin may be milky white and rose, to a deep hue of pink. A child with dark skin may have various brown, yellow, or olive-green or bluish tones. In addition, the skin of a child is usually smooth, slightly dry, and not oily or clammy. By comparison, the skin of a geriatric patient is often dry, wrinkly, with uneven pigmentation. The older patient often has thinning of the epidermal skin layers and decreased collagen production and may have various proliferative lesions associated with aging.

Height and Build

Patients generally can be described as average, tall, or short; with a slender, lanky, muscular, or stocky build. All of these factors can reflect overall health. For example, a patient can be excessively thin (as seen with some eating disorders) or trim and muscular. Age and lifestyle also may affect height and body build.

Sexual Development

Sexual characteristics should be appropriate for the patient's age and sex. Normal changes associated with puberty include facial hair and deepening of the voice in men, increased breast size in women, and hair growth in the axillary and groin areas in both sexes. As a rule, healthy men are taller, heavier, and more muscular than healthy women.

Weight

Ideally a patient's body weight should be proportionate to height and sex (Figure 20-9). Weight conditions that are easily observed in the general survey include patients who are emaciated (extremely lean from lack of nutrition), plump, or obese (body weight that is 20% greater than desirable body weight for a person's age, sex, height, and body build). A recent gain or loss is a key finding and may be clinically important. Like body height and build, body weight can reflect the patient's health, age, and lifestyle.

CRITICAL THINKING

Think about three medical conditions that might result in significant weight loss. Now, think about three that might cause a significant weight gain.

Vital Signs

Vital signs are a baseline measurement of function. They are used to assess respiration, pulse (circulation), and blood pressure (perfusion). The following is a brief overview of vital signs. assessment.

Text continued on p. 526

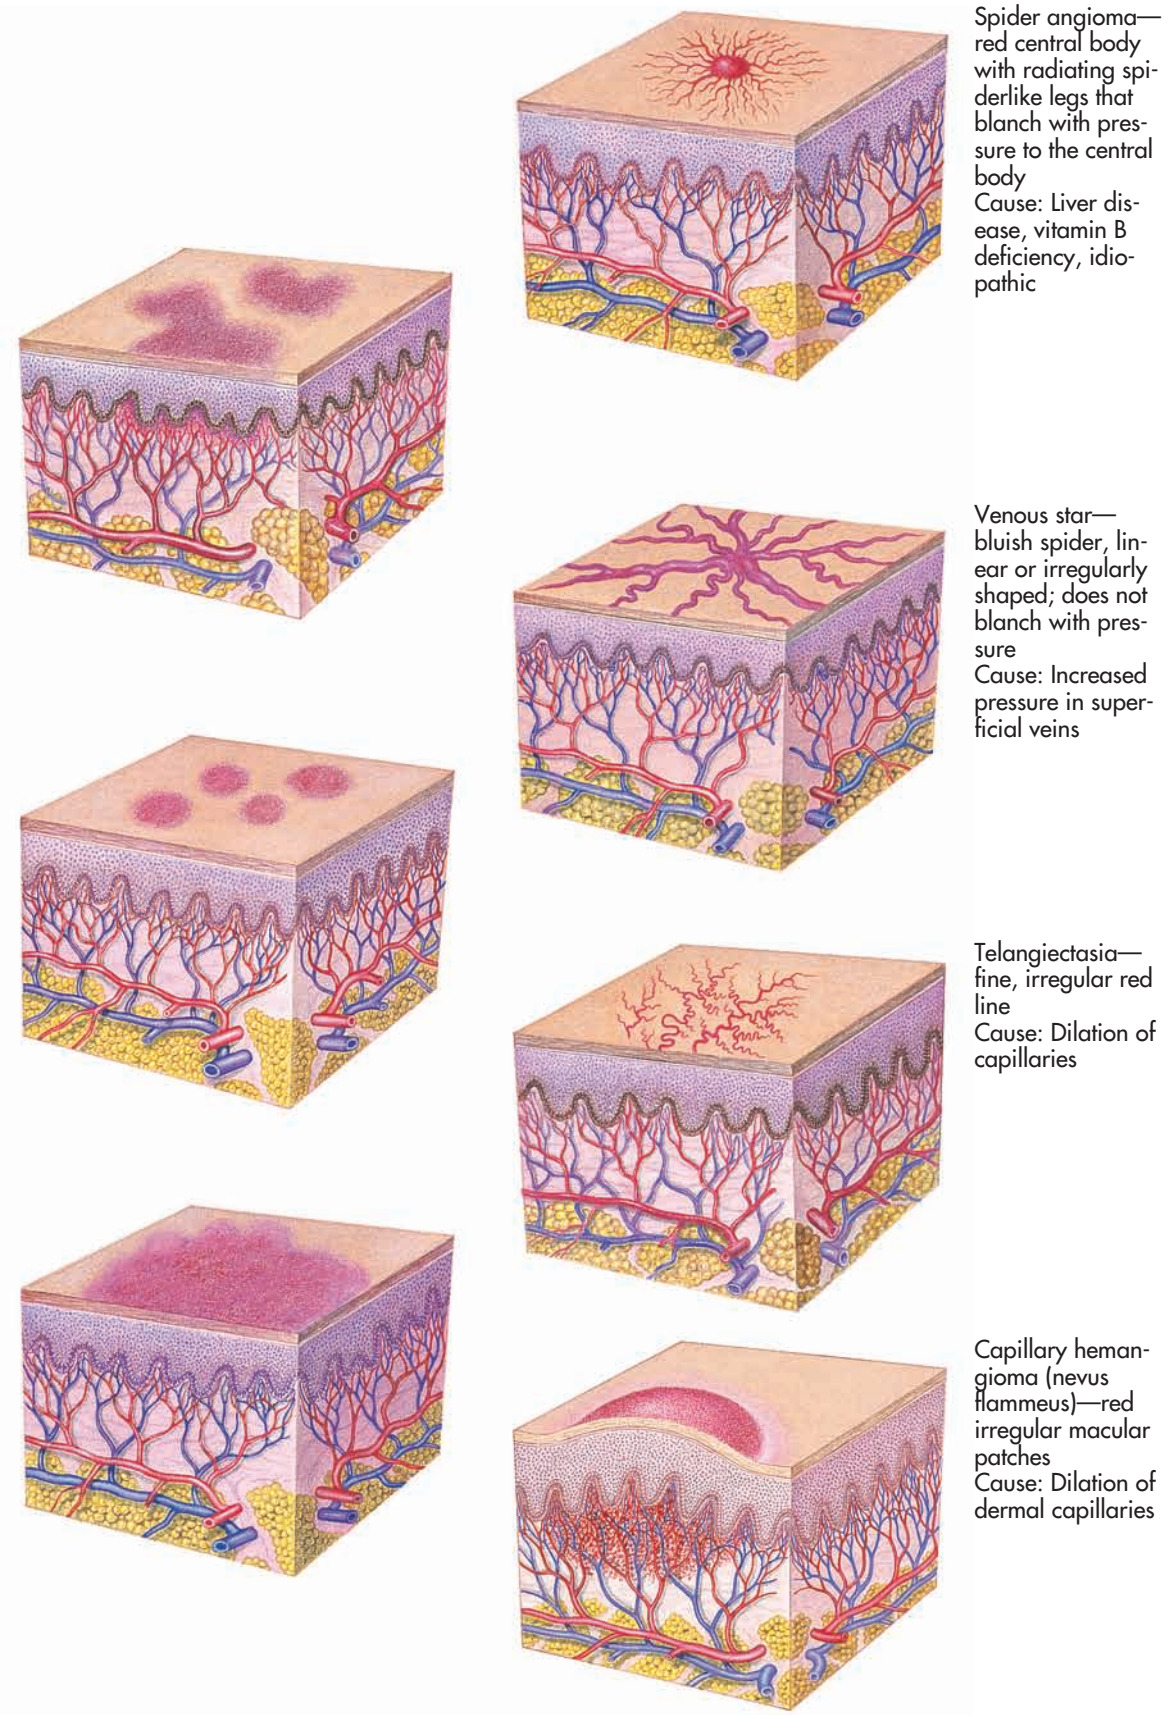

FIGURE 20-8 Characteristics and causes of vascular skin lesions. (From Seidel H, et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

TABLE 20-1 Primary Skin Lesions

Description	Examples	
Macule A flat, circumscribed area that is a change in color of the skin; less than 1 cm in diameter	Freckles, flat moles (nevi), petechiae, measles, scarlet fever 	Freckles (Marks and Miller, 2006)
Papule An elevated, firm, circumscribed area; less than 1 cm in diameter	Wart (verruca), elevated moles, lichen planus 	Lichen planus (Weston, Lane, and Morelli, 2007)
Patch A flat, nonpalpable, irregular-shaped macule greater than 1 cm in diameter	Vitiligo, port-wine stains, Mongolian spots, café au lait patch 	Vitiligo (White and Cox, 2006)
Plaque Elevated, firm, and rough lesion with flat top surface greater than 1 cm in diameter	Psoriasis, seborrheic and actinic keratoses 	Plaque (Weston, Lane, and Morelli, 2007)

Continued

TABLE 20-1 Primary Skin Lesions—cont'd

Description	Examples	
Wheal Elevated, irregular-shaped area of cutaneous edema; solid, transient, variable diameter	Insect bites, urticaria, allergic reaction 	Wheal (Weston, Lane, and Morelli, 2007)
Nodule Elevated, firm, circumscribed lesion; deeper in dermis than a papule; 1 to 2 cm in diameter	Erythema nodosum, lipomas 	Nodule (Marks and Miller, 2006)
Tumor Elevated and solid lesion; may or may not be clearly demarcated; deeper in dermis; greater than 2 cm in diameter	Neoplasms, benign tumor, lipoma, hemangioma 	Hemangioma (Marks and Miller, 2006)
Vesicle Elevated, circumscribed, superficial, not into dermis; filled with serous fluid; less than 1 cm in diameter	Varicella (chickenpox), herpes zoster (shingles) 	Vesicles caused by zoster (Weston, Lane, and Morelli, 2007)

TABLE 20-1 Primary Skin Lesions—cont'd

Description	Examples	
Bulla Vesicle greater than 1 cm in diameter	Blister, pemphigus vulgaris 	Bullous pemphigoid (White and Cox, 2006)
Pustule Elevated, superficial lesion; similar to a vesicle but filled with purulent fluid	Impetigo, acne 	Acne (Weston, Lane, and Morelli, 2007)
Cyst Elevated, circumscribed, encapsulated lesion; in dermis or subcutaneous layer; filled with liquid or semi-solid material	Sebaceous cyst, cystic acne 	Sebaceous cyst (Weston, Lane, and Morelli, 2007)
Telangiectasia Fine, irregular, red lines produced by capillary dilation	Telangiectasia in rosacea 	Telangiectasia (White and Cox, 2006)

From Seidel H et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby. Modified from Thompson JM, Wilson SF: *Health assessment for nursing practice,* ed 2, H, St Louis, 2001, Mosby.

TABLE 20-2 Secondary Skin Lesions

Description	Examples	
Scale Heaped-up, keratinized cells, flaky skin; irregular; thick or thin; dry or oily; variation in size	Flaking of skin with seborrheic dermatitis following scarlet fever, or flaking of skin following a drug reaction; dry skin 	Scale (Marks and Miller, 2006) Lichenification Rough, thickened epidermis secondary to persistent rubbing, itching, or skin irritation; often involves flexor surface of extremity	Chronic dermatitis 	Atopic dermatitis (Marks and Miller, 2006)
Keloid Irregular-shaped, elevated, progressively enlarging scar; grows beyond boundaries of wound; caused by excessive collagen formation during healing	Keloid formation following surgery 	Keloid (Weston, Lane, and Morelli, 2007) Scar Thin to thick fibrous tissue that replaces normal skin following injury or laceration to dermis	Healed wound or surgical incision 	Hypertrophic scar (White and Cox, 2006)

TABLE 20-2 Secondary Skin Lesions—cont'd

Description	Examples	
Excoriation Loss of epidermis; linear hollowed-out, crusted area	Abrasion or scratch, scabies	Scabies (Weston, Lane, and Morelli, 2007)
Fissure Linear crack or break from epidermis to dermis; may be moist or dry	Athlete's foot, cracks at corner of mouth	Fissure (Weston, Lane, and Morelli, 2007)
Erosion Loss of part of epidermis; depressed, moist, glistening; follows rupture of vesicle or bulla	Varicella, variola after rupture	Erosion (Marks and Miller, 2007)
Ulcer Loss of epidermis and dermis; concave; varies in size	Decubiti, stasis ulcers	Stasis ulcer (Marks and Miller, 2007)

Continued

TABLE 20-2 Secondary Skin Lesions—cont'd

Description	Examples	
Crust		
Dried serum, blood, or purulent exudates; slightly elevated; size varies; brown, red, tan, or straw-colored	Scab on abrasion, eczema 	Scab (Seidel et al, 2006)
Atrophy		
Thinning of skin surface and loss of skin markings; skin translucent and paper-like	Striae; aged skin 	Striae (Seidel et al, 2006/courtesy Dr. Antoinette Hood, Department of Dermatology, University of Indiana, Department of Medicine)

RESPIRATION

The normal respiratory rate for adults is between 12 and 24 breaths per minute.[2] The respiratory rate is assessed by watching the patient breathe, by feeling for chest movement, or by auscultating the lungs. The paramedic counts the respirations for 30 seconds, and then multiplies by 2 to measure breaths per minute. Rhythm and depth of respirations are assessed by visualization and auscultation of the thorax. Abnormal findings include shallow, rapid, noisy, or deep breathing; asymmetrical chest wall movement; use of accessory muscles of respiration; or congested, unequal, or diminished breath sounds.

PULSE

A normal resting pulse rate for an adult is usually between 60 and 100 beats per minute; it may be affected by the patient's age and physical condition (Table 20-3). For example, a child's pulse rate may be 80 to 100 beats per minute. A well-trained athlete's pulse rate may be 50 to 60 beats per minute. Factors such as pregnancy, anxiety, and fear also may produce a higher-than-normal pulse rate in healthy individuals.

Pulse rates may be obtained at the carotid artery in the neck or at any site where the artery lies close to the skin. To evaluate the radial pulse, the paramedic places the pads of the index and middle fingers at the distal end of the patient's wrist, just medial to the radial styloid. If pulsations are

TABLE 20-3 Average Vital Signs by Age

Age	Pulse (beats/min)	Respirations (breaths/min)	Blood Pressure (mm Hg)
Newborn	120-160	40-60	80/40
1 year	80-140	30-40	82/44
3 years	80-120	25-30	86/50
5 years	70-115	20-25	90/52
7 years	70-115	20-25	94/54
10 years	70-115	15-20	100/60
15 years	70-90	15-20	110/64
Adult	60-100	12-24	120/80

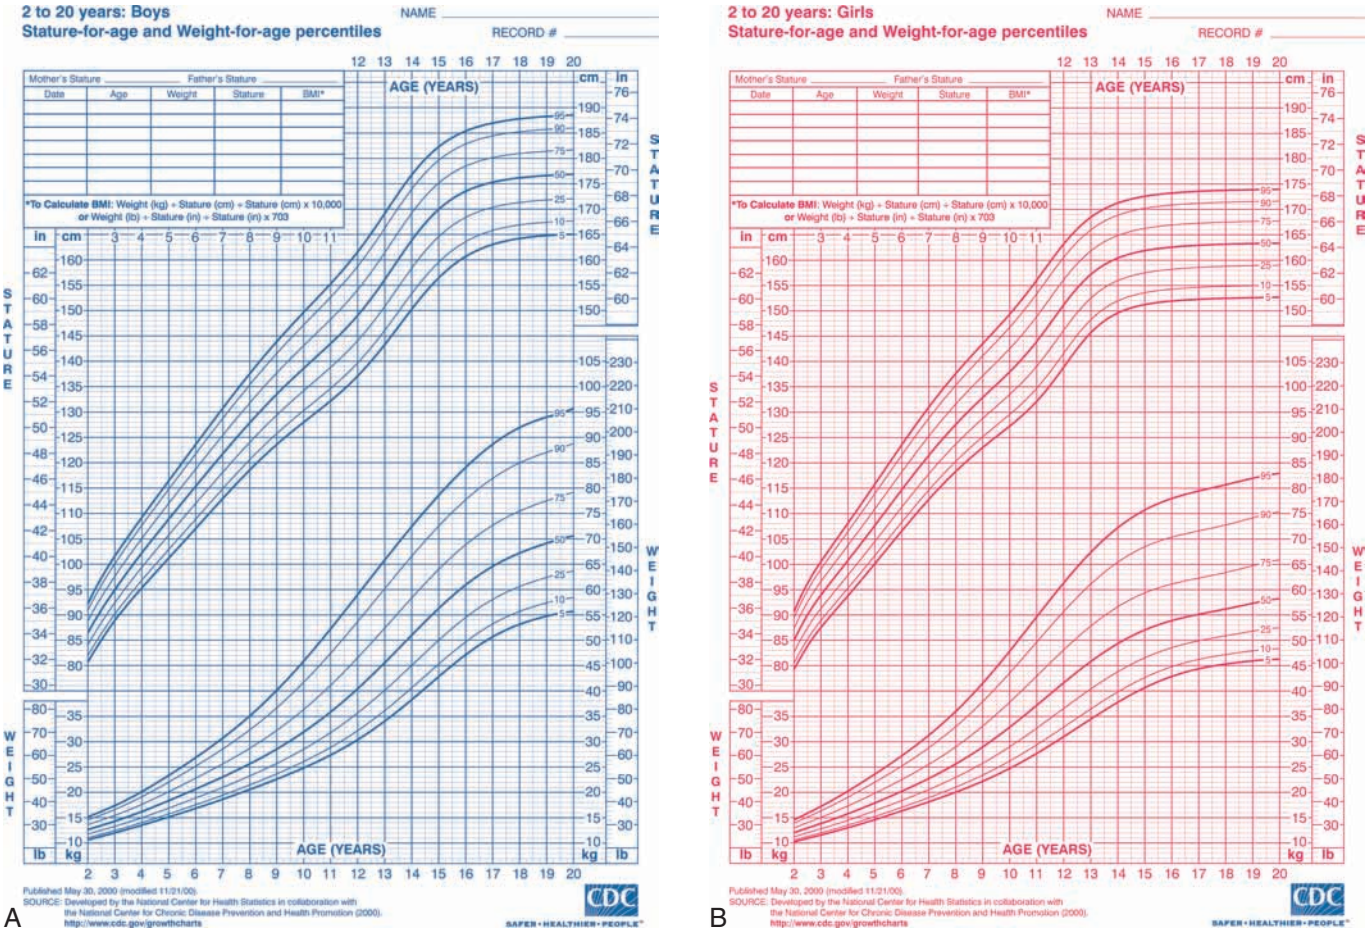

FIGURE 20-9 Physical growth curves and National Center for Health Statistics percentiles for children, age 2 through 18 years, for height and weight. **A,** Boys. **B,** Girls. (Developed by the National Council for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion 2000.)

regular, the paramedic should count for 15 seconds and multiply that number by 4 to determine the number of beats per minute. In addition to the number of times the heart beats per minute, the regularity and strength of the pulse also are important. For example, the pulse can be regular or irregular, weak or strong. Application of an electrocardiogram monitor also is useful in evaluating cardiovascular status after initial assessment of the pulse.

BLOOD PRESSURE

The **systolic blood pressure** is the pressure exerted against the arterial walls when the heart contracts. The **diastolic blood pressure** is the pressure exerted against the arterial walls when the heart relaxes. For all age groups,[3] systolic blood pressure ideally should be less than 120 mm Hg; diastolic pressure should be less than 80 mm Hg.

Blood pressure is best measured by auscultation or by an electronic device. The blood pressure cuff is placed on the patient's arm with the lower end of the cuff positioned 1 to 2 inches (2 to 5 cm) above the antecubital (AC) space. If measured manually, the cuff is inflated to a point about 30 mm Hg above where the brachial pulse can no longer be palpated. The stethoscope is placed over the brachial artery, and the cuff is slowly deflated at a rate of 2 to 3 mm Hg per second. As the pressure falls, the paramedic should observe the gauge and note where the first sound or pulsation is heard. This is the patient's systolic pressure. The point at which the sounds change in quality or become muffled is noted as the patient's diastolic pressure.

NOTE

At times, determining the correct diastolic pressure is difficult. The difference between the point of muffled tones and the complete disappearance of pulsations varies by person. In some persons, the difference is a few millimeters of mercury; however, in some persons, pulsations never totally disappear. The ability to measure accurate diastolic pressures comes from experience and requires careful listening in a quiet setting.

Blood pressure may be estimated by palpation when vascular sounds are difficult to hear with a stethoscope because of environmental noise. However, this method is less accurate than auscultation and can only estimate systolic pressure. To estimate blood pressure by palpation, the paramedic

should locate the brachial or radial pulse and apply the blood pressure cuff as described before. Finger contact should be maintained at the pulse site as the cuff slowly deflates. When the pulse becomes palpable, the gauge reading denotes the systolic pressure. Like pulse rates, a patient's blood pressure may be unusually high because of fear or anxiety. Other factors, such as a patient's age and normal level of physical activity, may be the cause of unusual blood pressure readings.

Alternate sites may be used to assess blood pressure when use of the patient's upper arm is not possible. Blood pressure readings in these alternate sites vary from those taken in the arm (Figure 20-10). Other methods used to assess oxygenation and perfusion include oxygen saturation, capnography (described in Chapter 15), and capillary refill (described in Chapter 19).

LOOK AGAIN
See Chapter 15: Airway, pp. 451-455.

EXAMINATION OF THE SKIN

The skin can reveal a great deal about a patient's status. Assessment includes skin color, temperature, and moisture. As discussed before, a patient's skin color and the presence of bruises, lesions, or rashes may indicate serious illness or injury.

Skin temperature may be normal (warm), hot, or cold. Evaluations of temperature may have specific applications in some patient situations. Examples of such situations are febrile seizures and hyperthermic and hypothermic emergencies. Skin that is hot to the touch indicates a possible fever or heat-related illness or injury. Cold skin may indicate decreased tissue perfusion and cold-related illness or injury. The dorsal surface of the hand is more sensitive than the palmar surface and should be used to estimate body temperature. Normal body temperature is 37° C (98.6° F). Oral, axillary, tympanic, or rectal temperatures can be measured using electronic, digital, temporal (artery), digital dot, or tympanic-membrane thermometers (Figure 20-11). The temperature probe should be covered by a disposable sheath. The sheath helps to prevent cross-contamination.

Oral Measurement. Oral temperature usually is measured in patients over the age of 6. The readings may be affected by crying, eating, drinking, smoking, oxygen administration by mask, or nebulizer treatments, and by the position of the thermometer in the patient's mouth. When using electronic devices, a brief tone will alert the paramedic when the measurement is complete. Children can be told to hold the thermometer in a "kiss" position and not to bite on the probe.

Axillary Measurement. The axillary site often is used to take the temperature in children. The axilla frequently is used in children less than 6 years of age. The axilla also is used in children who are uncooperative or have diseases that suppress the immune system and in patients who have an altered level of consciousness. Axillary temperature is measured by placing the electronic probe firmly in the center of the patient's axillary space. The patient's arm should be held against the side of the chest. A tone will

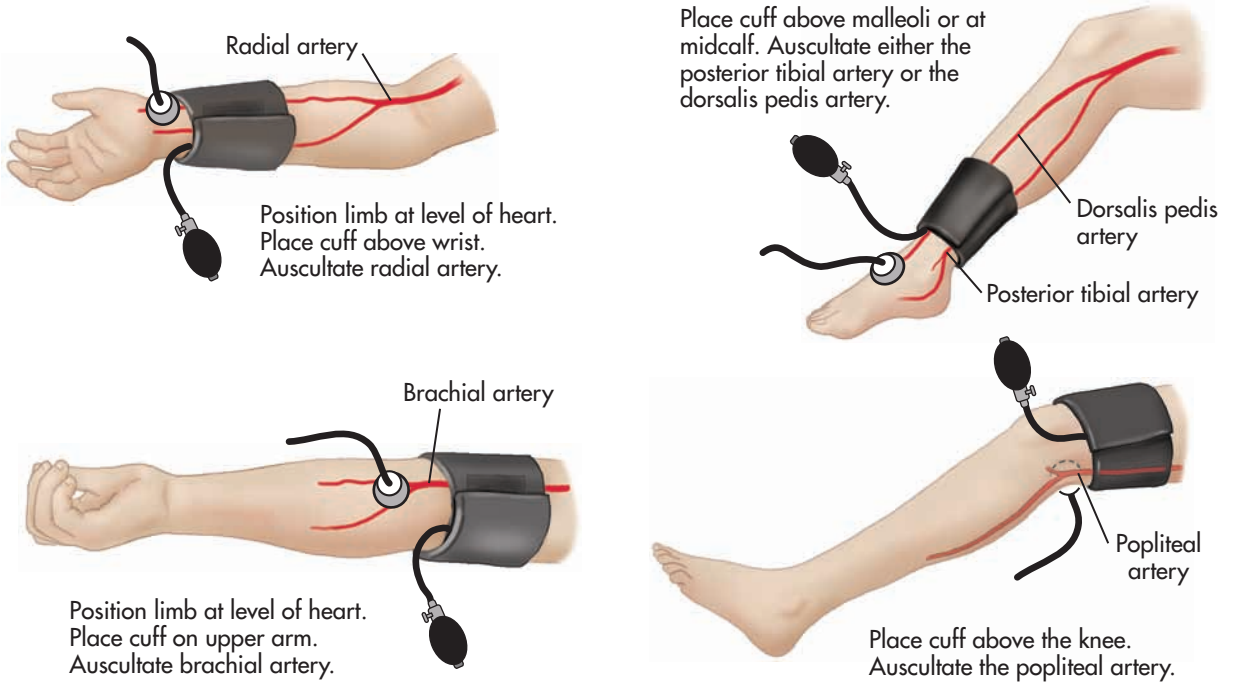

FIGURE 20-10 Blood pressure measurement sites.

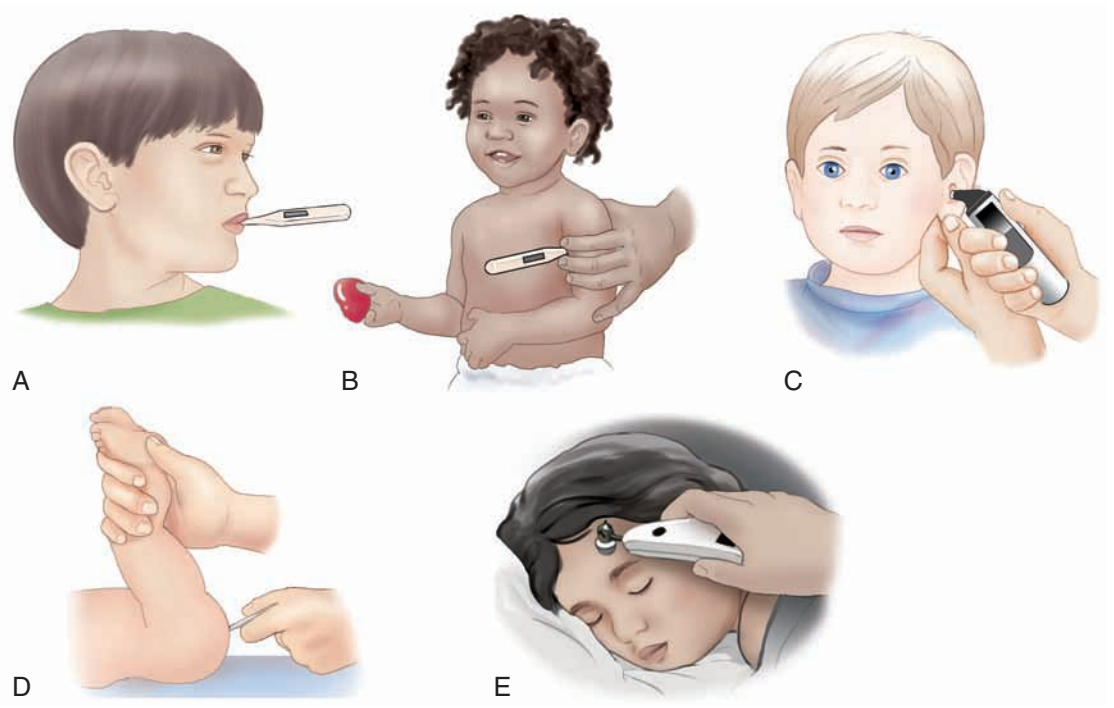

FIGURE 20-11 Temperature assessment. **A,** Oral temperature measurement. **B,** Axillary temperature measurement. **C,** Tympanic temperature measurement. **D,** Rectal temperature measurement. **E,** Temporal temperature assessment.

sound when the measurement is complete. The temperature assessed at this site is usually 1° F (0.6° C) lower than the core temperature of the body.

Tympanic Measurement. The tympanic membrane is close to the hypothalamus. This position makes the tympanic membrane an ideal place to measure core temperature. The paramedic takes this measurement by placing the tip of the probe into the patient's ear canal. To obtain the most accurate reading, the ear canal should be straightened by gently pulling the pinna of the ear down and back in children less than 3 years of age or up and back in patients 3 years of age or older. When the thermometer is in the correct position and is activated per the manufacturer's instructions, a temperature reading is obtained within seconds. Tympanic measurement is associated with significant variability in measurements. Readings can be inaccurate in patients who have had ear surgery; have otitis media or excessive earwax; have recently exercised; are in situations with extremes of temperature (incubators, wind or fans); and in children less than 3 years of age.[4]

Rectal Measurement. Measuring a patient's temperature by the rectal route poses a risk of perforation. In addition, the method can be distressing for the patient. This route generally is reserved for young children and patients who have an altered level of consciousness. When measuring rectal temperature, the paramedic should place the patient in the supine position (infants). The patient also can be placed in the left lateral recumbent position with the legs raised. This position exposes the anus. The paramedic inserts a lubricated probe no more than 2.5 cm (½ to 1 inch) into the rectum. The probe should be held securely in place until the electronic device sounds the alert. Rectal readings provide the most accurate assessment. However, they generally are impractical for prehospital use. Special hypothermic thermometers may be used to measure the rectal temperature of patients with hypothermia (see Chapter 45).

Skin moisture usually is classified as dry or wet. Dry skin is normal. Wet skin is clammy or diaphoretic. Diaphoretic skin may indicate a volume problem such as hypovolemia. It may also indicate other illness or injury that results in decreased tissue perfusion or increased sweat gland activity. Examples are cardiovascular and heat-related emergencies, respectively.

PUPILS

Examining the pupils for response to light may yield information on the neurological status of some patients. Unequal pupils (**anisocoria**) may be a normal finding in some patients. However, the pupils usually are equal and constrict when exposed to light. (The acronym **PERRL** indicates that the *p*upils are *e*qual, *r*ound, and *r*eact to *l*ight.) When testing the pupils for light response, the paramedic shines a penlight directly into one eye. The normal reaction is for the pupil exposed to the light to constrict. This occurs with a consensual constriction of the opposite eye. Table 20-4 lists abnormal pupillary reactions and possible causes.

TABLE 20-4 Abnormal Pupil Reactions

Pupil Size	Possible Causes
Equal	
Dilated or unresponsive	Cardiac arrest, central nervous system injury, hypoxia or anoxia, drug use (LSD [lysergic acid diethylamide], atropine, amphetamines)
Constricted or unresponsive	Central nervous system injury or disease, narcotic drug use (heroin, morphine), eye medications
Unequal	
One dilated or unresponsive	Cerebrovascular accident, head injury, direct trauma to eye, eye medications

FIGURE 20-12 Assessing skin turgor. (From Potter PA, Perry AG: *Basic nursing,* ed 7, St Louis, 2011, Mosby.)

ANATOMICAL REGIONS

The remainder of this chapter discusses techniques of the physical examination as they relate to anatomical regions of the body. The paramedic should recall that anatomical and physiological aspects of the human body are age-related. They vary by person as well. An examination of the anatomical regions should be guided by a patient's chief complaint. A full examination of all regions often is not necessary in the emergency setting, but will be described here for a complete discussion. Chapter 10 serves as a review of anatomical regions of the body.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 146-150.

Skin

The general assessment of the skin was described previously. In addition, the comprehensive physical examination should include an evaluation of the texture and turgor of the skin, hair, and nails.[2] (All of these are part of the integumentary system.)

TEXTURE AND TURGOR

The texture of the skin normally is smooth, soft, and flexible. In older adults, though, the skin may be wrinkled and leathery from decreased amounts of collagen and subcutaneous fat as well as reduced secretion from sweat glands. Abnormal skin texture may result from lesions, rashes, tumors, and localized trauma.

Turgor refers to the elasticity of the skin (which normally decreases with age). To test skin turgor, the paramedic should pinch ("tent") a fold of skin and assess the ease and speed at which the skin returns to its normal position. (Skin on the back of the patient's hand or over the sternum are good areas to test for turgor.) Tented skin that does not quickly return to its normal position may indicate dehydration (Figure 20-12).

HAIR

As part of the examination, the paramedic should inspect and palpate the patient's hair. The paramedic should note quantity, distribution, and texture. Key findings include a recent change in the growth or loss of hair. These may result from chemotherapy or hormone and endocrine disorders (e.g., menopause and diabetes). Thinning hair is common in older men and women.

FINGERNAILS AND TOENAILS

The paramedic should note the color and shape of the patient's fingernails and toenails and also assess for the presence or absence of lesions. Uncolored nails usually are transparent. Healthy nails are smooth and firm on palpation. Box 20-4 describes abnormal findings in the nails. With age, nails often develop longitudinal striations and may have a yellow tint because of insufficient calcium.

Head, Ears, Eyes, Nose, and Throat

An examination of the structures of the head and neck involves inspection, palpation, and auscultation.

HEAD AND FACE

To examine the head, the paramedic should inspect the skull for shape and symmetry, keeping in mind that hair can hide abnormalities. The hair should be parted in several places to assess for scaliness, lumps, or other lesions. The assessment should use a systematic palpation, moving from front to back, noting any swelling, tenderness, indentations, or depressions. The scalp should move freely over the skull, and the patient should be free of pain or discomfort during the examination.

The face should be inspected for symmetry, expression, and contour, noting any asymmetry, involuntary movements, masses, or edema. The paramedic should evaluate facial skin for color, pigmentation, texture, thickness, hair distribution, and any lesions.

BOX 20-4 Abnormal Nail Findings

Beau's lines: Transverse depressions in the nail that inhibit nail growth; associated with systemic illness, severe infection, and nail injury.

Clubbing: A change in the angle between the nail and nail base that approaches or exceeds 180 degrees; associated with flattening and often enlargement of the fingertips; may indicate chronic cardiac or respiratory disease.

Onycholysis: The separation of a nail from its bed; associated with psoriasis, dermatitis, fungal infection, and other conditions.

Paronychia: Inflammation of the skin at the base of the nail; may result from local infection or trauma.

Psoriasis: Pitting, discoloration, and subungual thickening of the nail plate; may lead to splinter hemorrhages.

Splinter hemorrhages: Red or brown linear streaks in the nail bed; associated with minor nail trauma, bacterial endocarditis, and trichinosis.

Terry's nails: The presence of transverse white bands that cover the nail except for a narrow zone at the distal tip; associated with cirrhosis.

Transverse white lines: Longitudinal white streaks in the nail plate; may indicate a systemic disorder.

White spots: The presence of white spots that appear in the nail plate; usually result from minor injury or cuticle manipulation.

EYES

The paramedic should verify that both eyes can see. Basic information is gathered during the patient history and by asking the patient about any visual disturbances. **Visual acuity** can be assessed by asking the patient to read printed material or count fingers at a distance, and by demonstrating the ability to distinguish light from dark through the use of various eye charts (e.g., a *Snellen chart*) (Figure 20-13).

Both eyes should move equally well in the **six cardinal fields of gaze** (Figure 20-14). To evaluate a patient's gaze, the paramedic should hold the patient's chin. The patient's eyes should be observed as they track a penlight or finger (or a toy, in the case of a child) when it moves through the six visual fields in an H pattern. Any **nystagmus** (involuntary jerking movements of the eyes) or **disconjugate gaze** (deviation of the eyes to opposite sides) should be noted. Another method to check visual fields is to ask the patient to look at his or her nose. The paramedic then extends his or her arms with elbows at right angles and wiggles both index fingers at the same time to test peripheral vision. Asking the patient to identify finger movements and to track a moving object can demonstrate if visual fields are grossly normal. This test should be performed in four quadrants (up, down, right, and left). The eyes should also be assessed for normal position and alignment.

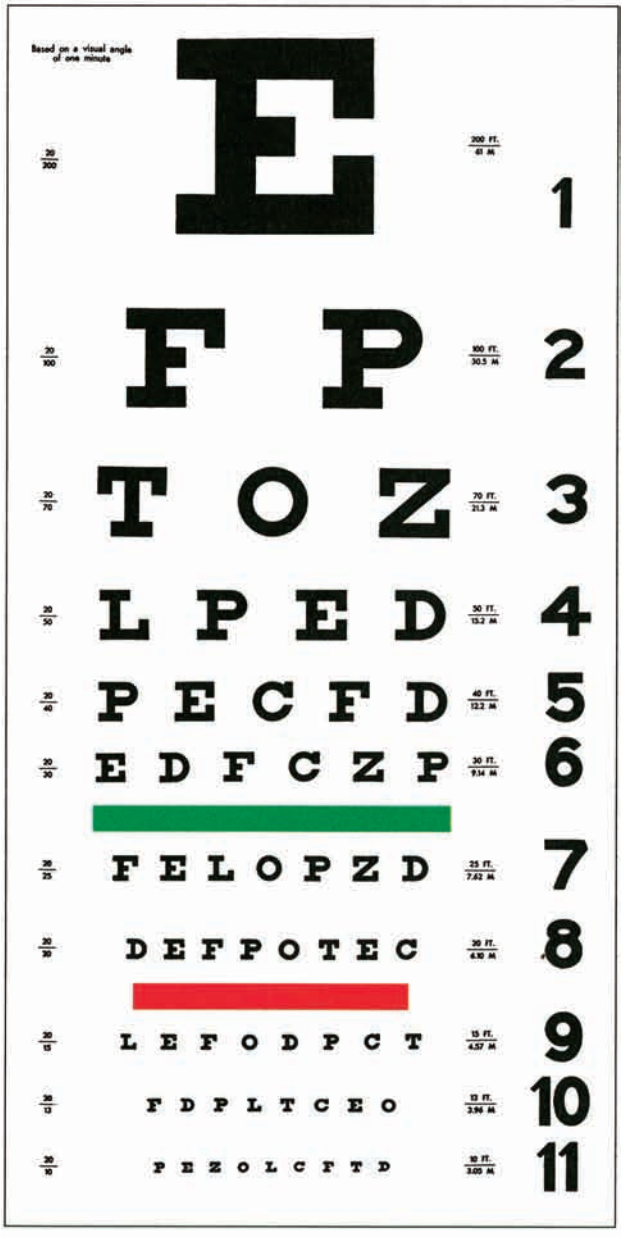

FIGURE 20-13 Snellen chart. (From Seidel H et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

CRITICAL THINKING

When you perform an examination of the eyes, you are evaluating components of at least four body systems. What are they?

The patient's orbital area should be assessed for edema and puffiness. The eyebrows should be free of scaliness. Inspection of the eyelids consists of noting the width of *palpebral fissures* (the elliptical opening between the upper and lower lids), edema, color, lesions, condition and direction of the eyelashes, adequacy of lid closure, and drainage. The paramedic also briefly should inspect the regions of the lacrimal gland and lacrimal sac for swelling. Excessive

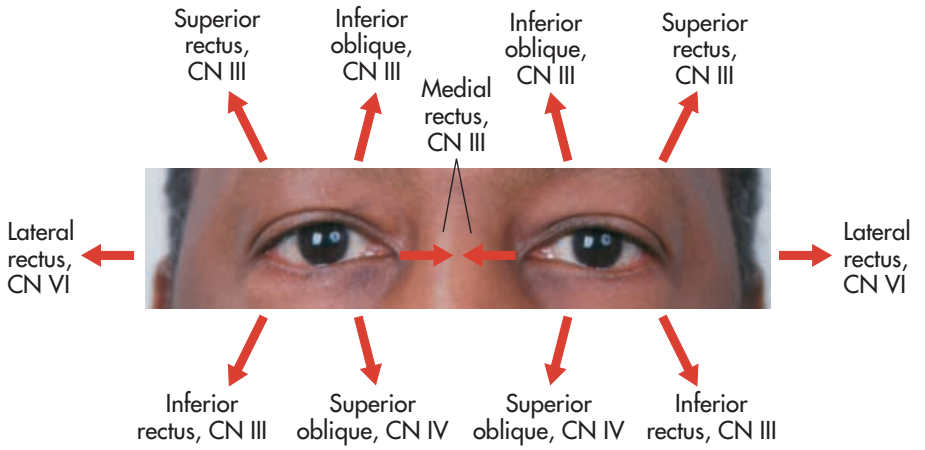

FIGURE 20-14 Six cardinal fields of gaze. Cranial nerves and extraocular muscles associated with the six cardinal fields of gaze. (From Seidel H et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

tearing or dryness of the eye should be noted (see Chapter 10).

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 206-208.

The patient's conjunctiva and sclera are examined by asking the patient to look up while the paramedic depresses both lower lids with the thumbs (Figure 20-15). The sclera should be white; the cornea and the iris should be clearly visible; and the pupils should be of equal size, round, and reactive to light. Palpating the patient's lower orbital rim determines structural integrity. The paramedic should be alert to the presence of contact lenses and ocular prostheses when examining a patient's eyes.

Ophthalmoscope Examination. The ophthalmoscope is used to assess the cornea for foreign bodies, lacerations, abrasions, and infection; the anterior chamber for the presence of blood or pus; and under the eyelid for the presence of foreign bodies. In addition, the retinal vessels, the optic nerve, and the retina of the fundus can be examined along with the vitreous. Ophthalmoscopic examinations should be performed in a darkened room so that the pupils are dilated. Contact lenses do not need to be removed.

To perform an examination with an ophthalmoscope, the paramedic should follow these steps for each eye:

1. Ask the patient to fixate on a distant object.
2. Sit facing the patient at the same seat height.
3. Turn on the ophthalmoscope light and select the 0 lens setting.
4. Use the right hand and eye to examine the patient's right eye and the left hand and eye to examine the patient's left eye.
5. Direct the patient to look over your shoulder, keeping both eyes open.
6. Hold the scope against your face and shine the light on the patient's pupil at a distance of about 10 inches from the face and at a 45-degree angle. A bright orange glow in the pupil ("red reflex") normally is visible (Figure 20-16).
7. Move the light slowly toward the pupil to see the structures of the fundus. Rotate the lens to improve focus as needed.
8. Inspect the size, color, and clarity of the disk and the integrity of vessels; assess for retinal lesions and the appearance of the macula. A normal examination will reveal the following[5] (Figure 20-17):

FIGURE 20-15 Examining the cornea and sclera. (From Seidel H et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

FIGURE 20-16 Paramedic using an ophthalmoscope.

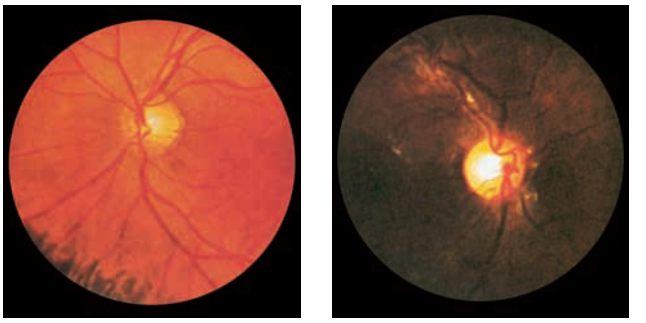

FIGURE 20-17 Normal fundus examination. (From Potter PA, Perry AG: *Basic nursing,* ed 7, St Louis, 2011, Mosby.)

- A clear, yellow optic nerve disk
- Yellow to creamy-pink retina (depending on patient's race)
- Light red arteries and dark red veins
- A 3:2 vein-to-artery ratio in size proportion
- The avascular macula

EARS

The paramedic should inspect the external ear and surrounding tissues for signs of bruising, deformity, or discoloration. No discharge should be present in either ear canal. Pulling gently on the earlobes should not produce pain or discomfort. The patient's skull and facial bones surrounding the ear should be palpated. The mastoid area should be inspected for tenderness or discoloration. A patient who is alert and able to hear and who speaks the same language as the paramedic should be able to respond to questions without many requests for repetition. Hearing aids should be noted. An assessment of gross auditory keenness can be made by covering one ear at a time and asking the patient to repeat short test words spoken in soft and loud tones.

Otoscopic Examination. An otoscope is used to evaluate the inner ear for discharge and foreign bodies and to assess the eardrum. The paramedic performs an otoscopic exam using the following steps for each ear (Figure 20-18):

1. Select the appropriate size of speculum.
2. Check the ear for foreign bodies before inserting the speculum.
3. Instruct the patient not to move during the examination to avoid injury to the canal and tympanic membrane. (Infants and young children may need to be restrained.)
4. Turn on the otoscope and insert the speculum into the ear canal, slightly down and forward. To ease insertion, pull the auricle up and backward in adults; back and downward in infants.
5. Identify cerumen and look for foreign bodies, lesions, or discharge.

FIGURE 20-18 Paramedic performing an otoscopic exam.

6. Visualize and inspect the tympanic membrane for tears or breaks. A normal examination will reveal the following:
   - Cerumen will be dry (tan or light yellow) or moist (dark yellow or brown).
   - The ear canal should not be inflamed (a sign of infection).
   - The tympanic membrane should be translucent or pearly gray (pink or red indicates inflammation).

NOSE

The patient's nose should be inspected for shape, size, color, and stability. The column of the nose should be midline with the face and the nares positioned symmetrically. (Slight asymmetry of nares is considered normal.) The paramedic should palpate the column of the nose and surrounding soft tissues for pain, tenderness, or deformity. The frontal and maxillary sinuses may be inspected for the presence of swelling. They may also be palpated for tenderness along the bony brow on each side of the nose and the zygomatic processes.

Discharge from the nose can have a number of causes. For example, cerebrospinal fluid may be present as a result of head trauma; a bloody discharge (**epistaxis**) may result from trauma or from mucosal erosions involving blood

vessels, hypertension, or bleeding disorders. A mucous discharge commonly results from allergy, upper respiratory tract infection, sinusitis, or cold exposure.

MOUTH AND PHARYNX

The paramedic should inspect the lips for symmetry, color, edema, and skin surface irregularities. The lips should be pink. Pallor of the lips is associated with anemia; cyanosis is associated with cardiorespiratory insufficiency; red lips sometimes are a late finding in carbon monoxide poisoning (see Chapter 34). The lips should show no swelling, deformity, or pain on palpation.

Healthy gums in the oral cavity are pink and free of lesions and swelling. Patchy areas of pigmentation in the mouths of African Americans are not uncommon. Enlarged gums may indicate pregnancy, leukemia, poor oral hygiene, puberty, or use of some medications (e.g., ***phenytoin***). The mouth should be free of loose or broken teeth. Dental appliances may be present.

The patient's tongue should be inspected for size and color. The tongue should be positioned in the midline of the oral cavity and appear nonswollen, dull red, moist, and glistening. To inspect the oropharynx, a tongue blade is used to depress the patient's tongue. The normal palate is white or pink. If the oral cavity is inflamed or covered with exudate, an infection may be present. (Specific breath odors may indicate alcohol or other drug consumption or illness.) The tonsils normally are pink and smooth without edema, ulceration, or inflammation. A patient with a typical sore throat often has a reddened and edematous uvula and tonsillar pillars. A yellow exudate sometimes is present.

NECK

The paramedic should inspect the neck in the patient's normal anatomical position. If trauma is suspected, spinal precautions should be used. The trachea should be midline. No use of accessory muscles or tracheal tugging should occur during respiration. To palpate the neck, the paramedic places both thumbs along the sides of the distal trachea and systematically moves the hands toward the head (Figure 20-19). Care should be taken not to apply bilateral pressure to the carotid arteries, as syncope or bradycardia may result.

The lymph nodes should not be tender. (Tender or swollen lymph nodes usually are the result of inflammation.) The thyroid and cricoid cartilages should be free of pain and should move when the patient swallows. Bubbling or crackling sensations that can be palpated in the soft tissues of the neck may indicate the presence of **subcutaneous emphysema** (the presence of air in the subcutaneous tissues). The paramedic should note distended neck veins or prominent carotid arteries (see Chapter 22).

HEAD AND CERVICAL SPINE

The temporomandibular joint connects the mandible of the jaw to the temporal bone of the skull. The joint sometimes can become painful or dislocated. Normally the patient should be able to open and close the mouth without pain or limitation in movement. **Temporomandibular joint dysfunction** is a common complaint.

FIGURE 20-19 Position of the thumbs to evaluate the midline position of the trachea.

For the patient who has not undergone trauma, the paramedic should inspect the cervical spine by palpating for tenderness or deformities. Range of motion can be tested in the following manner:

- Flexion: touching the chin to the chest
- Rotation: touching the chin to each shoulder
- Lateral bending: touching each ear to each shoulder
- Extension: tilting the head backward

The neck of a trauma patient may need to be moved for a general or neurological examination. Any such movement must be accompanied by the application of continuous manual protection and stabilization techniques for suspected cervical spine injury (see Chapter 41).

Chest

A thorough knowledge of the structure of the thoracic cage is needed to perform an adequate respiratory and cardiac assessment. The ribs protect the vital organs within the thorax. They also offer support for respiratory movements of the diaphragm and intercostal muscles (see Chapter 10). Damage to the actual bony structure of the thoracic cavity, such as a flail chest, can prevent or limit respiratory function. The ribs of the thorax also are used as anatomical landmarks in locating specific areas for examination. Figure 20-20 shows the landmarks of the chest. The thorax can be evaluated by using imaginary lines to note examination findings (Figure 20-21). The thorax is assessed through inspection, palpation, percussion, and auscultation.

INSPECTION

The patient's chest wall should be inspected for symmetry on the anterior and posterior surfaces. The thorax is not completely symmetrical. However, a visual inspection of one side should offer a reasonable comparison to the other. Chest wall diameter often is increased in patients with

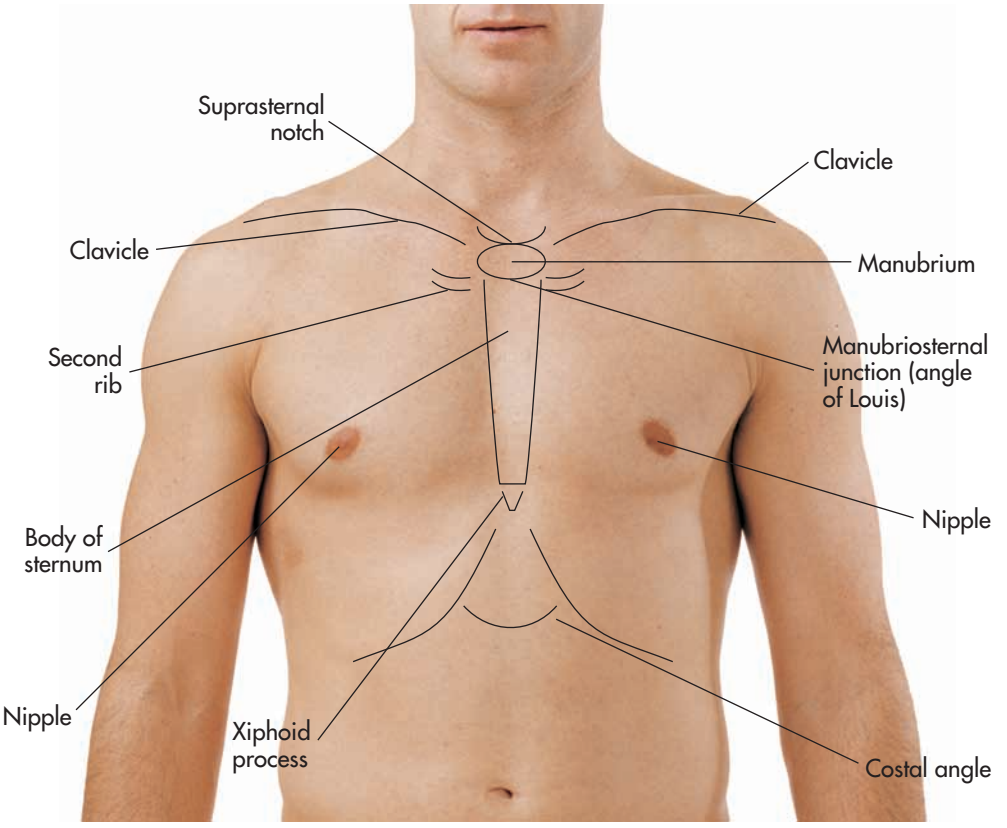

FIGURE 20-20 Topographical landmarks of the chest. (From Seidel H et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

obstructive pulmonary disease. This results in a barrel-shaped appearance of the thorax. Other causes for chest wall deformities or asymmetry include a *funnel chest* (an indentation of the lower sternum above the xiphoid process), *pigeon chest* (a prominent sternal protrusion), *thoracic kyphosis* (a posterior deviation of the spine that results in increased convexity of the chest), and *scoliosis* (a lateral deviation of the spine that results in an abnormal curvature) (Figure 20-22).

CRITICAL THINKING

Evaluate breathing in a supine patient or friend while standing to the person's side, then at the head, and finally at the feet. Which position provides the best view of the symmetry of the thorax?

The paramedic should inspect the skin and nipples for cyanosis and pallor. The presence of suture lines from chest wall surgery, skin pockets enclosing implanted pacemaker devices, implanted central venous lines or ports, and dermal medication patches (e.g., ***nitroglycerin, fentanyl,*** and contraceptives) should be noted. The pattern or rhythm of the patient's respirations should be assessed, noting any use of accessory respiratory muscles (e.g., intercostal or supraclavicular retractions or both). In addition, observing the rise and fall of the patient's chest during breathing provides a rough measurement of tidal volume (see Chapter 15).

LOOK AGAIN

See Chapter 15: Airway, pp. 416-418.

PALPATION

The paramedic should palpate the thorax for pulsations, tenderness, bulges, depressions, crepitus, subcutaneous emphysema, and unusual movement and position. The examination begins by noting the position of the patient's trachea, which should be midline and directly above the sternal notch. Starting with the patient's clavicles, both sides of the patient's chest wall are firmly palpated at the same time, front to back and right side to left side. The examination should proceed systematically without pain or discomfort.

To evaluate the anterior chest wall for equal expansion during inspiration, the paramedic places both thumbs along the patient's costal margin and the xiphoid process. The palms should be lying flat on the chest wall. Equal movement should occur as the patient inhales and exhales. The posterior chest wall should be examined for

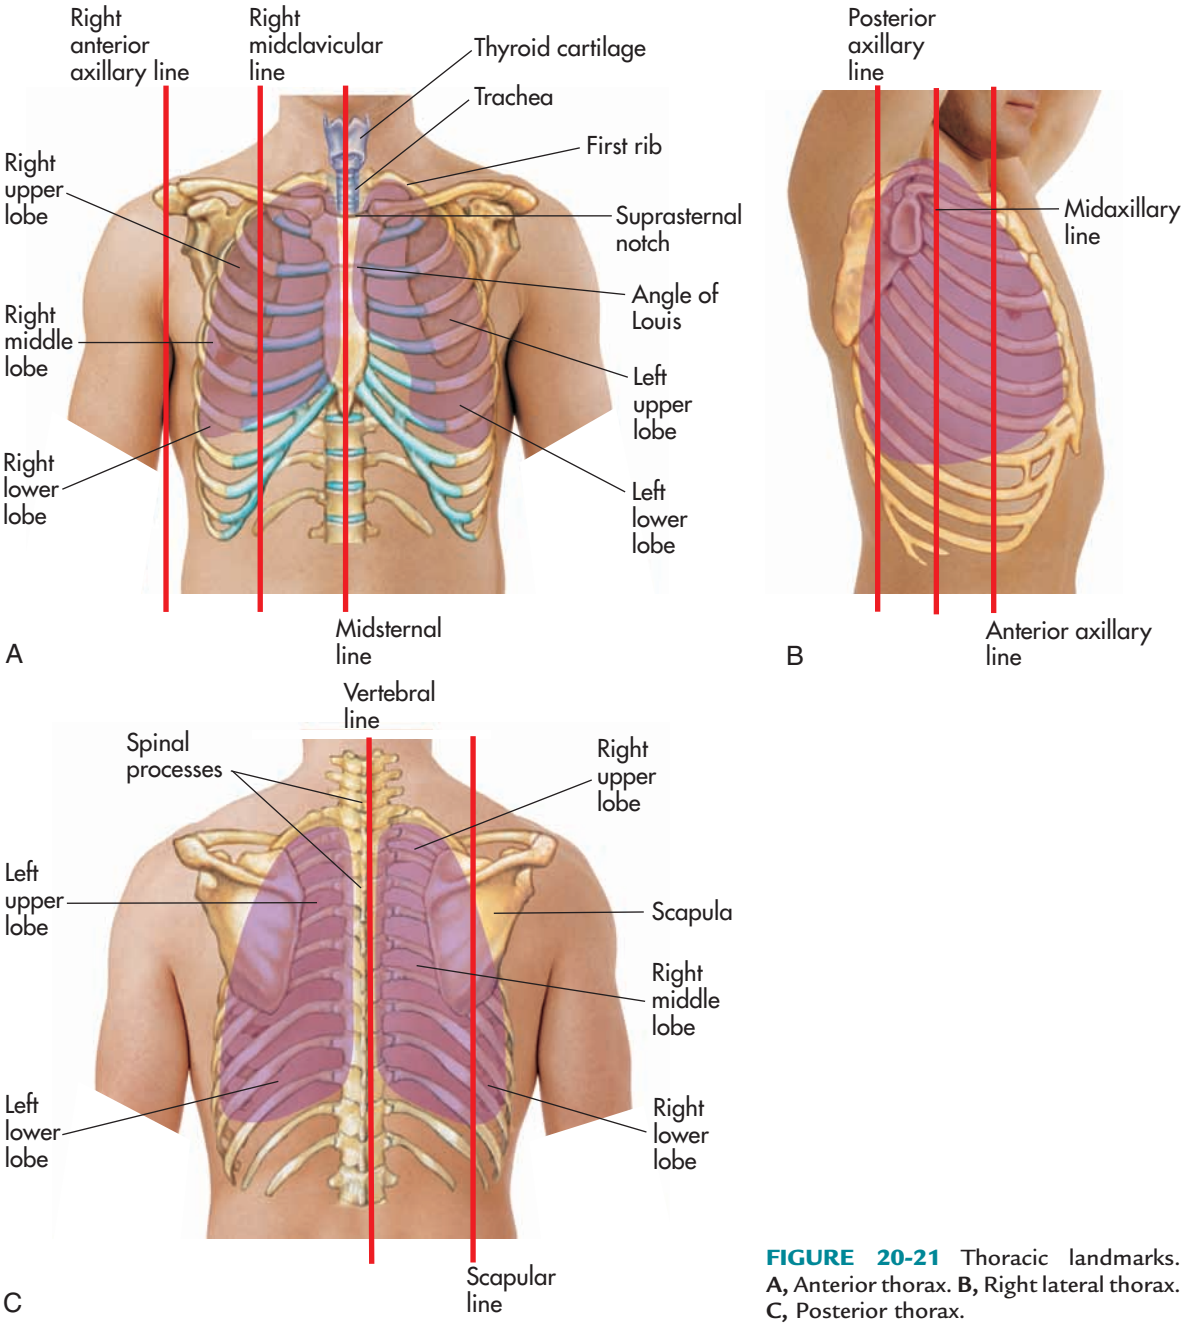

FIGURE 20-21 Thoracic landmarks. **A,** Anterior thorax. **B,** Right lateral thorax. **C,** Posterior thorax.

symmetrical respiratory movement by placing the thumbs along the spinous processes at the level of the tenth rib (Figure 20-23).

PERCUSSION

The paramedic should perform percussion in symmetrical locations from side to side to compare the percussion note (Figure 20-24). *Resonance* usually is heard over all areas of healthy lungs. *Hyperresonance* is associated with overinflation, or hyperinflation, of the lungs. Hyperresonance may indicate pulmonary disease, pneumothorax, or asthma. *Dullness* or *flatness* suggests the presence of fluid or pulmonary congestion. The level and movement of the diaphragm during breathing may be limited by disease or pain. Examples of such disease may be emphysema or tumor. An example of pain is from rib fracture.

AUSCULTATION

The thorax is best auscultated with the patient sitting upright (if possible). The patient should breathe deeply and slowly through an open mouth during the examination. The paramedic should be alert to the chance of resulting hyperventilation and fatigue that may occur in ill and older patients.

The diaphragm of the stethoscope is used to auscultate the high-pitched sounds of the patient's lungs. The

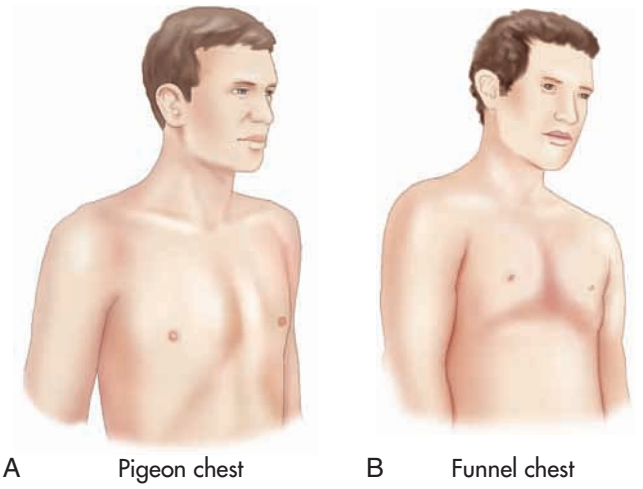

FIGURE 20-22 Chest wall deformities. **A,** Pigeon chest. **B,** Funnel chest.

FIGURE 20-23 Palpating the thoracic expansion. The thumbs are at the level of the tenth ribs.

stethoscope is held firmly on the patient's skin and the paramedic listens carefully as the patient breathes. The chest auscultation should be systematic and thorough. Auscultation should allow evaluation of the anterior and the posterior lung fields.

Breath Sounds. Air movement creates turbulence as it passes through the respiratory tract and produces breath sounds during inhalation and exhalation. During inhalation, air moves first into the trachea and major bronchi. Then air moves into progressively smaller airways. Next, air moves to its final destination, the alveoli. During exhalation, the air flows from small airways to larger ones. This creates less turbulence. Therefore normal breath sounds generally are louder during inspiration.

Normal Breath Sounds. Normal breath sounds are classified as *vesicular, bronchovesicular,* and *bronchial* (Figure 20-25). Vesicular breath sounds are heard over most of the lung fields and are the major normal breath sound. Lungs considered "clear" make normal vesicular breath sounds. These sounds are low pitched and soft and have a long inspiratory phase and a shorter expiratory phase.

Vesicular breath sounds are classified further as *harsh* or *diminished*. Harsh vesicular sounds may result from vigorous exercise. With vigorous exercise, ventilations are rapid and deep. These harsh sounds also occur in children who have thin and elastic chest walls in which breath sounds are more easily audible. Vesicular breath sounds may be diminished in older persons who have less ventilation volume. Vesicular breath sounds also may be diminished in obese or muscular persons, whose additional overlying tissue muffles the sound.

Bronchovesicular breath sounds are heard over the major bronchi and over the upper right posterior lung field. These sounds are louder and harsher than vesicular breath sounds. Bronchovesicular breath sounds are considered to be of medium pitch. Bronchovesicular breath sounds have equal inspiration and expiration phases. They are heard throughout respiration.

Bronchial breath sounds are heard only over the trachea and are the highest in pitch. They are coarse, harsh, loud sounds with a short inspiratory phase and a long expiration. A bronchial sound heard anywhere but over the trachea is considered an abnormal breath sound.

Abnormal Breath Sounds. Abnormal breath sounds are classified as *absent, diminished,* and *incorrectly located bronchial sounds* and as *adventitious breath sounds*. Absent breath sounds may indicate total cessation of the breathing process (e.g., complete airway obstruction). Breath sounds also may be absent only in a specific area. Causes of localized absent breath sounds include endotracheal tube misplacement, pneumothorax, and hemothorax.

Diminished breath sounds may result from any condition that lessens the airflow. Examples include endotracheal tube misplacement, pneumothorax, partial airway obstruction, and pulmonary disease. Although some airflow is present, diminished breath sounds usually indicate that some portion of the alveolar tissue is not being ventilated.

Bronchial breath sounds auscultated in the peripheral lung field indicate the presence of fluid or exudate in the alveoli. Either of these conditions may block airflow. Diseases that contribute to this condition are tumors, pneumonia, and pulmonary edema.

Adventitious Breath Sounds. Adventitious breath sounds are abnormal sounds. They are heard in addition to normal breath sounds. They may be divided into two categories: *discontinuous* and *continuous*. Adventitious breath sounds result from obstruction of the large or small airways. Adventitious breath sounds are most commonly heard during inspiration. They are classified as *crackles* (formerly known as *rales*), wheezes, and rhonchi (Figure 20-26).

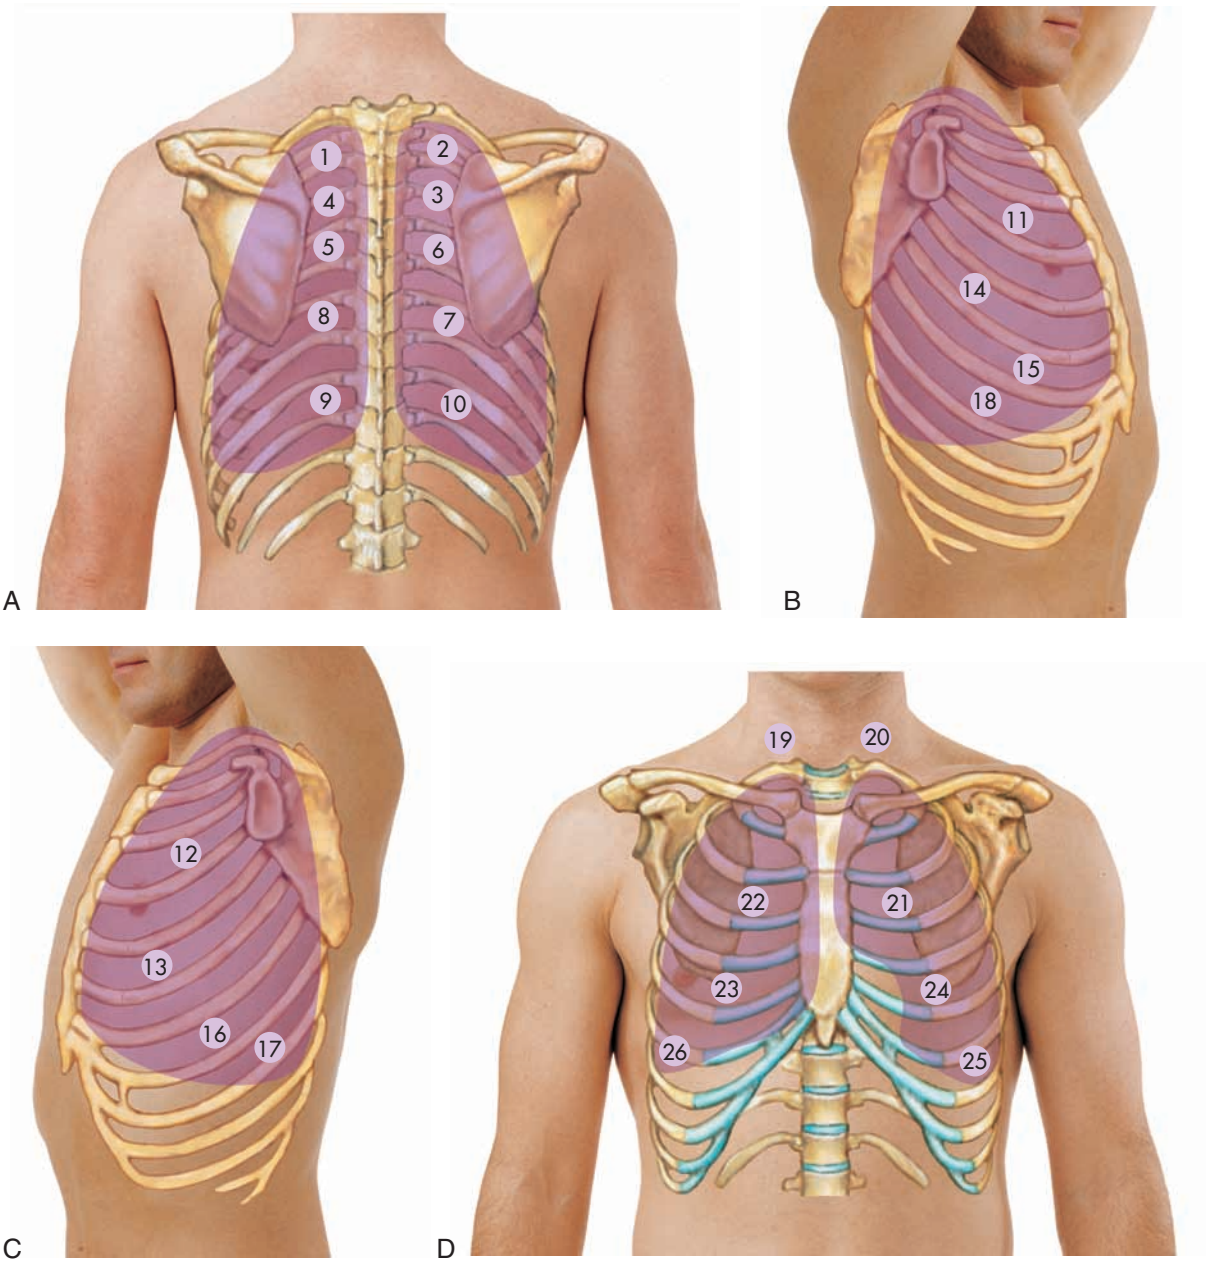

FIGURE 20-24 Suggested sequence for systematic percussion and auscultation of the thorax. **A,** Posterior thorax. **B,** Right lateral thorax. **C,** Left lateral thorax. **D,** Anterior thorax. (From Seidel H et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

Discontinuous Breath Sounds. **Crackles** are the high-pitched, discontinuous sounds that usually are heard during the end of inspiration. The sound is similar to the sound of hair being rubbed between the fingers. Crackles are caused by the disruptive passage of air in the small airways or alveoli, or both, and may be heard anywhere in the peripheral lung field.

The most typical causes of crackles are pulmonary edema and pneumonia in its early stages. Because gravity draws fluid downward, crackles often start in the bases of the lungs. Crackles may be classified further as *coarse crackles* (wet, low-pitched sounds) and *fine crackles* (dry, high-pitched sounds). Crackles are discrete and sometimes difficult to hear and may be overridden by louder respiratory sounds. If the paramedic suspects crackles when auscultating the chest, the patient should be asked to cough. A cough may clear secretions and make crackles more audible.

Continuous Breath Sounds. **Wheezes** are also known as *sibilant wheezes.* They are high-pitched musical noises that usually are louder during expiration. Wheezes are caused by high-velocity air traveling through narrowed airways. They may occur because of asthma and other constrictive diseases and congestive heart failure. When wheezing occurs

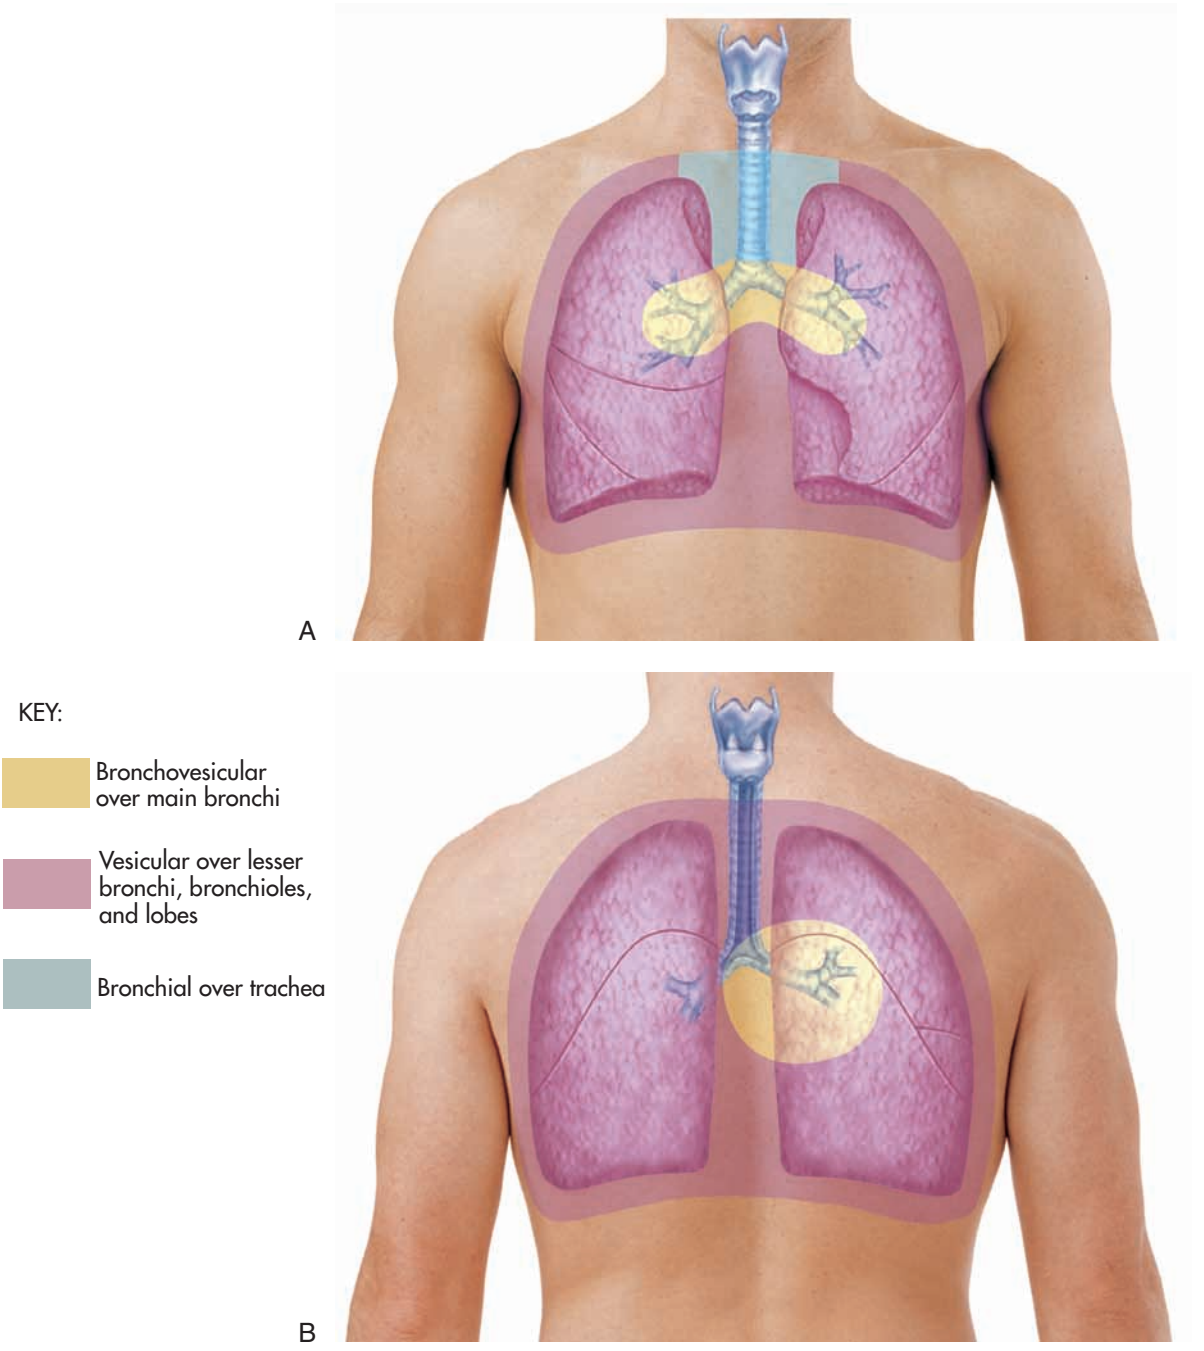

FIGURE 20-25 Expected auscultatory sounds. **A,** Anterior view. **B,** Posterior view. (From Seidel H et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

in a localized area, the paramedic should suspect a foreign body obstruction, tumor, or mucous plug. Wheezes are classified as mild, moderate, and severe. They should be described as occurring on inspiration or expiration or both.

CRITICAL THINKING

Breathe in and out through an open mouth. Gradually purse your lips until only a small opening is present while you continue to inhale and exhale. How do the sounds change? As you narrow the opening, is the noise louder on inspiration or expiration?

Rhonchi are also known as *sonorous wheezes*. They are continuous, low-pitched, rumbling sounds usually heard on expiration. Although rhonchi sound similar to wheezes, they do not involve the small airways. Rhonchi are less discrete than crackles and are auscultated easily. Rhonchi are caused by the passage of air through an airway obstructed by thick secretions, muscular spasm, new tissue growth, or external pressure collapsing the airway lumen. These breath sounds may result from any condition that increases secretions. Examples are pneumonia and drug overdose.

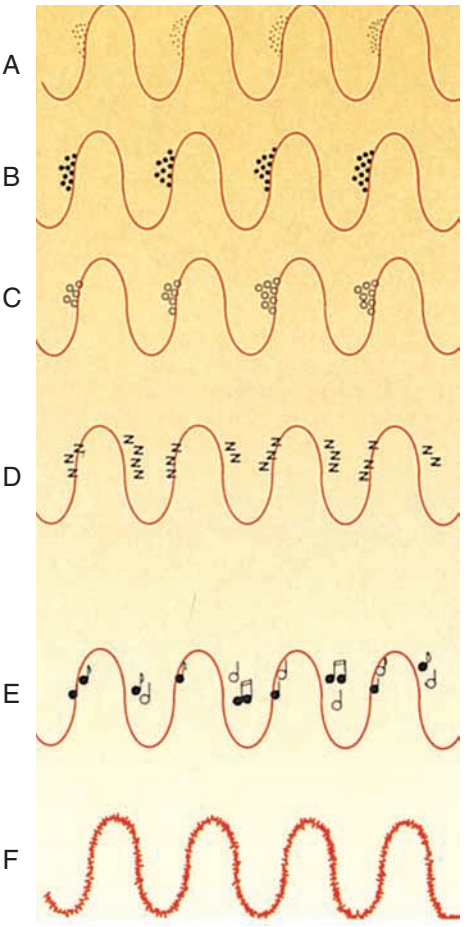

FIGURE 20-26 Adventitious breath sounds. **A,** Fine crackles. **B,** Medium crackles. **C,** Coarse crackles. **D,** Rhonchi. **E,** Wheeze. **F,** Pleural friction rub. (From Seidel H et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

Stridor usually is an inspiratory, crowing-type sound that can be heard without the aid of a stethoscope. It indicates significant narrowing or obstruction of the larynx or trachea, and may be caused by epiglottitis, viral croup, anaphylaxis, foreign body aspiration, or more than one of these factors. Stridor is heard best over the site of origin, usually the larynx or trachea. This breath sound often indicates airway compromise that may be life-threatening, especially in children. Its presence calls for careful observation for ventilatory failure and hypoxia.

Pleural Friction Rub. Although occurring outside the respiratory tree, a pleural friction rub also may be considered an adventitious breath sound. **Pleural friction rub** is a low-pitched, dry, rubbing or grating sound. It is caused by the movement of inflamed pleural surfaces as they slide on one another during breathing. The friction rub may be auscultated on inspiration and expiration and usually is loudest over the lower lateral anterior surface of the chest wall. Presence of a pleural friction rub may indicate pleurisy, viral infection, tuberculosis, or pulmonary embolism (see Chapter 24). Figure 20-27 shows a schema of breath sounds in ill and well patients.

SHOW ME THE EVIDENCE

In this study, researchers compared the ability of paramedics and physicians to interpret tape-recorded breath sounds. Each participant listened to a tape with crackles, rhonchi, stridor, wheezing, and normal lung sounds. The first time they listened, no patient history was provided. On a subsequent test history, age and presence or absence of dyspnea was available. On the third attempt more history was provided. Physicians' median score was 5 for each attempt; experienced paramedics' median score was 3 for trials 1 and 2 and a median score of 4 for trial 3. Scores for new paramedics were similar to those for experienced paramedics. Although significant, this study was limited by the small number of participants and the use of recorded versus real patient breath sounds.

From Wigder HN et al: Assessment of lung auscultation by paramedics, *Ann Emerg Med* 28(3):309-312, 1996.

VOCAL RESONANCE

As part of the respiratory examination, vocal sounds heard on auscultation (vocal resonance) should be assessed to evaluate the presence of lung consolidation. This consolidation usually indicates pneumonia or pleural effusion. Any change in the character of the spoken voice that is higher pitched and less muffled than normal during auscultation should be noted. Normally, the sound of the patient's voice becomes less distinct as the auscultation moves peripherally. Vocal sounds may remain loud at the periphery of the lungs or sound louder than usual over a distinct area when consolidation is present. The following tests can be used to assess vocal resonance:

Bronchophony. In this test the patient is asked to whisper "toy boat" or "blue balloons" while the lungs are auscultated. Vocal sounds will be louder where the consolidation is present.

Egophony. In this test the patient is asked to say the letter "e-e-e." If the vocal sounds more closely resemble the letter "a," lung consolidation may be present.

Whispered Pectoriloquy. The patient is asked to whisper as the posterior lungs are auscultated. If vocal sounds are transmitted clearly or there is an increased loudness of whispering during auscultation, it is often a sign of lung consolidation.

Heart

In the prehospital setting the heart must be examined indirectly. In spite of this, a skilled assessment can collect information about the size and effectiveness of the heart's pumping action. This assessment includes palpation and auscultation.

PALPATION

The **apical impulse** is a visible and palpable force. It is produced by the contraction of the left ventricle. Palpation of this impulse may be useful to compare the relationship of peripheral pulses with the pulse produced by ventricular contraction. The hearts of some patients with

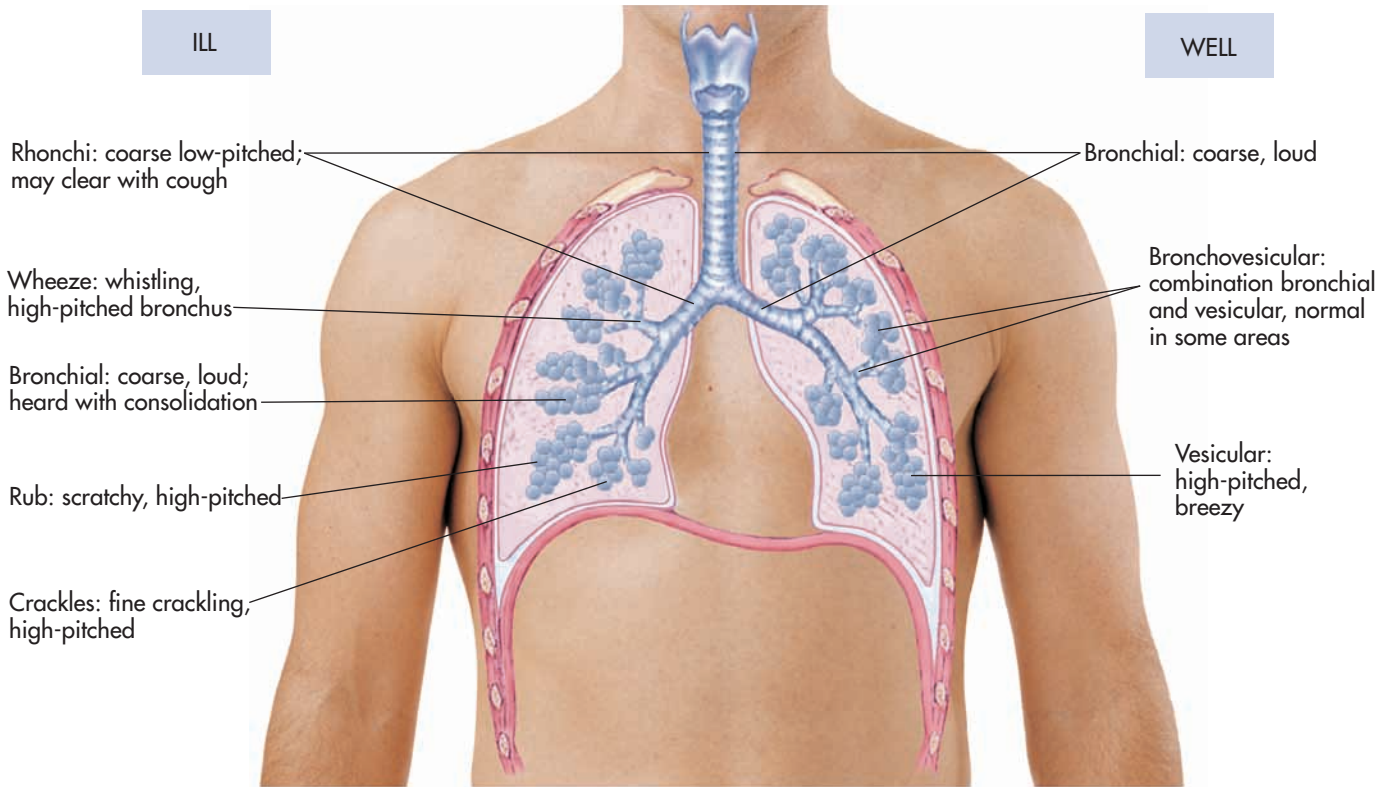

FIGURE 20-27 Schema of breath sounds in ill and well patients (From Seidel H, et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

cardiac irregularities, for example, do not always produce a peripheral pulse with every ventricular contraction. By palpating or auscultating the apical impulse and the carotid pulse at the same time, the paramedic can note these **pulse deficits** (Figure 20-28). Factors such as obesity, large breasts, and muscularity may make this landmark hard to see or palpate.

AUSCULTATION

Heart sounds may be auscultated for frequency (pitch), intensity (loudness), duration, and timing in the cardiac cycle (Figure 20-29). A full evaluation of heart sounds calls for a high level of skill and experience, a quiet environment, and ample time to listen closely. However, the paramedic may assess two basic heart sounds quickly. These sounds may help to improve understanding of the patient's condition. The basic heart sounds S_1 and S_2 are normal sounds that occur when the heart contracts. They are best heard toward the apex of the heart at the fifth intercostal space. For evaluation of heart sounds, the patient should be sitting up and leaning slightly forward (Figure 20-30, *A*), supine (Figure 20-30, *B*), or in a left lateral recumbent position (Figure 20-30, *C*). These positions bring the heart closer to the left anterior chest wall. To listen for S_1, the paramedic should ask the patient to breathe normally and hold the breath in expiration. To listen for S_2, the paramedic should ask the patient to breathe normally again and hold the breath in inspiration.

FIGURE 20-28 Simultaneous palpation of the carotid artery and apical impulse.

Heart sounds may be muffled or diminished by obesity or obstructive lung disease. Muffling also may occur as a result of the presence of fluid in the pericardial sac surrounding the heart muscle. The accumulation of fluid usually is the result of penetrating or severe blunt chest trauma, cardiac tamponade, or cardiac rupture and is considered a true emergency. Other causes of muffled or diminished heart sounds include infectious uremic pericarditis

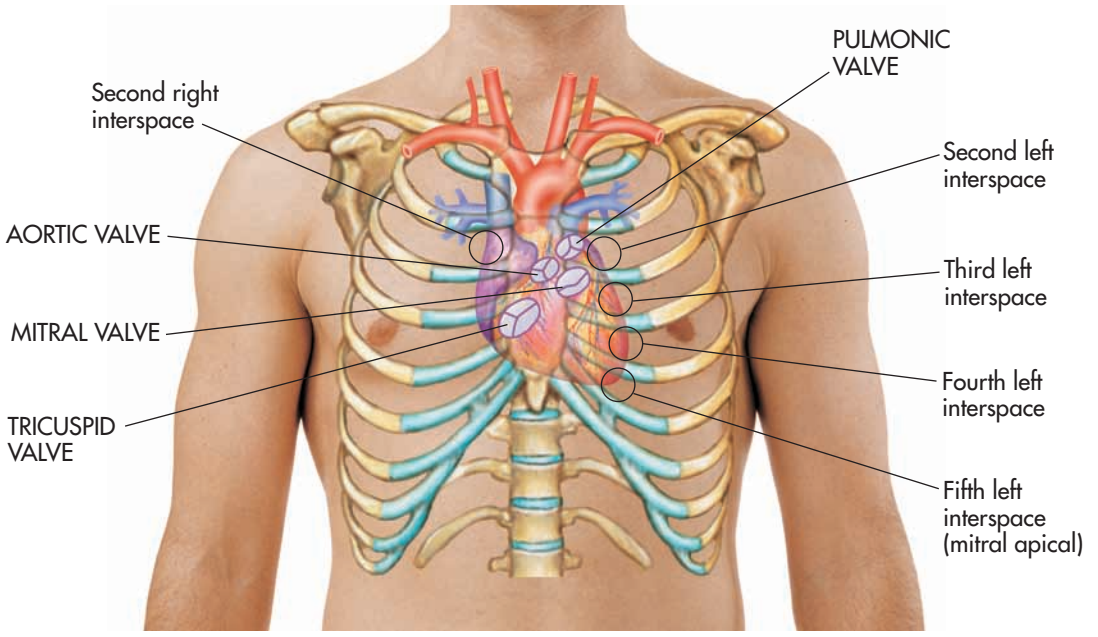

FIGURE 20-29 Areas for auscultation of the heart. (From Seidel H, et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby.)

and malignancy. (See Chapter 22 for further discussion of abnormal heart sounds.)

Inflammation of the pericardial sac may cause a rubbing sound that is audible with a stethoscope. This is a **pericardial friction rub.** The rub may result from infectious pericarditis, myocardial infarction, uremia, trauma, and autoimmune pericarditis. These rubs have a scratching, grating, or squeaking quality. They tend to be louder on inspiration. They can be differentiated from pleural friction rubs by their continued presence when the patient holds the breath.

EXTRA SOUNDS

Extra sounds that sometimes can be heard during auscultation or can be felt by palpation include heart murmurs, bruits, and thrills. **Heart murmurs** are prolonged sounds caused by a disruption in the flow of blood into, through, or out of the heart. Most murmurs are caused by valvular defects. Some heart murmurs are serious. Others (e.g., some that occur in children and adolescents), though, are benign and have no apparent cause. Heart murmurs can be detected during auscultation of the heart.

A **bruit** is an abnormal sound or murmur that may be heard during auscultation of the carotid artery or another organ or gland. A bruit may indicate local obstruction. Bruits usually are low pitched and difficult to hear. To assess blood flow in the carotid artery, the paramedic should place the bell of the stethoscope over the carotid artery at the medial end of the clavicle. The patient is then asked to hold his or her breath (Figure 20-31).

Thrills are similar to bruits but are described as fine vibrations or tremors that may indicate blood flow obstruction. Thrills may be palpable over the site of an aneurysm or on the precordium (the area of the chest wall that overlays the heart and epigastrium). Like murmurs and bruits, thrills may be serious or benign.

Abdomen

The abdomen is divided by two imaginary lines. These lines separate the abdominal region into four quadrants. The quadrants are the upper right, lower right, upper left, and lower left (Figure 20-32). These quadrants and their contents provide the basis for inspection, auscultation, percussion, and palpation (Box 20-5).

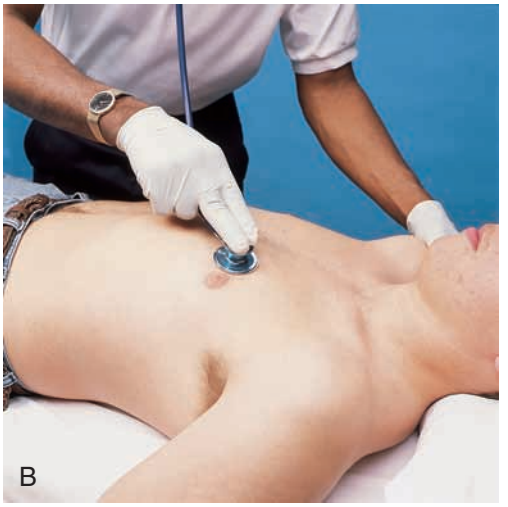
LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 196-199.

When examining a patient's abdomen, the paramedic should ensure that the patient is comfortable (with an empty bladder, if possible), and in a supine position. The paramedic's hands and stethoscope should be warm. The patient should be approached slowly and respectfully. Any painful area should be examined last to avoid "patient guarding" when the painful area is examined first. Discoloration found in the flank (*Grey Turner's sign*) or around the umbilicus (*Cullen's sign*) may indicate possible injury or disease (see Chapter 29).

INSPECTION

The paramedic should inspect the abdomen visually for signs of cyanosis, pallor, jaundice, bruising, discoloration, swelling (ascites), masses, and aortic pulsations. Surgical



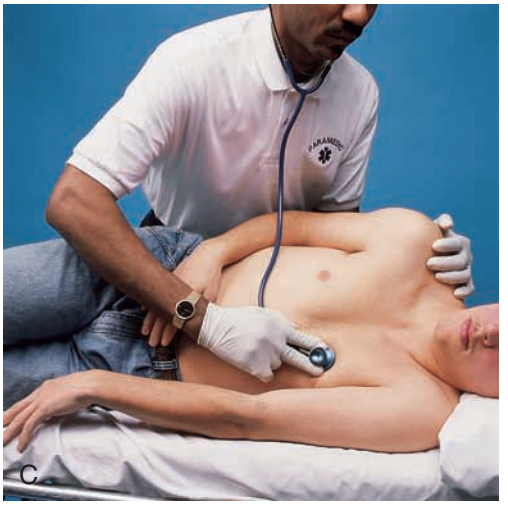


FIGURE 20-30 Patient positions for auscultation. **A,** Sitting up, leaning slightly forward. **B,** Supine. **C,** Left lateral recumbent.

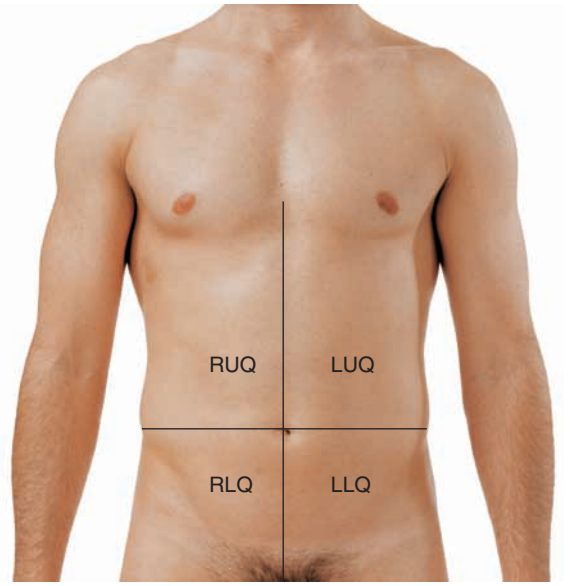

FIGURE 20-32 Four quadrants of the abdomen. *RUQ,* Right upper quadrant; *LUQ,* left upper quadrant; *RLQ,* right lower quadrant; *LLQ,* left lower quadrant.

scars and implanted medical devices should also be noted (see Chapter 22). The abdomen should be evenly round and symmetrical (Figure 20-33). Symmetrical distention of the abdomen may result from obesity, enlarged organs, fluid, or gas. Asymmetrical distention may result from hernias, tumor, bowel obstruction, or enlarged abdominal organs. A flat abdomen is common in adults who are athletic. Convex abdomens are common in children and in adults who have poor exercise habits. The umbilicus should be free of swelling, bulges, and signs of inflammation. The normal umbilicus usually is inverted, or it may protrude slightly.

BOX 20-5 Abdominal Quadrants

Right Upper Quadrant
Liver and gallbladder
Pylorus
Duodenum
Head of pancreas
Right adrenal gland
Portion of right kidney
Hepatic flexure of colon
Portions of ascending and transverse colon

Left Lower Quadrant
Lower pole of left kidney
Sigmoid colon
Portion of descending colon
Bladder (if distended)
Ovary and salpinx
Uterus (if enlarged)
Left ureter

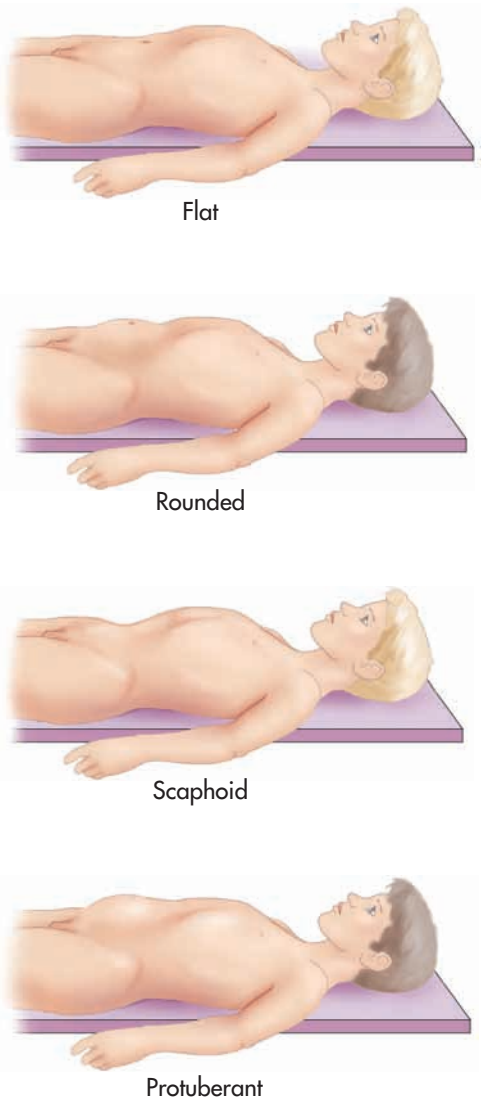

FIGURE 20-33 Shape of the abdomen.

Abdominal movement during respiration should be smooth and even. As a rule, males have more abdominal involvement than females during respiration, so limited abdominal movement in the male patient with symptoms may indicate a pathological abdominal condition. Visible pulsations produced by blood flow through the aorta in the upper abdomen may be normal in thin adults. However, marked pulsations may indicate an abdominal aortic aneurysm (see Chapter 22).

AUSCULTATION

Noting the presence or absence of bowel sounds to assess motility and to discover vascular sounds has limited value in the prehospital setting. Such findings do not affect or determine the approach to patient care. Moreover, the time needed for complete bowel sound assessment (about 5 minutes per quadrant) far exceeds the justifiable scene time for most patients. If auscultation is to be performed, though, it should always precede palpation. (Palpation may alter the intensity of bowel sounds.)

To auscultate bowel sounds, the paramedic holds the diaphragm of the stethoscope on the abdomen with light pressure. If bowel sounds are present, they usually are heard as rumblings or gurgles. These sounds should occur irregularly and may range in frequency from 5 to 35 per minute. Auscultation should be performed in all four quadrants. A minimum of 5 minutes per quadrant is needed to determine that normal bowel sounds are absent. Increased bowel sounds may indicate gastroenteritis or intestinal obstruction. Decreased or absent bowel sounds may indicate peritonitis (inflammation of the lining of the abdominal cavity) or ileus (inactive peristaltic activity resulting from one of several causes) (see Chapter 30).

PERCUSSION AND PALPATION

Percussion and palpation of the abdomen may help to detect the presence of fluid, air, and solid masses. The paramedic should use a systematic approach, moving from side to side or clockwise. Any rigidity, tenderness, or abnormal skin temperature or color should be noted. The patient's face should be observed for signs of pain or discomfort. If the patient is complaining of abdominal pain, the painful quadrant should be examined last so that the patient will not unnecessarily tighten or guard the abdominal area. The abdominal assessment should begin with a light palpation, using an even pressing motion. As stated before, the paramedic's hands should be warm, and sharp and quick jabs should be avoided. Palpation may be done simultaneously with percussion.

Percussion begins by evaluating all four quadrants of the abdomen in turn for tympany and dullness. (**Tympany** is the major sound that should be noted during percussion because of the normal presence of air in the stomach and intestines [gastric bubble]. Dullness should be heard over organs and solid masses.) When percussing the abdomen, proceeding from an area of tympany to an area of dullness is best. That way, the change in sound is easier to detect. Individual assessments of the liver and spleen (described in the following paragraphs) may be performed if indicated by patient complaint or mechanism of injury. Patients who may require surgery for abdominal illness or injury are best served by rapid assessment, stabilization, and transport to an appropriate medical facility.

Percussion and Palpation of the Liver. The paramedic percusses the liver by starting just above the umbilicus in the right midclavicular line in an area of tympany. Percussion should continue in an upward direction until the change from tympany to dullness occurs. This change usually occurs slightly below the costal margin. It indicates the lower border of the liver. To determine the upper border of the liver, the percussion should begin in the same midclavicular line at the midsternal level, proceeding downward until the tympany from the lung area changes to dullness (usually between the fifth and seventh intercostal spaces). Liver size and span (usually 6 to 12 cm; 2 to 5 inches) are related to age and sex. The liver usually is proportionately larger in adults than in children. The liver also is larger in males than in females.

For palpation of the liver, the patient should be supine and comfortable and should have a relaxed abdomen. The paramedic should perform the examination from the patient's right side and should begin by placing the left hand under the patient in the area of the eleventh and twelfth ribs (Figure 20-34). The right hand should be placed on the abdomen, with the fingers pointing toward the patient's head and extended, resting just below the edge of the costal margin. The conscious patient should be instructed to breathe deeply through the mouth. During exhalation, the paramedic presses upward with the hand under the patient and gently pushes in and up with the right hand. If the liver is felt, it should be firm and nontender. (A healthy liver usually cannot be palpated unless the patient is thin.)

Percussion and Palpation of the Spleen. For percussion of the spleen, the patient must be lying supine or in a right lateral recumbent position. Percussion should begin at the area of lung tympany, just posterior to the midaxillary line on the left side. When percussing downward, a change from tympany to dullness should be audible between the sixth and tenth ribs. Large areas of dullness suggest an enlarged spleen. Stomach contents and air-filled or feces-filled intestines make splenic assessment by percussion difficult. These and other factors may affect percussion tones of dullness and tympany.

Palpation is a more useful assessment technique for evaluating the spleen. The patient should be lying supine with the paramedic positioned at the patient's left side. The paramedic places the left hand under the patient, supporting the lower left rib cage. The paramedic places the right hand just below the patient's lower left costal margin (Figure 20-35). The area should be gently palpated by lifting

FIGURE 20-34 Palpation of the liver.

FIGURE 20-35 Palpation of the spleen.

up the left hand and pressing down with the right hand. (A normal spleen usually cannot be palpated in an adult. A palpable spleen is probably enlarged 3 times its normal size.) Palpation of the spleen can produce rupture of the organ. Palpation should be performed with caution.

Female Genitalia

Examination of the genitalia of either sex of patient can be awkward. The patient and the paramedic may feel uncomfortable. When possible, paramedics of the same sex as the patient should perform these exams. If that is not possible, a second person who acts as a chaperone should be present during the examination.

NOTE
Examination of the genitalia of both men and women should only be performed in the prehospital setting if indicated by patient complaint, pregnancy in women, or mechanism of injury.

The external genitalia should be inspected visually to note any swelling, redness, discharge, bleeding, or evidence of trauma. Discoloration or tenderness of the genital tissue may be the result of traumatic bruising. Ulcers, vesicles, and discharges (with or without pain) indicate sexually transmitted disease. If touching the anal area is necessary, the paramedic should change the gloves afterward to prevent bacteria from being introduced into the vaginal area.

CRITICAL THINKING
Examination of a patient's genitalia in the presence of another care provider is advisable. Why might this be important?

MALE GENITALIA

When examining the male genitalia, the paramedic should inspect the area visually. Bleeding or signs of trauma should be noted. The shaft of the penis should be nontender and flaccid. Rarely, patients with leukemia, sickle cell disease, or spinal injury may have a persistent painful erection (priapism). The urethral opening should be free of blood (a possible result of pelvic trauma). The opening also should be free of discharge (a sign of sexually transmitted disease). The scrotum should be nontender and slightly asymmetrical. A swollen or painful scrotum may result from infection, herniation, testicular torsion, or trauma. Discoloration of the genitals is called *Coopernail's sign* and may indicate peritoneal bleeding.

ANUS

Examination of the anus is indicated in the presence of rectal bleeding or trauma to the area. Examination can be performed with the patient in one of several positions. Most patients will find the side-lying position to be most comfortable. (The paramedic should protect the patient's privacy and use proper drapes.) Inspection of the sacrococcygeal and perineal areas should consider abnormal findings, which may include lumps, ulcers, inflammation, rashes, and excoriations (surface injuries caused by scratching or abrasions). Inflamed external hemorrhoids are common in adults and pregnant women.

EXTREMITIES

When examining the upper and lower extremities, a paramedic should pay attention to function and structure (see Chapter 10). The patient's general appearance, body proportions, and ease of movement are key. In particular, any limitation in the range of motion or an unusual increase in the mobility of a joint should be noted. Abnormal findings include the following:

- Signs of inflammation
  - Swelling
  - Tenderness
  - Increased heat
  - Redness
  - Decreased function
- Asymmetry
- Crepitus
- Deformities
- Decreased muscular strength
- Atrophy

EXAMINING UPPER AND LOWER EXTREMITIES

A full assessment of the upper and lower extremities includes an evaluation of the skin and tissue overlying the muscles, cartilage, and bones. It also includes an examination of the joints. Each extremity should be assessed for soft tissue injury, discoloration, swelling, and masses. The upper and lower extremities should be symmetrical in structure and muscularity. The paramedic should assess the circulatory status of each extremity by determining skin color, temperature, sensation, and the presence of distal pulses. The bones, joints, and surrounding tissues of the extremities are assessed for structural integrity and continuity. Muscle tone should be firm and nontender. Joints are assessed for function by moving each joint through its full range of motion (described in Chapter 10). A normal range of motion occurs without pain, deformity, limitation, or instability.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 167-171.

Hands and Wrists. The paramedic should inspect both hands and wrists for contour and positional alignment (Figure 20-36). The wrists, hands, and joints of each finger should be palpated for tenderness, swelling, or deformity. To determine range of motion, the patient should be asked to flex and extend the wrists, make a fist, and touch the thumb to each fingertip. All movements should be performed without pain or discomfort.

FIGURE 20-36 Hands and wrists.

Elbows. The patient's elbows should be inspected and palpated in the flexed and extended positions (Figure 20-37). To determine the range of motion of the elbow, the patient should be asked to rotate the hands from palm up to palm down. The paramedic should inspect the grooves between the epicondyle and olecranon by palpation. Pain and tenderness should not be present when pressing on the lateral or medial epicondyle.

Shoulders and Related Structures. The patient's shoulders should be inspected and palpated for symmetry and integrity of the clavicles, scapulae, and humeri. Pain, tenderness, or asymmetrical contour may indicate a fracture or dislocation. The paramedic should ask the patient to shrug shoulders and raise and extend both arms. These movements should be made without pain or discomfort. The following regions should be palpated, noting any tenderness or swelling (Figure 20-38):

- Sternoclavicular joint
- Acromioclavicular joint
- Subacromial area
- Bicipital groove

Ankles and Feet. The paramedic should inspect the patient's feet and ankles for contour, position, and size. Tenderness, swelling, and deformity are abnormal findings on palpation. The toes should be straight and aligned with each other. Range of motion can be determined by asking the patient to bend the toes, point the toes, and rotate the feet inward and outward from the ankle (Figure 20-39). These movements should be possible without pain or discomfort. The paramedic should inspect all surfaces of the ankles and feet for deformities, nodules, swelling, calluses, corns, and skin integrity.

Pelvis, Hips, and Knees. The structural integrity of the pelvis should be verified. To palpate the iliac crest and the symphysis pubis, the paramedic places both hands on each anterior iliac crest and presses downward and outward (Figure 20-40). To determine stability, the heel of the hand should be placed on the patient's symphysis pubis, pressing downward. Deformity and point tenderness of the pelvis may be signs of fracture. These signs may mask major structural and vascular injury.

FIGURE 20-37 Palpation of the lateral and medial epicondyles.

The hips should be inspected for instability, tenderness, and crepitus. The paramedic can examine the supine or unconscious patient by assessing the structural integrity of the iliac crest. A mobile patient should be able to walk without discomfort. A supine patient should be able to

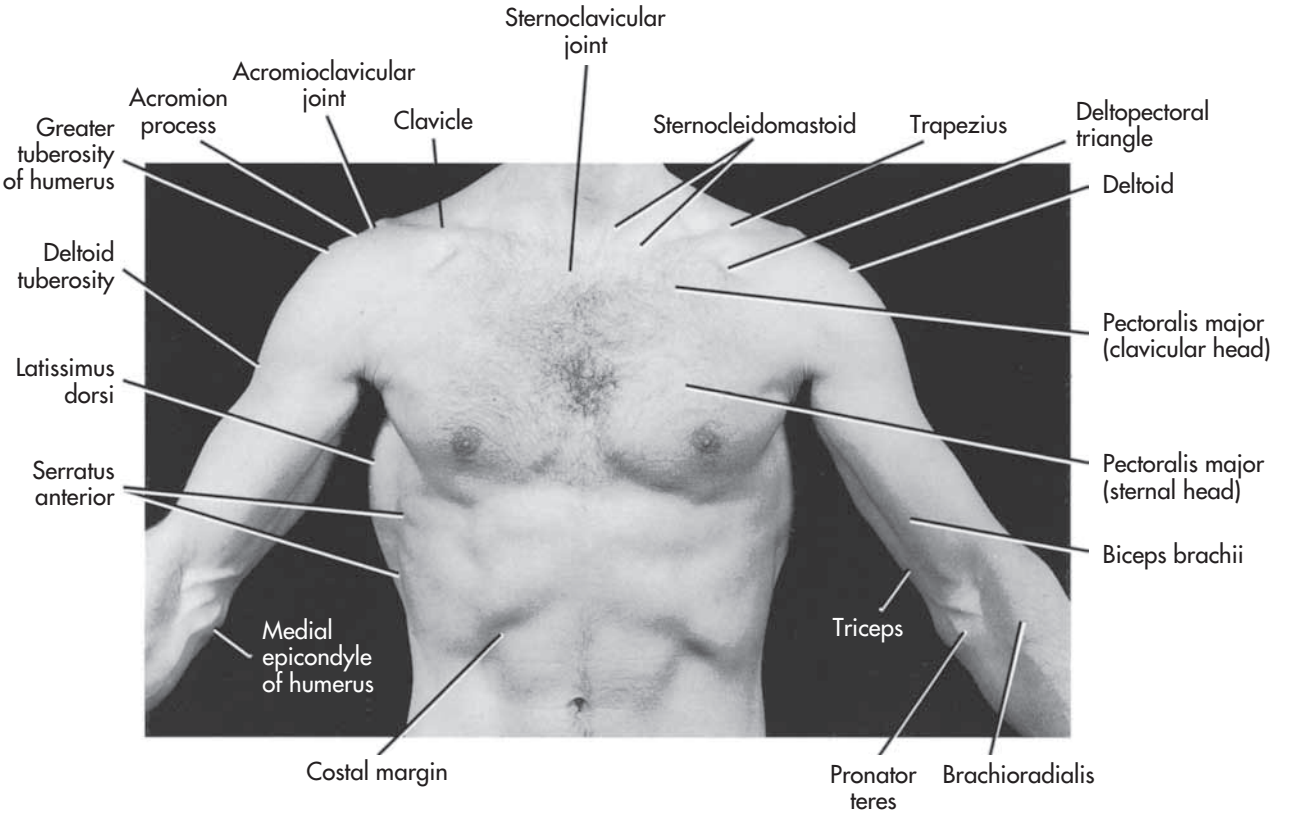

FIGURE 20-38 Evaluation of shoulder and related structures. (From Snell RS, Smith MS: *Clinical anatomy for emergency medicine,* St Louis, 1993, Mosby.)

raise the legs and knees and rotate the legs inward and outward.

The knees should be inspected and palpated for swelling and tenderness. The patella should be smooth, firm, nontender, and midline in position. The patient should be able to bend and straighten each knee without pain.

PERIPHERAL VASCULAR SYSTEM

The peripheral vascular system includes arteries, veins, and the lymphatic system and lymph nodes. It also includes the fluids exchanged in the capillary bed. These can be evaluated during the physical examination of the upper and lower extremities.

Arms. When evaluating the arms, the paramedic should inspect from fingertips to shoulders, noting size, symmetry, swelling, venous pattern, color of the skin and nail beds, and texture of the skin. If arterial insufficiency is noted because of a weak radial pulse, the brachial pulse should be palpated. Epitrochlear nodes and brachial nodes should be nonswollen and nontender (Figure 20-41). A fine venous network on upper and lower extremities often is visible. The paramedic should be alert for enlargement of superficial veins during the exam.

Legs. During examination of the lower extremities, the patient should be supine and draped for privacy. (Shoes, socks, and hosiery should be removed for a full examination.) The paramedic should inspect visually from the groin and buttocks to the feet, noting the following:

- Size and symmetry
- Swelling
- Venous pattern and venous enlargement
- Pigmentation
- Rashes, scars, or ulcers
- Color and texture of the skin
- Presence or absence of hair growth (indicating compromised arterial circulation)

The superficial inguinal nodes in the groin should be palpated to assess for swelling and tenderness. The paramedic should assess all lower extremity pulse sites for circulation, strength, and regularity. These sites include the femoral pulse, the popliteal pulse, the dorsalis pedis pulse, and the posterior tibial pulse (see Chapter 10). The temperature of the feet and legs should be warm, indicating adequate circulation. The paramedic can evaluate for pitting edema over the dorsum of each foot, behind each medial malleolus, and over the shins. This can be done by pressing firmly on the skin with the thumb for at least 5 seconds. Edema is said to be "pitting" when depression of the tissue remains after removal of pressure.

Abnormal Findings. Findings that are considered abnormal during a peripheral vascular assessment include the following:

FIGURE 20-39 Motor function of the foot and ankle. **A,** Bend toes. **B,** Point toes. **C,** Rotate feet in and out.

- Swollen or asymmetrical extremities
- Pale or cyanotic skin
- Weak or diminished pulses
- Skin that is cold to the touch
- Absence of hair growth
- Pitting edema

Spine

A full physical examination includes an assessment of the spine. This begins with a visual assessment of the cervical, thoracic, and lumbar curves. From the patient's side, any curvature of the spine, including curvature associated with abnormal lordosis, kyphosis, and scoliosis should be noted (Figure 20-42). In addition, the paramedic should look for any differences in the height of the shoulders or iliac crests (hips) that may result from abnormal spinal curvature.

FIGURE 20-40 Palpating the pelvis for stability.

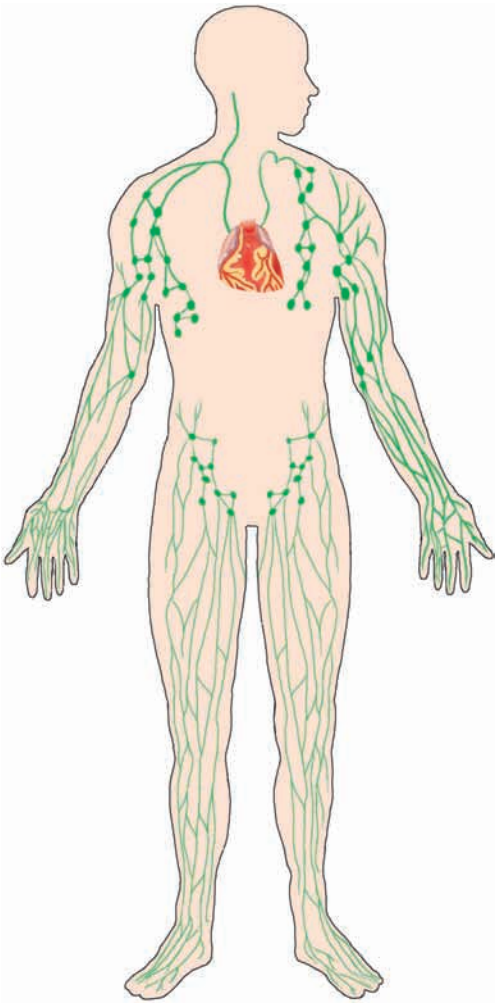

FIGURE 20-41 Nodes of upper and lower extremities.

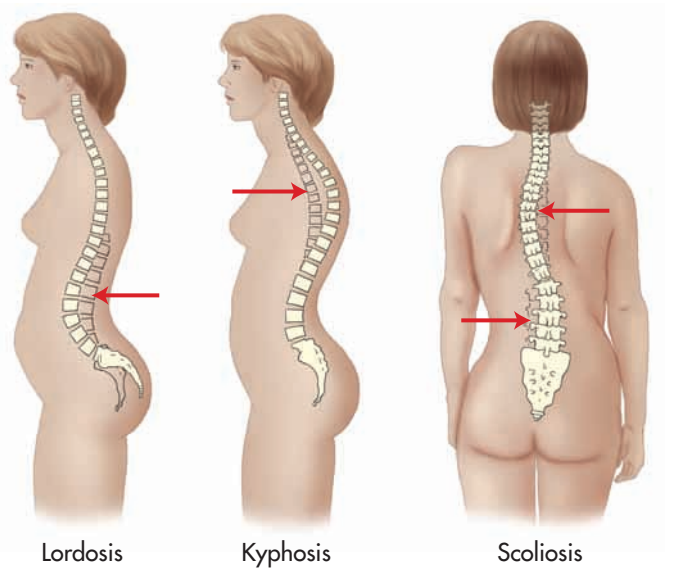

FIGURE 20-42 Abnormal spinal curvatures. Lordosis, kyphosis, scoliosis.

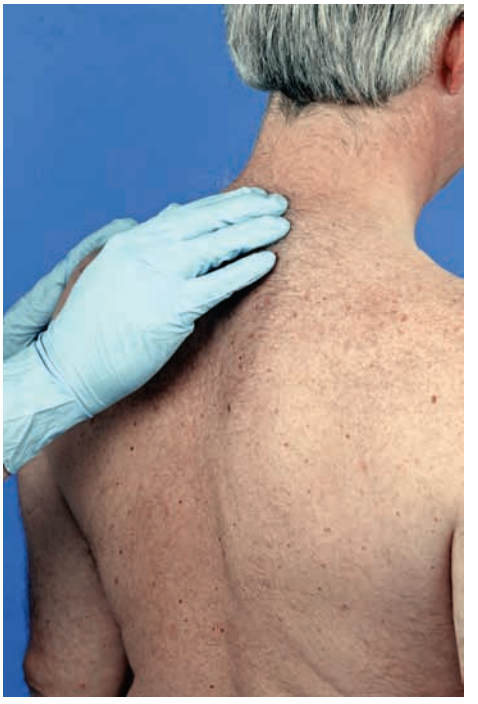

FIGURE 20-43 Palpation of the seventh cervical spinous process.

CRITICAL THINKING

Consider a case in which no deformity of the spine is found during an examination. Can spine fracture or dislocation be ruled out?

CERVICAL SPINE

The patient's neck should be in a midline position. If the patient is alert and denies neck pain, the paramedic should palpate the posterior aspect for point tenderness and swelling. The only palpable landmark should be the spinous process of the seventh cervical vertebra at the base of the neck (Figure 20-43). In the absence of suspected injury, the paramedic tests range of motion by directing the patient to

NOTE

The paramedic will need to test range of motion. However, the paramedic should never attempt to move the neck of a person who is unconscious. The paramedic also should never attempt this with a person who is unable or unwilling to do so on his or her own. Spontaneous cervical muscle spasm frequently is associated with significant cervical spine injury in the trauma victim.

bend the head forward, backward, and from side to side. These movements should not cause pain or discomfort.

THORACIC AND LUMBAR SPINE

The thoracic and lumbar areas should be inspected for signs of injury, swelling, and discoloration. Palpation should begin at the first thoracic vertebra and move downward to the sacrum. Under normal conditions, the spine is nontender to palpation. The paramedic can evaluate range of motion by asking the patient to bend at the waist forward and backward and to each side and also to rotate the upper trunk from side to side in a circular motion.

Nervous System

The details of an appropriate neurological examination vary greatly. The exam usually depends on the origin of the patient's complaint. For example, the exam may depend on whether the complaint refers to the peripheral nervous system or the central nervous system. The assessment and examination of the nervous system may be performed separately. However, neurological assessment often is completed during other assessments. A neurological examination may be organized into five categories:

- Mental status and speech
- Cranial nerves
- Motor system
- Sensory system
- Reflexes

MENTAL STATUS AND SPEECH

As discussed before, a healthy patient should be oriented to person, place, and date. Patients also should be able to organize their thoughts and converse freely (provided they have no hearing or speech impediments). Abnormal findings include unconsciousness, confusion, slurred speech, aphasia, dysphonia, and dysarthria.

CRANIAL NERVES

The 12 cranial nerves can be categorized as sensory, somatomotor and proprioceptive, and parasympathetic (see Chapter 10). The following methods can be used to assess each of the cranial nerves:

Nerve	Nerve Function and Test
Cranial nerve I	*Olfactory*: Test sense of smell with aromatic substance (Jarvis).
Cranial nerve II	*Optic*: Test for visual acuity (previously described).
Cranial nerves II and III	*Optic and oculomotor*: Inspect the size and shape of the pupils; test the pupil response to light.
Cranial nerves III, IV, and VI	*Oculomotor, trochlear, abducens*: Test extraocular movements by asking the patient to look up and down, to the left and right, and diagonally up and down to the left and right (the six cardinal directions of gaze).
Cranial nerve V	*Trigeminal*: Test motor movement by asking the patient to clench the teeth while you palpate the temporal and masseter muscles. Test sensation by touching the forehead, cheeks, and jaw on each side.
Cranial nerve VII	*Facial*: Inspect the face at rest and during conversation, noting symmetry, involuntary muscle movements (tics), or abnormal movements. Ask the patient to raise the eyebrows, frown, show upper and lower teeth, smile, and puff out both cheeks. The paramedic can assess strength of the facial muscles by asking the patient to close eyes tightly so they cannot be opened and gently attempting to raise the eyelids. Observe for weakness or asymmetry.
Cranial nerve VIII	*Acoustic*: Assess hearing acuity (previously described).
Cranial nerves IX and X	*Glossopharyngeal and vagus*: Assess the patient's ability to swallow with ease; to produce saliva; and to produce normal voice sounds. Instruct the patient to hold the breath, and assess for normal slowing of the heart rate. Testing for the gag reflex also will test the cranial nerves.
Cranial nerve XI	*Spinal accessory*: Ask the patient to raise and lower the shoulders and to turn the head.
Cranial nerve XII	*Hypoglossal*: Ask the patient to stick out the tongue and to move it in several directions.

CRITICAL THINKING

Why should abnormal findings in examination of one or more of the cranial nerves concern you?

MOTOR SYSTEM

An evaluation of a patient's motor system includes observing the patient during movement and at rest. The paramedic should evaluate abnormal involuntary movements for quality, rate, rhythm, and fullness of range. Other body movement assessments include posture, level of activity, fatigue, and emotion.

Muscle Strength. Muscle strength should be bilaterally symmetrical. In addition, the patient should be able to provide reasonable resistance to opposition. One way to evaluate muscle strength in the upper extremities is to ask the patient to extend the elbow. Then the paramedic instructs the patient to pull the arm toward the chest against opposing resistance (Figure 20-44, *A*). Muscle strength in the lower extremities is assessed by asking the

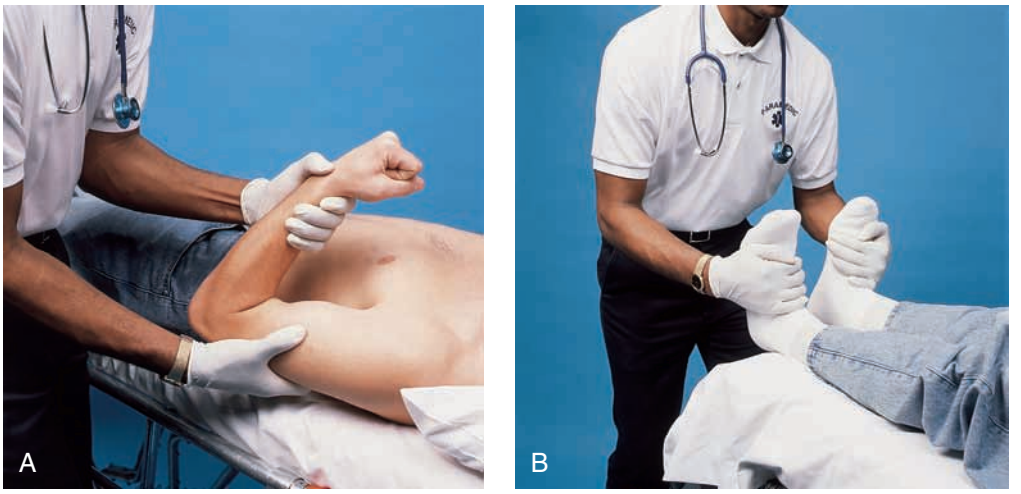

FIGURE 20-44 Evaluating muscle strength of the upper **(A)** and lower **(B)** extremities.

patient to push the soles of the feet against the paramedic's palms. Next, the paramedic directs the patient to pull the toes toward the head while the paramedic provides opposing resistance (Figure 20-44, *B*). The patient should be able to perform both of these actions easily without evident fatigue. Other methods to evaluate muscle strength and agility (illustrated in Chapter 10) include testing for flexion, extension, and abduction of the upper and lower extremities.

Coordination. To evaluate a patient's coordination, the paramedic should assess the patient's ability to perform rapid alternating movements. These include point-to-point movements, gait, and stance.

One point-to-point movement that the patient can perform easily is to touch the finger to the nose, alternating hands. Another test is to ask the patient to touch each heel to the opposite shin. Both movements should be done numerous times and quickly to assess coordination, which should be smooth, rapid, and accurate.

Gait can be evaluated in many ways. A healthy patient should be able to perform each of the following tasks without discomfort or losing balance:

- Walk heel to toe
- Walk on the toes
- Walk on the heels
- Hop in place
- Do a shallow knee bend
- Rise from a sitting position without assistance

Stance and balance can be evaluated by using **Romberg's test** and the **pronator drift test.** To perform Romberg's test, the paramedic asks the patient to stand erect with the feet together and arms at the sides (Figure 20-45). The patient's eyes initially should be open and then closed. Although slight swaying is normal, a loss of balance is abnormal (a positive Romberg's sign). A patient should be able to stand in this position with one foot raised for 5 seconds without losing balance.

FIGURE 20-45 Romberg's test.

NOTE

The paramedic should stay close to the patient being tested for gait, stance, and balance. That way, the paramedic can help to prevent injury from a fall or loss of balance. The paramedic also should consider the patient's age and physical condition in deciding the appropriateness of these examinations.

The pronator drift test (also known as an *arm drift test*) is performed by having the patient close the eyes and hold both arms out from the body (Figure 20-46). A normal test will reveal that both arms move the same or both arms do not move at all. Abnormal findings include one arm that

does not move in concert with the other or one arm that drifts down compared with the other.

SENSORY SYSTEM

The sensory pathways of the nervous system conduct sensations of pain, temperature, position, vibration, and touch. A healthy patient is expected to be responsive to each of these stimuli. Common assessments of the sensory system include evaluating the patient's response to pain and light touch. Each of the responses should be considered in relation to dermatomes (see Chapter 10).

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 176-178.

In conscious patients the paramedic should perform a sensory examination with light touch on each hand and each foot. If the patient cannot feel light touch or is unconscious, the sensation may be evaluated by gently pricking the hands and soles of the feet with a sharp object. The paramedic should ensure the object will not penetrate the skin (e.g., a paper clip or cotton swab). The sensory examination should proceed from head to toe. The exam should compare symmetrical areas on each side of the body and the distal and proximal areas of the body. A lack of sensory response may indicate spinal cord damage (see Chapter 41).

REFLEXES

Testing a patient's reflexes can evaluate the function of certain areas of the nervous system as they relate to sensory impulses and motor neurons. Reflexes may be categorized as superficial reflexes and deep tendon reflexes (Table 20-5). Both types of reflexes should be tested as part of a thorough neurological examination.

SUPERFICIAL REFLEXES

Superficial reflexes are elicited by sensory afferents from skin. These include the upper abdominal, lower abdominal, cremasteric (for males), and plantar reflexes. All superficial reflexes are tested using the edge of a tongue blade (or similar object) or the end of a reflex hammer. An absent reflex may indicate an upper or lower motor neuron disorder.

- *Upper and lower abdominal reflex:* Place the patient supine. Gently stroke each quadrant of the abdomen with the tongue blade. A normal reflex is a slight movement of the umbilicus toward each area that is stroked.
- *Cremasteric reflex:* Place the patient supine. Gently stroke the inner thigh (proximal to distal). The testicle and scrotum should rise on the side that is stroked.
- *Plantar reflex:* Place the patient with legs extended. Gently stroke the lateral side of the foot from heel to the ball and then across the foot to the medial side. Fanning of all the toes should occur with the direction of the stroke (Figure 20-47). The Babinski sign is present when there is dorsiflexion of the great toe with or without fanning of the other toes. It should be noted that the Babinski sign is an abnormal finding in older children and adults, but a normal response in children less than 2 years of age. Other normal reflexes for infants and children were described in Chapter 12.

FIGURE 20-46 Pronator drift test.

TABLE 20-5 Superficial and Deep Tendon Reflexes

Reflex	Spinal Level Evaluated
Superficial	
Upper abdominal	T7, T8, and T9
Lower abdominal	T10 and T11
Cremasteric	T12, L1, and L2
Plantar	L4, L5, S1, and S2
Deep Tendon	
Biceps	C5 and C6
Brachioradial	C5 and C6
Triceps	C6, C7, and C8
Patellar	L2, L3, and L4
Achilles	S1 and S2

Modified from Rudy EB: *Advanced neurological and neurosurgical nursing*, St. Louis, 1984, Mosby.

LOOK AGAIN
See Chapter 12: Life Span Development, pp. 259-260.

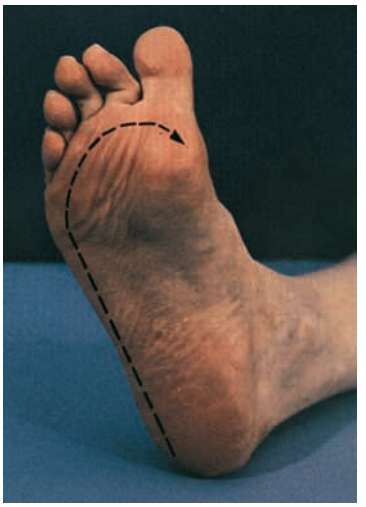

FIGURE 20-47 Plantar reflex indicating the direction of the stroke and the Babinski sign—dorsiflexion of the great toe with or without fanning of the toes.

TABLE 20-6 Scoring Deep Tendon Reflexes

Grade	Deep Tendon Reflex Response
0	No response
1+	Sluggish or diminished
2+	Active or expected response
3+	More brisk than expected, slightly hyperactive
4+	Brisk, hyperactive, with intermittent or transient clonus

DEEP TENDON REFLEXES

Deep tendon reflexes are elicited by sensory afferents from muscle rather than bone. They include the biceps reflex, brachioradial reflex, triceps reflex, patellar reflex, and the Achilles reflex. These reflexes should be tested on each extremity with a reflex hammer and a comparison made for visible and palpable responses. Deep tendon reflexes are graded using the scoring system in Table 20-6 and are recorded on a stick figure. Diminished or absent reflexes may indicate damage to lower motor neurons or the spinal cord. Hyperactive reflexes may suggest a motor neuron disorder. All reflexes are tested with the patient in a sitting position in the following manner (Figure 20-48):

- *Biceps reflex:* Flex the patient's arm to 45 degrees at the elbow. Palpate the biceps tendon in the antecubital fossa. Place your thumb over the tendon and your fingers under the elbow. Strike your thumb with the reflex hammer. Contraction of the biceps muscle should cause visible or palpable flexion of the elbow.
- *Brachioradial reflex:* Flex the patient's arm up to 45 degrees. Rest the patient's forearm on your arm with the hand slightly pronated. Strike the brachioradial tendon (about 1 to 2 inches above the wrist) with the reflex hammer. Pronation of the forearm and flexion of the elbow should occur.
- *Triceps reflex:* Flex the patient's arm at the elbow up to 90 degrees and rest the patient's hand against the side of the body. Palpate the triceps tendon and strike it with the reflex hammer, just above the elbow. Contraction of the triceps muscle should cause visible or palpable extension of the elbow.
- *Patellar reflex:* Flex the patient's knee to 90 degrees, allowing the lower leg to hang loosely. Support the leg with your hand. Strike the patellar tendon just below the patella. Contraction of the quadriceps muscle should cause extension of the lower leg.
- *Achilles reflex:* Flex the patient's knee to 90 degrees. Keep the ankle in a neutral position and hold the heel of the patient's foot in your hand. Strike the Achilles tendon at the level of the ankle malleoli. Contraction of the gastrocnemius muscle should cause plantar flexion of the foot.

REASSESSMENT

Reassessment refers to the ongoing assessment that follows the paramedic's initial evaluation of the patient. The purpose of reassessment is twofold: (1) It "re-focuses" the primary assessment to ensure that the patient continues to be stable and that initial interventions continue to be successful; (2) it also allows the paramedic to "trend" the patient's condition. That is, is the patient's condition improving or is it deteriorating while at the scene and during transport? Reassessment includes a second look at the following:

- The patient's level of consciousness
- The patient's vital signs
- The patient's response to initial care and treatment
- Positive or negative trends in the patient's condition
- Care interventions that may need to be changed or altered

Other examples of reassessment include reevaluating pulse and sensation in an extremity that has been splinted, verifying lung sounds before and after moving a patient who has been intubated, monitoring the electrocardiogram (ECG) after administering drugs, and monitoring pulse oximetry readings in a patient receiving airway support.

Reassessment also allows the paramedic to verify that nothing was missed or overlooked in the primary or secondary assessments, where the focus of patient care was on identifying and managing life-threatening conditions. Reassessment is an important aspect of providing good patient care.

SHOW ME THE EVIDENCE

Army researchers evaluated the value of vital sign trends in trauma patients. They retrospectively assessed vital signs of patients being transported to a level I trauma center in two time periods: 0-7 and 14-21 minutes. They concluded that vital sign trends over 21 minutes or less are unlikely to be diagnostically useful. Higher acuity patients' vital signs were much more variable and had periodic episodes of instability rather than a steady decline.

From Liangyou C et al: Exploration of prehospital vital sign trends for the prediction of trauma outcomes, *PEC* 13(3):286-294, 2009.

PHYSICAL EXAMINATION OF INFANTS AND CHILDREN

Examining the ill or injured child requires special assessment skills. Children differ physiologically, psychologically, and anatomically from adults. Thus a pediatric patient assessment must take age and development into account.

Approaching the Pediatric Patient

The assessment and management objectives in caring for critically ill or injured children are similar to those for any other patient. The approach to the pediatric patient must differ, though. The initial encounter with the sick or injured child sets the tone for the entire patient care episode. Thus the paramedic must consider the patient's age. The paramedic also must be sensitive to how the child perceives the emergency environment. The following six guidelines should be considered when approaching the pediatric patient[6]:

1. Remain calm and confident. The parent's anxiety is infectious. Stay under control and take charge of the situation in a gentle but firm manner.
2. Do not separate the child from the parent unless absolutely necessary. In fact, once parents are reassured, encourage them to touch, hold, or cuddle the child when such actions are practical. This comforts the parents and the child.
3. Establish rapport with the parents and the child. Much of a child's fear and anxiety reflects the parent's behavior. When the family is calm, the child is reassured and is less fearful.
4. Be honest with the child and parent. In simple, direct, nonmedical language, explain to the parent and the child what is happening as it occurs. When a procedure is going to hurt, inform the child. Never lie. Do not give the impression that there are options when none exist. For example, do not say, "Would you like to go for a ride in the ambulance?" The child may answer "No."

5. Whenever possible, assign one paramedic to stay with the child. This person should obtain the history and be the primary person to initiate therapy. Even in a few moments, one person who remains on the child's level can establish a trusting relationship.
6. Observe the patient before the physical examination. If possible, the paramedic should at first assess the alert child with no touching. After the physical examination begins, the child's behavior may change radically. This may make it difficult to assess whether the behavior is a reaction to a physical state or to the perceived intrusion. The paramedic usually can assess the patient's general appearance, skin signs, level of consciousness, respiratory rate, and behavior easily before approaching the patient. During this observation, the paramedic also should note any area of the body that looks painful and avoid manipulating this area until the end of the examination. The paramedic should inform the child that he or she will give warning before touching the area.

CRITICAL THINKING

The next time you are in a room with an infant or small child, try this "across the room" assessment technique.

What can you tell about the level of distress and cardiopulmonary function by doing this?

General Appearance

A child's general appearance is assessed best at a distance. While the patient is in safe, familiar surroundings (e.g., a parent's arms), the paramedic visually should assess the child's level of consciousness, spontaneous movement, respiratory effort, and skin color. The child's body position also can offer helpful information. For example, the child may be lying limp or sitting upright to aid breathing. Other clues may help determine the child's willingness to cooperate during the examination. These clues may include crying, eye contact, concentration, and distractibility.

A visual inspection of the child's general appearance can be helpful. Appearance is a fairly reliable indicator of the patient's need for emergency care. Children who are seriously ill or injured usually do not attempt to hide their state. Their actions generally reflect the severity of the situation. Thus the patient's appearance is a valuable tool for the paramedic. Table 20-7 provides the key aspects of general appearance in initial assessment of the pediatric patient.

Physical Examination

A physical examination is best conducted with knowledge of the development of children and changes that occur within age groups (see Chapter 12). The guidelines that follow vary according to the child's development. However, these guidelines may be used as a reference during the exam. Parents and family members also may be a source of information. The paramedic may direct questions regarding "normal" behavior and activity levels to the parents.

TABLE 20-7 Components of General Appearance for Assessment

Assessment Finding	Evaluation Considerations
Alertness	How perceptive is the child, and how responsive is the child to the presence of a stranger or to other aspects of the environment?
Distractibility	How readily does a person, object, or sound draw the child's attention? For example, drawing a child's attention to a toy when the child initially appeared disinterested in the surroundings is a positive sign
Consolability	Can a distressed child be comforted? For example, stopping a child from crying by speaking softly or offering a pacifier or a toy is an encouraging sign.
Speech or cry	Is the speech or cry strong and spontaneous? Weak and muffled? Hoarse? Absent unless stimulated? Absent altogether?
Spontaneous activity	Does the child appear flaccid? Do the extremities move only in response to stimuli, or are movements spontaneous?
Color	Is there pallor, a flushed appearance, cyanosis, or mottling? Does the skin coloring of the trunk differ from that of the extremities?
Respiratory efforts	Are there intercostal, supraclavicular, or suprasternal retractions in the resting state? Nasal flaring also indicates respiratory difficulty.
Eye contact	Does the child appear to gaze aimlessly, or does the child maintain eye contact with objects or persons? Even small infants, when well, preferentially fix their gaze on a face rather than other objects.

BIRTH TO 6 MONTHS

Children under 6 months of age typically are not frightened by the approach of a stranger. Thus the physical examination is fairly easy. During the examination, the paramedic should maintain the child's body temperature.

Healthy and alert infants usually are in constant motion. They may have a lusty cry. If the patient is under 3 months of age, poor head control is normal. Infants are "abdominal breathers." This causes the stomach to protrude and the infant's chest wall to retract during inspiration. This diaphragmatic involvement may give the impression of labored breathing. Skin color, nasal flaring, and intercostal muscle retraction are the best indicators of respiratory insufficiency.

In the infant, assessing the fontanelles is particularly important (Figure 20-49). These sutures between the flat bones of the skull are fairly wide to allow a "give" in the skull during the birth process. (The anterior fontanelle, known as the *soft spot,* usually is present up to the age of 18 months.) The anterior fontanelle should be level with the

FIGURE 20-49 Palpation of the anterior fontanelle.

FIGURE 20-50 Examining a child.

skull or slightly depressed and soft. The fontanelle usually bulges during crying and may feel firm if the child is lying down. In the absence of injury, the fontanelle is best examined with the child in an upright position. A sunken fontanelle may indicate dehydration, and a bulging fontanelle in the noncrying upright infant may indicate an increase in intracranial pressure.

7 MONTHS TO 3 YEARS

Patients from 7 months to 3 years of age often are difficult to evaluate. They have little capacity to understand the emergency event. In addition, they are likely to experience emotional problems as a result of illness, injury, or hospitalization. Children of this age fear strangers and may show separation anxiety. If possible, parents should be present and should be allowed to hold the child during the examination (Figure 20-50). The paramedic should approach the child with a quiet, reassuring voice. If time permits, the paramedic should allow the patient to become accustomed to the examination environment.

During the physical assessment, each activity should be explained in short, simple sentences. The paramedic should give this explanation even though it may not improve cooperation. The best approach is to be gentle and firm and to complete the examination as quickly as possible. If physical restraint is necessary and if patient care activities will not be hindered, the paramedic should restrain the child with hands rather than mechanical devices (e.g., backboards).

4 TO 10 YEARS

Children in the 4- to 10-year age group are developing a capacity for rational thought. They may be cooperative during the physical examination. Depending on the child's age and the emergency scenario, the child may be able to provide a limited history of the event. These children also may experience separation anxiety and may view their illness or injury as punishment. Therefore the paramedic should approach the child slowly and speak in quiet and reassuring tones. Questions should be simple and direct.

During the examination, the paramedic should allow the child to take part by holding the stethoscope, penlight, or other pieces of equipment. This "helping" activity may lessen the child's fear. Helping also may improve the paramedic-patient relationship. Children of this age group have a limited understanding of their bodies. They also are reluctant to allow the paramedic to see or touch their "private parts" (seldom necessary in the prehospital setting). The paramedic should explain all examination procedures simply and completely. The paramedic should advise the child of any expected pain or discomfort.

ADOLESCENTS (11 TO 18 YEARS OF AGE)

Adolescents generally understand what is happening. They usually are calm, mature, and helpful. These patients are more adult than child and should be treated as such. Adolescents are preoccupied with their bodies. Usually they are concerned about modesty, disfigurement, pain, disability, and death. If appropriate, reassurance should be provided about these concerns during the examination.

During the patient interview, the paramedic should respect the patient's need for privacy. Some adolescents may hesitate to reveal relevant history in the presence of family and friends. If the adolescent gives vague answers or seems uncomfortable, the parents and patient should be interviewed privately. The possibility of alcohol or other drug use should be considered, as well as the possibility of pregnancy (for postpubescent girls).

PHYSICAL EXAMINATION OF OLDER ADULTS

As with pediatric patients, age-related physiological and psychological variations may create special challenges in patient assessment of older adults. The paramedic should not assume that all older adults are victims of age-related disorders. Individual differences in knowledge, mental reasoning, experience, and personality influence how these patients respond to examination.

Communicating With the Older Adult

Some older adults have sensory losses. This may make communications more difficult. Hearing and visual impairments, for example, are not uncommon. In addition, some older adults experience some memory loss and may become easily confused. Extra time may be needed to communicate effectively with these patients.

The paramedic should remain close to the patient during the interview. The older adult generally perceives a reassuring voice and gentle touch as comforting. Short and simple questions are best. Speaking more loudly than usual may be necessary and questions may need to be repeated. The paramedic must be patient and careful not to patronize or offend patients by assuming that they have a hearing impairment or cannot understand a particular line of questioning.

Patient History

Older patients often have multiple health problems present at the same time. Patients may be vague and nonspecific when describing their chief complaint, making it difficult to isolate a nonapparent injury or illness. Moreover, normal signs and symptoms of illness or injury may be absent because of decreased sensory function in some older adult patients.

Older patients with many health problems often take several medications. These medications increase the risk of illness from use and misuse. The paramedic should try to gather a full medication history and must be alert to the relationship among drug interactions, disease, and the aging process (see Chapter 49).

As part of the history, the paramedic should assess the patient's functional abilities and any recent changes in *instrumental activities of daily living* (IADL). Many older adults attribute these changes to age. They may not mention them unless asked. These details may help indicate patient conditions that are not readily observable. They may also reveal the need for other pertinent lines of questioning. Examples of functional abilities and instrumental activities to be discussed with the patient include the following:

- Walking
- Getting out of bed
- Dressing
- Driving a car
- Using public transportation
- Preparing meals
- Taking medications
- Sleeping habits
- Bathroom habits

Physical Examination

During examination, the paramedic should ensure comfort for the older adult patient. All exam procedures should be explained clearly. All questions should be answered sensitively. Many older patients with chronic illness may have lived with pain or discomfort for a long time. Thus their perception of what is painful may be different from that of other patients. The paramedic should observe for signs such as grimacing or wincing during the examination. These signs may indicate pain or a possible injury site. If the situation permits, the paramedic should perform the examination slowly and gently with consideration to the patient's feelings and needs.

Many older adults believe they will die in a hospital. If transportation is needed, patients may become fearful and anxious. The paramedic should be sensitive to these concerns. If appropriate, the patient should be reassured that his or her condition is not serious. The paramedic should attempt to calm these patients and advise them that they will be well treated in the hospital. All examination findings should be carefully recorded (see Chapter 4).

SUMMARY

- The secondary assessment integrates patient assessment findings with knowledge of epidemiology and pathophysiology to form a field impression and to identify an appropriate treatment plan.
- The examination techniques commonly used in the physical examination are inspection, palpation, percussion, and auscultation.
- Equipment used during the comprehensive physical examination includes the stethoscope, ophthalmoscope, otoscope, and blood pressure cuff.
- The physical examination is performed in a systematic manner. The exam is a step-by-step process. Emphasis is placed on the patient's present illness and chief complaint.
- The physical examination is a systematic assessment of the body that includes mental status, general survey, vital signs, skin, head, eyes, ears, nose and throat, chest, abdomen, posterior body, extremities, and neurological examination.
- The first step in any patient care encounter is to note the patient's appearance and behavior. This includes assessing for level of consciousness. This may include assessment of posture, gait, and motor activity; dress, grooming, hygiene, and breath or body odors; facial expression; mood, affect, and relation to person and things; speech and language; thought and perceptions; and memory and attention.

- During the general survey, the paramedic should evaluate the patient for signs of distress, apparent state of health, skin color and obvious lesions, height and build, sexual development, and weight. The paramedic also should assess vital signs.
- The comprehensive physical examination should include an evaluation of the texture and turgor of the skin, hair, and fingernails and toenails.
- Examination of the structures of the head and neck involves inspection, palpation, and auscultation.
- A full knowledge of the structure of the thoracic cage is needed. This knowledge aids in performing a good respiratory and cardiac assessment. Air movement creates turbulence as it passes through the respiratory tree. Air movement produces breath sounds during inhalation and exhalation. In the prehospital setting the paramedic must examine the heart indirectly. However, the paramedic can obtain details about the size and effectiveness of pumping action through a skilled assessment that includes palpation and auscultation.
- The four quadrants of the abdomen and their contents provide the basis for inspection, auscultation, percussion, and palpation of this body region.
- An examination of the genitalia of either sex can be awkward for the patient and the paramedic. The paramedic should inspect the genitalia for bleeding and signs of trauma (if indicated).
- Examination of the anus is indicated in the presence of rectal bleeding or trauma to the area.
- When examining the upper and lower extremities, the paramedic should direct his or her attention to function. The paramedic also should pay attention to structure.
- Assessment of the spine begins with a visual assessment of the cervical, thoracic, and lumbar curves. The assessment continues with a region-by-region examination for pain, swelling, and range of motion.
- A neurological examination may be organized into five categories: mental status and speech, cranial nerves, motor system, sensory system, and reflexes.
- Reassessment is the ongoing assessment of the patient to determine changes in condition and response to treatment.
- When approaching the pediatric patient, the paramedic should remain calm and confident. The paramedic should observe the child before beginning the physical examination. The paramedic also should make sure to avoid separation of the child and parent. Moreover, the paramedic must establish a rapport with parents and child and must be honest. One caregiver should be assigned to the child.
- The paramedic should not assume that all older adults are victims of disorders related to aging. Individual differences in knowledge, mental reasoning, experience, and personality influence how these patients respond to examination.

CHAPTER

21 Clinical Decision Making

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. List the key elements of paramedic practice.
2. Discuss the limitations of protocols, standing orders, and patient care algorithms.
3. Outline the key components of the critical thinking process for paramedics.
4. Identify elements necessary for an effective critical thinking process.
5. Describe situations that may necessitate the use of the critical thinking process while delivering prehospital patient care.
6. Describe the six elements required for effective clinical decision making in the prehospital setting.

KEY TERMS

application of principle A component of critical thinking in which the examiner makes patient care decisions based on conceptual understanding of the situation and interpretation of data gathered from the patient.

concept formation A component of critical thinking that refers to all elements that are gathered to form a general impression of the patient.

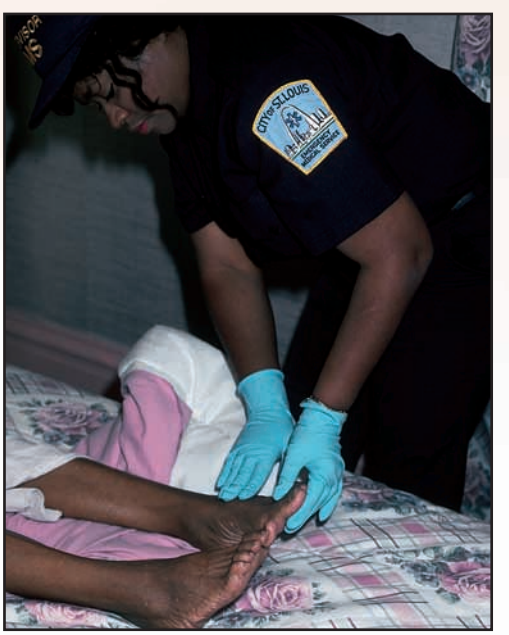
data interpretation A component of critical thinking in which the examiner gathers the necessary data to form a field impression and working diagnosis.

evaluation A component of critical thinking in which the examiner assesses the patient's response to care.

patient management plan A plan of care that is based on principles and applications of findings in the patient assessment.

reflection on action A component of critical thinking (usually performed after the event) in which the examiner evaluates a patient care episode for possible improvement in similar future responses.

Unique to the EMS profession is the uncertainty of the prehospital environment. The uncertainty is influenced heavily by factors that do not exist in other medical settings. Paramedics must be able to gather, evaluate, and synthesize information. They also must be able to develop and apply appropriate ***patient management plans.*** *Finally, they must apply judgment, exercise independent decision making, and work effectively under pressure. These are the cornerstones of effective paramedic practice.*



(Courtesy Monroe Yancie, St. Louis, Mo.)

DID YOU KNOW?

The Critical Thinker

The first step in critical thinking is to be aware of your assumptions. The second step is to beware of your assumptions. The final steps are to debate alternatives and look for proof. A critical thinker[1]:

- Asks pertinent questions.
- Assesses statements and arguments.
- Is able to admit a lack of understanding or information.

- Has a sense of curiosity and creativity.
- Is interested in finding new solutions.
- Is able to clearly define a set of criteria for analyzing ideas.
- Is willing to examine beliefs, assumptions, and opinions and weigh them against facts.
- Listens carefully to others and is able to give feedback.
- Suspends judgment until all facts have been gathered and considered.
- Looks for evidence to support assumption and beliefs.
- Is able to adjust opinions when new facts are found.
- Looks for proof.
- Examines problems closely.
- Is able to reject information that is incorrect or irrelevant.

THE SPECTRUM OF PREHOSPITAL CARE

As described in Chapter 19 and Chapter 20, the paramedic must have a wide base of knowledge and skills to make good patient care decisions in the prehospital setting. On any given workday, the paramedic may be exposed to obvious critical life threats, potential life threats, and non–life-threatening situations (Box 21-1). On each call the paramedic also is expected to provide proper care and treatment.

Protocols, standing orders, and patient care algorithms help to promote a standardized approach to patient care for "classic" presentations. These presentations clearly define and outline performance parameters. However, these standards have some limitations. First, they may not apply to nonspecific patient complaints that do not fit the "model." Second, these standards do not address multiple disease etiologies or multiple treatment modalities. Third, they promote linear thinking, such as standardized care is appropriate for all patients ("cookbook medicine"). The paramedic must develop critical thinking skills to assist in unique patient care situations.

BOX 21-1 Spectrum of Prehospital Care

Obvious Critical Life Threats
Major multisystem trauma
Devastating single-system trauma
End-stage disease presentations
Acute presentations of chronic conditions

Potential Life Threats
Non–major multisystem trauma
Multiple disease etiologies

Non–Life-Threatening Presentations
Minor illness or injury
Emergency medical services system misuse

DID YOU KNOW?

Clinical Decision Rules

A key element in clinical decision making is to determine risk. Risk is the "probability that a particular adverse event occurs ..."[2] Increasingly, the medical community is devising clinical decision rules and tools that help assign the risk or probability that a patient has a particular injury or illness. These rules are based on key examination findings. *The Nexus low-risk clinical screening criteria for cervical spine injury* is an example of a clinical decision-making tool. Patients who have blunt trauma are considered low risk for cervical spine injury if they do not have tenderness over the spine, altered alertness, distracting injury, intoxication, or focal neurological changes. This tool has a sensitivity of 99% for cervical spine injury and almost 100% for clinically significant cervical spine injury. In other words, there is little chance that patients who are examined using this criterion will have a clinically significant cervical spine injury. On the other hand, the test is not very specific. A significant number of patients who have one or more positive findings also will not have cervical spine injury.[3]

Researchers are continually searching for evidence-based reliable decision-making tools—tools to help guide clinical practice and evaluate patient risk in emergency care. Areas of focus have been chest pain, syncope, triage, extremity injuries, and others. Each EMS system should evaluate the applicability of a given decision rule to their patient population before it is adopted.

CRITICAL THINKING PROCESS FOR PARAMEDICS

Specific aspects, stages, and sequences are linked with the critical thinking process. These include concept formation, data interpretation, application of principles, evaluation, and reflection on action[4] (Figure 21-1).

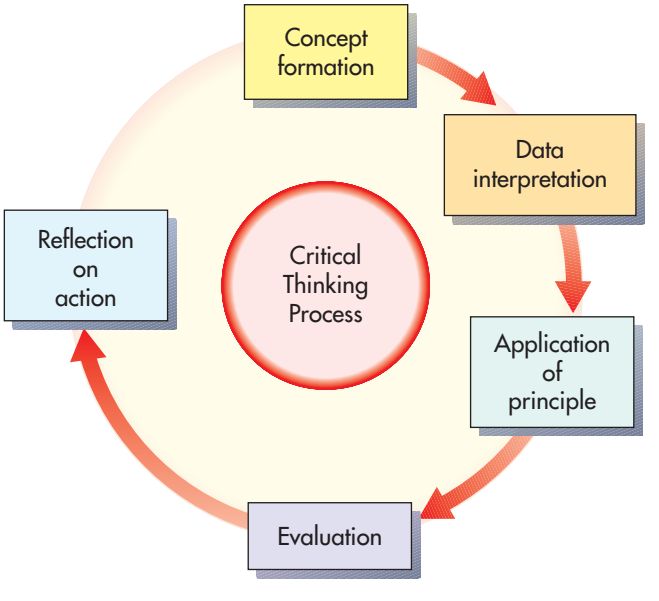


FIGURE 21-1 Critical thinking process.

Concept Formation

Concept formation refers to all elements gathered to form a general impression of the patient. Concept formation is the "what" of the patient story. These elements are described in Chapter 19 and Chapter 20 and include the following:

- Scene assessment (mechanism of injury, social setting)
- Chief complaint
- Patient history
- Patient affect
- Initial assessment and physical examination
- Diagnostic tests

SCENARIO PART ONE

Your crew has been dispatched to a local park for a person with "difficulty breathing." On your arrival at the scene, you find an 18-year-old female sitting on a park bench surrounded by her friends. The scene is safe. She is crying and tells you that she cannot catch her breath. You attempt to calm the patient and provide her with supplemental oxygen. You obtain a history from the patient and her friends that she and her boyfriend had quarreled recently and that she became emotional during the argument. Her lung sounds are clear. She has no allergies and no significant medical history other than a recent sinus infection. She denies any injury or pain. Aside from her increased respiratory rate, her vital signs are within normal range. Consider your concept formation for this patient.

CRITICAL THINKING

What effect would wrong or incomplete concept formation have on your critical thinking process during patient care? How can you enhance your concept formation skills while in your paramedic program?

Data Interpretation

Following concept formation, the paramedic must gather the needed data to form a field impression. This process is known as **data interpretation:** a component of critical thinking that helps the paramedic to form a working diagnosis. This is the "working phase" of patient care. The quality of data interpretation rests on a few elements: the paramedic's knowledge of anatomy and physiology, pathophysiology, intuition, and previous experience in providing patient care. During the interpretation of data, the paramedic attempts to obtain a complete "picture" of the patient's situation. The success of this phase of critical thinking can be greatly affected by the paramedic's attitude. It can also be affected by the way in which the paramedic-patient encounter proceeds (see Chapter 17). In some cases, the paramedic must condense and convey these data to the online physician, who can help determine appropriate actions.

SCENARIO PART TWO

While assessing this patient, you recall a similar emergency response. In that response, you provided care to a young male with difficulty breathing. He had just lost a big tennis match. At first you assumed that the patient was having breathing difficulty because of emotions that resulted from his loss. Like the female patient you are caring for now, this male patient had no allergies and no significant medical history and denied any recent injury. His vital signs were within normal range. However, lung sounds were diminished slightly on the patient's left side. The patient also complained of mild pain on inspiration. You administered supplemental oxygen. Then you rapidly transported the patient to the emergency department. After obtaining a chest x-ray film, the emergency physician confirmed your suspicion of a spontaneous pneumothorax (which resolved during the patient's hospitalization). Compare this interpretation of data to that of the female patient you are caring for now.

Application of Principles

The next step in the critical thinking process is the **application of principles** of proper patient care. These principles are based on the paramedic's conceptual understanding of the situation. They also are based on the interpretation of the data gathered from the patient. Once the paramedic establishes the field impression and working diagnosis, treatment can often be initiated through protocols and standing orders. If necessary, consultation can be made with direct/online medical direction.

SCENARIO PART THREE

Based on your experience, your knowledge of patient care, and your interpretation of the data gathered from your patient, you decide that she is hyperventilating. You initiate proper treatment with calming measures and encourage her to slow her respiratory rate. Although the female patient you are caring for presented much like the male patient you recall, your working diagnosis is different. You reach this conclusion because the female patient had clear, bilateral lung sounds. She also denied any pain on respiration.

Evaluation

The **evaluation** component of critical thinking requires an ongoing assessment of the patient's response to the care provided. Evaluation includes the following:

- Reassessment of the patient (ongoing assessment)
- Reflection of action (effectiveness of the intervention)
- Revision of field impression (a change in the working diagnosis)
- Review of the appropriateness of the protocol, standing orders, or direct orders for the patient
- Revision of the treatment or intervention as needed

SCENARIO PART FOUR

After you have provided calming measures and oxygen to your patient, she has slowed her breathing. She also appears to be more relaxed. You reassess the patient. You find that her vital signs remain normal and her lung sounds remain clear. Based on these findings, you know that your field

impression of hyperventilation was correct and that there is no need to change your working diagnosis or to revise your treatment. After consulting with medical direction, the decision is made that the patient's condition does not warrant transportation for physician evaluation.

Reflection on Action

Reflection on action happens "after the event." It usually occurs through a run critique whereby the call is evaluated for improvement in similar future responses. Reflection on action provides paramedics with an avenue to add to or alter their experience base.

DID YOU KNOW?

Avoiding Errors in Clinical Judgment

Assessing and managing patients in the prehospital environment is a difficult task. Errors in decision making are possible. To avoid errors consider using the following strategies:

1. Consciously think about your thinking and question your decision making.[5] Ask yourself, "Is this the right decision?" or "Does this make sense?" If the answer is no, reexamine your data, consult medical direction, or gather more information.
2. Recognize error-prone situations and use extra caution in those instances. For example, it is known that a significant number of patients who refuse care will seek emergency care soon after the refusal.[6] Be especially careful in those situations. Always ensure the patient knows that he or she can call again for help, even after refusing care.
3. Recognize your biases and use extreme caution when making decisions in situations that involve those biases. For example, you may be frustrated when caring for a patient who is intoxicated with alcohol. This may create a tendency for you to immediately attribute the patient's signs and symptoms to the intoxication. A personal bias such as this could lead you to overlook a serious head injury or other medical problem that might be the cause of the patient's presentation. Bias is a known cause of cognitive errors in medicine.[7]

SHOW ME THE EVIDENCE

These authors evaluated 72 blunt trauma patients to compare 3 measures of intoxication in an attempt to find the best sobriety measure: blood alcohol level (BAL); a clinical sobriety assessment tool (CSAT); and physician judgment. The CSAT is a clinical sobriety tool developed by law enforcement personnel and the World Health Organization.

The researchers found the CSAT had greater sensitivity to assess sobriety than physician judgment. There was poor agreement between CSAT and BAL data. The authors felt that chronic alcohol abusers sometimes appear sober with BAL above the designated level of intoxication.

From Pattani S, Mahler S: Use of a clinical sobriety assessment tool in blunt trauma patients is more sensitive than physician judgment in determining sobriety, *Ann Emerg Med* 50(3, suppl):S64-S65, 2007.

SCENARIO PART FIVE

En route back to quarters, you discuss the call with a paramedic student. This student has just begun her field internship. Like you, she instantly thought that the patient was hyperventilating because of the fight that she had with her boyfriend. The student admitted that she had read about a spontaneous pneumothorax in her initial EMT training. However, she had never seen a patient who had one. Moreover, she would not have considered this possibility when caring for this patient. You discuss the pathology of a tension pneumothorax with her and the importance of assessing bilateral lung sounds in a patient who is having difficulty breathing. This reflection on action reinforces your data interpretation skills. It also adds to the student's experience base.

FUNDAMENTAL ELEMENTS OF CRITICAL THINKING FOR PARAMEDICS

For an effective critical thinking process, some basic elements must be present. These elements include adequate knowledge and the ability to do the following:

- Focus on specific and multiple elements of data at the same time.
- Gather and organize data and form concepts.
- Identify and deal with medical ambiguity (patients who do not "fit" the model).
- Differentiate between relevant and irrelevant data.
- Analyze and compare similar situations from past experience.
- Recall cases in which the working diagnosis was wrong.
- Articulate decision-making reasoning and construct arguments to support or discount the decision.

All of these elements were present in the previous scenario. At the scene, the paramedic dealt with the patient's symptoms and the input of friends. In addition, he focused on assessment and history findings. At the same time, he offered initial emergency care. The paramedic did this all within moments of arriving at the patient's side. He gathered and organized the data. He then concluded that the patient fit the model for hyperventilation syndrome. The paramedic also decided that the patient's sinus infection was not likely related to her present respiratory distress. He recalled a previous case where his initial working diagnosis of hyperventilation syndrome was wrong. Even so, the paramedic used clinical decision making to support the diagnosis of hyperventilation syndrome for this patient. His decision making was based on his experience and on his assessment findings.

FIELD APPLICATION OF ASSESSMENT-BASED PATIENT MANAGEMENT

Assessment-based patient management places huge responsibility on the paramedic. The paramedic must have a systematic means of analyzing a patient's problems, determining how to solve them, carrying out a plan of action, and evaluating effectiveness of the treatment. The

success of assessment-based patient management in the prehospital setting depends on an integration of interpersonal skills, scientific knowledge, and physical activities (skills).

The Patient Crisis Severity Spectrum

EMS is set into action daily for many reasons. Yet few prehospital calls present true threats to life.[8] Minor medical and trauma events require little critical thinking. They result in fairly easy decision making for the paramedic. Likewise, patients with clear life threats pose limited critical thinking challenges because they often fit the "model" for standardized treatment (e.g., cardiac arrest). However, some patients fall in the spectrum between minor and life-threatening events. These patients pose the most critical thinking challenges for the paramedic. An example is a patient with mild to moderate respiratory distress. Another is a patient with diffuse abdominal pain. Either of these situations could be minor or could have life-threatening consequences.

Thinking Under Pressure

Hormonal influences from the fight-or-flight response (described in Chapter 2) can have positive and negative effects on critical decision making. The response may offer greater visual acuity and auditory keenness and improved reflexes and muscle strength. These can be positive when critical decisions must be made and action must be taken. The negative aspects of the response may include reduced critical thinking skills. This can result from a decrease in concentration and assessment ability. The key to strong performance under pressure is mental conditioning. This results in "instinctive performance" and "automatic responses" for technical procedures.

Mental Checklist for Thinking Under Pressure

Mental conditioning takes a good deal of practice. A checklist for thinking under pressure may help the paramedic to concentrate during stressful events. The mental checklist the paramedic should use is as follows:

- Stop and think.
- Scan the situation.
- Decide and act.
- Maintain clear and effective control.
- Regularly and continually reevaluate the patient.

CRITICAL THINKING

Do you think you can improve your performance under pressure by practicing imaginary critical situations in your head? Why or why not?

Practicing this checklist when under pressure will result in behaviors that improve clinical decision making. One of these positive behaviors is staying calm (not panicking). Another is assuming a plan for the worst case (erring on the side of the patient). A third is maintaining a systematic assessment pattern. In addition, the paramedic can learn to balance the various styles of situation analysis, data processing, and decision making. Applying the styles of situational analysis (reflective versus impulsive), data processing (divergent versus convergent), and decision making (anticipatory versus reactive) allows the paramedic to provide the best possible care in most situations. In time, paramedics are able to apply all of these approaches with skill.

SITUATIONAL ANALYSIS: REFLECTIVE VERSUS IMPULSIVE

In most patient care situations, paramedics should avoid quickly stopping the pursuit of new data. One may do this to try to reach a correct working diagnosis. For example, consider a patient who has abdominal pain in his lower right quadrant. This patient should not be assigned automatically a working diagnosis of appendicitis. (This is an impulsive decision because the patient fits the model.) Rather, the paramedic should take time to reflect on other conditions, such as food poisoning, that could be the cause of the patient's pain. In other situations (e.g., a patient with foreign body airway obstruction), the impulsive decision to clear the patient's airway with chest thrusts and back blows would be the most prudent course of action to follow.

Reflective Example

When choosing an intravenous (IV) catheter for an elderly patient with small and fragile veins, the paramedic chooses a smaller gauge catheter that she knows will provide venous access, versus a larger bore catheter that might "blow the vein."

Impulsive Example

The paramedic immediately attempts IV access with a large-bore catheter because it is the gauge she "always uses."

DATA PROCESSING: DIVERGENT VERSUS CONVERGENT

Paramedics should avoid the trap of gathering only partial data that may lead them down the wrong diagnostic or therapeutic path. This is similar to impulsive situational analysis, and is known as convergent data processing. The convergent approach may be best in some cases (e.g., giving a standard drug dose to a patient in cardiac arrest). However, the convergent approach can hinder care in complex cases (e.g., an older patient with multiple complaints). A divergent approach in data processing looks at all sides of a case. The paramedic does this before arriving at a solution (e.g., multiple illnesses and polydrug use in the elderly patient).

Divergent Data Processing Example

An EMS training coordinator researches drug references and consults with medical direction for dosing suggestions for a new asthma drug being carried on the ambulance.

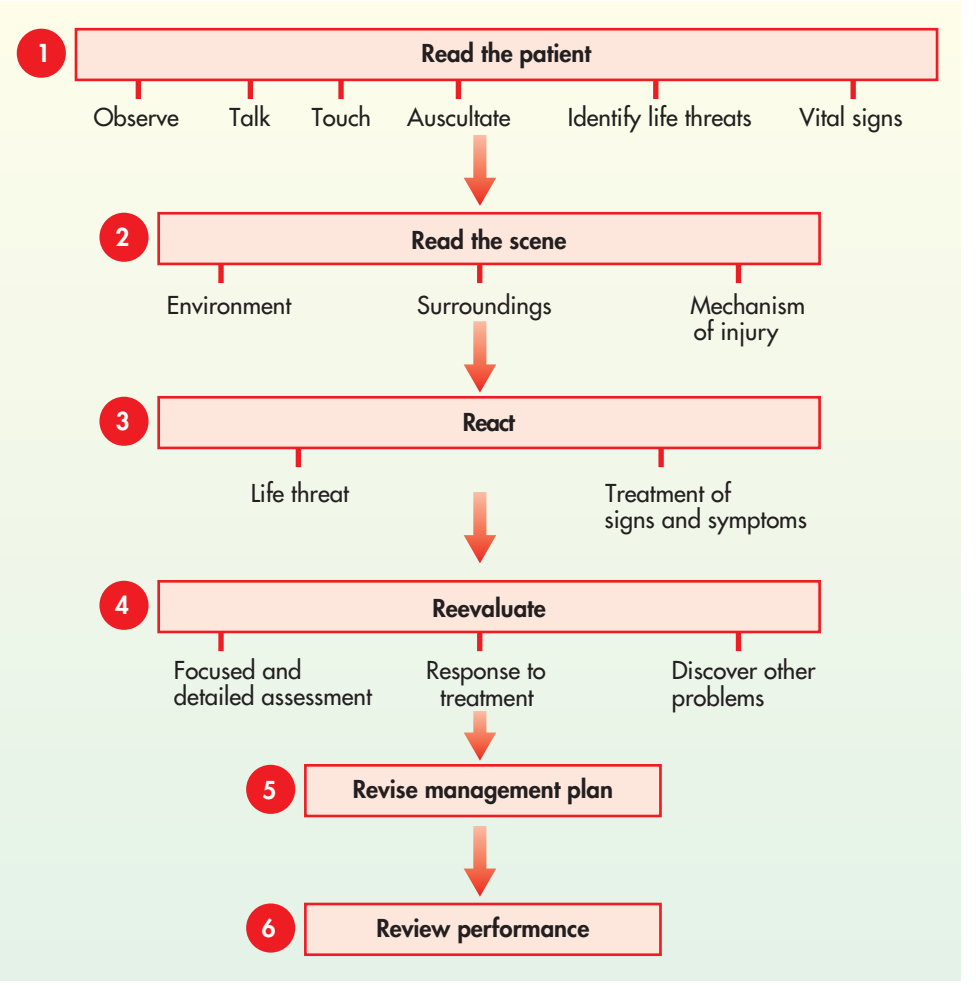

FIGURE 21-2 The six R's.

Convergent Data Processing Example

At an in-house training session, the paramedics are told "the package insert says to give this amount ..."

DECISION MAKING: ANTICIPATORY VERSUS REACTIVE

A paramedic's decision making can be seen as anticipatory or reactive. Anticipatory decision making is the process used by most health care professionals. It is based on continuing data collection and evolution of the patient's condition. With reactive decision making, decisions are made only after a problem occurs. This type of decision making can have negative effects on patient care.

Anticipatory Decision Making Example

A patient with large second-degree burns is being transported to a burn center that is 30 miles away. The paramedic requests orders for IV ***morphine*** before leaving the scene.

Reactive Decision Making Example

A paramedic caring for the same patient waits until the patient complains of pain before requesting the ***morphine*** order.

PUTTING IT ALL TOGETHER: THE SIX R'S

To put all components required for effective clinical decision making into action, the paramedic can think in terms of the six R's listed next (Figure 21-2):

1. *Read the patient*. The paramedic should observe the patient's level of consciousness and skin color. Position of the patient should be noted along with any obvious deformity or asymmetry. Talking to the patient will determine the chief complaint. This will also identify the presence of a worsening or preexisting condition. Skin temperature and moisture should be evaluated. Pulses should be assessed for rate, strength, and regularity. Auscultation of the lungs will reveal upper or lower airway problems. The paramedic should identify all life threats and obtain an accurate set of vital signs.
2. *Read the scene*. As a part of scene size-up, the paramedic should assess general environmental conditions. The paramedic should evaluate the immediate surroundings and attempt to identify any mechanism of injury or clinical clues of illness.

3. *React*. All life threats should be managed when they are found. The paramedic should determine the most common and likely cause of the life threat that fits the patient's initial presentation. If a clearly defined and recognizable presentation of medical illness cannot be defined in a priority patient, treatment should be based on presenting signs and symptoms.
4. *Reevaluate*. Reevaluation includes a focused and detailed assessment. This assessment analyzes the patient's response to management and interventions and may lead the paramedic to find other problems. These problems may not have been evident during the primary assessment.
5. *Revise management plan*. Findings obtained during reevaluation may require the paramedic to revise the management plan. This revision will address more clearly the needs of the patient. The facts that patient conditions change and that patients do not respond in the same way to identical treatment intervention highlight the importance of ongoing assessment and reassessment.
6. *Review performance at run critique*. Reviewing the details of the call through a run critique allows for improvements to be made to similar calls in the future. The interest and investment of paramedics in the outcome of their personal cases often is the strongest stimulus to change their practice patterns favorably. This process also enhances the paramedic's experience base and in turn leads to improvement of data interpretation skills.

NOTE

Vital signs can be used as a triage tool. The paramedic can use vital signs to estimate severity. Vital signs also can help the paramedic identify the majority of life-threatening conditions. The paramedic should remember that the patient's age and physical and medical conditions (including medications) can affect vital signs.

CRITICAL THINKING

Consider a negative or punitive run critique. How do you think this would influence your ability to perform under a similar circumstance in the future?

SUMMARY

- The paramedic must be able to do several things at the same time. The paramedic must be able to gather, evaluate, and synthesize information. The paramedic also must be able to develop and implement appropriate patient management plans. The paramedic must apply judgment and exercise independent decision making as well. Lastly, the paramedic must be able to think and work effectively under pressure.
- Protocols, standing orders, and patient care algorithms have several limitations. They may not apply to nonspecific patient complaints that do not fit the model. They also do not address multiple disease etiologies or multiple treatment plans. Moreover, they may promote linear thinking. Clinical decision rules may help determine risk when evaluating patients.
- The critical thinking process includes concept formation, data interpretation, application of principles, evaluation, and reflection on action.
- To reduce the risk of errors in decision making, consciously ask yourself "Is this the right decision?" Be cautious in error-prone situations. Recognize your biases and use care when making decisions in cases that involve those biases.
- For effective critical thinking, a paramedic must have a solid knowledge base. The paramedic must be able to cope with a large amount of data all at once as well. The paramedic must be able to organize these data, deal with ambiguity, and relate the situation to similar past experience. The paramedic also must be able to reason and construct arguments to support or discount the decision.
- When using assessment-based patient management, the paramedic must analyze a patient's problems, determine how to solve them, carry out a plan of action, and evaluate its effectiveness.
- Effective clinical decision making requires the paramedic to read the patient and the scene. The paramedic also must be able to react, reevaluate, and revise the management plan. Then the paramedic must be able to review performance at a run critique.

PART SIX

Cardiovascular

Chapter 22: Cardiology

CHAPTER

22 Cardiology

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Identify risk factors and prevention strategies associated with cardiovascular disease.
2. Describe the normal anatomy and physiology of the heart.
3. Discuss electrophysiology as it relates to the normal electrical and mechanical events in the cardiac cycle.
4. Outline the activity of each component of the electrical conduction system of the heart.
5. Describe basic monitoring techniques that permit interpretation of an electrocardiogram (ECG).
6. Explain the relationship of the ECG tracing to the electrical activity of the heart.
7. Describe in sequence the steps in ECG interpretation.
8. Identify the characteristics of normal sinus rhythm.
9. When shown an ECG tracing, identify the rhythm, site of origin, possible causes, and clinical significance and the prehospital management indicated.
10. Outline the appropriate assessment of a patient who may be experiencing a cardiovascular disorder.
11. Describe prehospital assessment and management of patients with selected cardiovascular disorders based on knowledge of the pathophysiology of the illness.
12. Describe the cause and nature of selected congenital cardiovascular defects.
13. List indications, contraindications, and prehospital considerations when using selected cardiac interventions, including basic life support, monitor-defibrillators, defibrillation, implantable cardioverter-defibrillators, synchronized cardioversion, and transcutaneous cardiac pacing.
14. List indications, contraindications, dose, and mechanism of action for pharmacological agents used to manage cardiovascular disorders.
15. Identify appropriate actions to terminate resuscitation in the prehospital setting.

KEY TERMS

abdominal aortic aneurysm A localized dilation of the wall of the abdominal aorta.

aberration Refers to the abnormal conduction of impulses through cardiac conduction pathways.

absolute refractory period The portion of the action potential during which the membrane is insensitive to all stimuli regardless of strength.

accelerated junctional rhythm A dysrhythmia that results from increased automaticity of the atrioventricular junction

acute arterial occlusion A sudden blockage of arterial flow, most commonly is caused by trauma, embolus, or thrombosis.

acute coronary syndrome (ACS) A spectrum of clinical disease that includes acute myocardial infarction and unstable angina.

acute deep vein thrombosis Occlusion of a vessel by a thrombus in any portion of the deep venous system.

acute dissecting aortic aneurysm Separation of the arterial wall of the aorta.

acute myocardial infarction (AMI) The sudden interruption of blood supply to the heart, resulting in death of cardiac tissue.

afterload The total resistance against which blood must be pumped. Also known as *peripheral vascular resistance*.

algorithms Lists used to summarize information, such as prehospital and in-hospital management recommendations.

amyloidosis A condition that results from deposits of abnormal protein in heart tissue.

aneurysm A localized dilation of a wall of a blood vessel.

angina pectoris Ischemic chest pain most often caused by myocardial anoxia as a result of atherosclerosis of the coronary arteries.

angioplasty Repair of damaged vessels.

anterior hemiblock Failure in conduction of the cardiac impulse in the anterior division of the left bundle branch.

artifact A deflection on the electrocardiogram display or tracing produced by factors other than the electrical activity of the heart.

artificial pacemaker A rhythm that is generated by regular electrical stimulation of the heart through an electrode implanted in the heart.

asystole A life-threatening cardiac condition characterized by the absence of electrical and mechanical activity of the heart.

atherosclerosis A common arterial disorder characterized by yellowish plaques of cholesterol, lipids, and cellular debris in the inner layers of the walls of large and medium-sized arteries.

atrial fibrillation A dysrhythmia that results from multiple areas of reentry within the atria or from an ectopic atrial pacemaker.

atrial flutter A dysrhythmia that usually results from rapid atrial reentry of electrical impulses.

atrial kick The priming force contributed by atrial contraction immediately before ventricular systole that acts to increase the efficiency of ventricular ejection due to acutely increased preload.

atrial tachycardia A rhythm disturbance that arises from an irritable site in the atria, producing tachycardia.

atrioventricular dissociation A conduction disturbance in which atrial and ventricular contractions occur rhythmically but are unrelated to each other.

atrioventricular node An area of specialized cardiac muscle that receives the cardiac impulse from the sinoatrial node and conducts it to the bundle of His.

atrioventricular junction An area formed by the AV node and the bundle of His; serves as the only electrical link between the atria and ventricles in a normal heart.

augmented limb leads Unipolar leads that record the difference in electrical potential in cardiac muscle.

automaticity A property of specialized excitable tissue that allows self-activation through spontaneous development of an action potential.

AV nodal reentry tachycardia A type of reentry supraventricular tachycardia, usually caused by a premature atrial contraction.

AV reentry tachycardia A type of reentry supraventricular tachycardia; results from a reentry circuit in the AV node by way of congenital accessory pathways in the heart muscle.

axis The imaginary straight line that joins the positive and negative electrodes of each ECG lead.

bifascicular block Refers to the blockage of two of three pathways (fascicles) for ventricular conduction.

bipolar lead A lead composed of two electrodes of opposite polarity.

bradycardia A heart rate of less than 60 beats per minute.

bruit An abnormal sound or murmur heard while auscultating an artery, organ, or gland.

bundle of His A band of fibers in the myocardium through which the cardiac impulse is transmitted from the atrioventricular node to the ventricles.

bundle of Kent Fibers that connect atrial muscle to ventricular muscle, bypassing the AV node; also known as *Kent fibers*.

cannon A waves Waves of pulse pressure that are visible in the jugular veins of a patient in ventricular tachycardia.

cardiac ejection fraction The percentage of ventricular blood volume released during a contraction.

cardiogenic shock Shock that results when cardiac action is unable to deliver sufficient circulating blood volume for tissue perfusion.

cardiomyopathy Any disease that affects the myocardium.

coarse ventricular fibrillation Fibrillatory waves that are greater than 3 mm in amplitude.

compensatory pause A pause following a premature beat; confirmed by measuring the interval between the R wave before the premature ventricular complex and the R wave after it.

congestive heart failure An abnormal condition that reflects impaired cardiac pumping, usually a result of myocardial infarction, ischemic heart disease, or cardiomyopathy.

contiguous leads Two or more ECG leads that are anatomically close together and that cover the same general area of the heart; specifically, the walls of the left ventricle.

delta wave A slurring or notching of the onset of the QRS complex that is a diagnostic finding in Wolff-Parkinson-White syndrome.

defibrillation The delivery of electrical current through the chest wall; used to terminate ventricular fibrillation and pulseless ventricular tachycardia.

depolarization A change in electrical charge difference across the cell membrane that causes the difference to be smaller or closer to 0 mV; a phase of the action potential in which the membrane potential moves toward zero or becomes positive.

diastole Relaxation of the atria and ventricles.

dyspnea Difficulty breathing.

dysrhythmia Variation from a normal rhythm.

ectopic focus An excitable group of cells that causes a premature heart beat outside the normally functioning sinus node of the heart.

ejection The forceful expulsion of blood from the ventricle of the heart.

electrical capture A large QRS complex produced by an artifical pacemaker which indicates ventricular contraction.

electrocardiogram (ECG) A graphic representation of the electrical activity of the heart.

end-diastolic volume The volume of blood returning to each ventricle.

endocarditis An infection of the endocardium (inner layer of the heart).

enhanced automaticity The cause of dysrhythmias in Purkinje fibers and other myocardial cells with a high resting membrane potential; it results from an acceleration of phase 4 depolarization commonly caused by abnormally high leakage of sodium ions into the cells, which causes the cells to reach threshold prematurely.

fine ventricular fibrillation Fibrillatory waves less than 3 mm in amplitude.

first-degree atrioventricular block A dysrhythmia in which there is a delay in conduction, usually at the level of the atrioventricular node.

fusion beat A premature ventricular contraction that occurs at approximately the same time that an electrical impulse of the underlying rhythm is activating the ventricles, thereby causing ventricular depolarization to occur simultaneously in two directions; it results in a QRS complex that has the characteristics of the premature ventricular contraction and the QRS complex of the underlying rhythm.

hexaxial reference system The system of intersecting lines of the standard limb leads and three other intersecting lines of reference: aV_R, aV_L, and aV_F leads.

high-grade atrioventricular block Occurs when at least two consecutive atrioventricular impulses (atrial P waves) fail to be conducted to the ventricles.

high-output heart failure A classification of heart failure where cardiac output remains high but is unable to meet the metabolic needs of the body.

hypertension A disorder characterized by elevated blood pressure, which persistently exceeds 140/90 mm Hg.

hypertensive encephalopathy A set of symptoms—including headache, convulsions, and coma—that result solely from elevated blood pressure.

interventricular septum The tissue that separates the right and left ventricles of the heart.

joule A measurement of electrical energy; one joule is the product of 1 V (potential) multiplied by 1 A (current) multiplied by 1 second.

jugular vein distention Engorgement of jugular veins caused by an increase in central venous pressure; it is estimated by positioning the head of a supine patient at a 45-degree angle and observing the neck veins.

junctional escape beat One or more that occurs when the rate of the SA node falls below that of the AV junction.

junctional tachycardia A type of supraventricular tachycardia caused by a reentry mechanism in the junction of the atrioventricular node.

left axis deviation A pattern of electrical activity that occurs in the heart there is a deviation of the axis to the left within the quadrant of 0 degrees and –90 degrees.

left bundle branch A division in the bundle of His that provides pathways for impulse conduction.

left bundle branch block A conduction disturbance in the left bundle branch that alters normal septal activation and sends it in the opposite direction.

left ventricular assist device (LVAD) A battery-operated device that assumes the pumping action of the left ventricle.

left ventricular failure A condition that occurs when the left ventricle fails to work as an effective forward pump, causing a back pressure of blood into the pulmonary circulation.

low-output heart failure A type of heart failure where cardiac output is decreased, leading to impaired peripheral circulation and vasoconstriction.

mechanical capture Occurs when an associated pulse is generated with the electrical capture of an artificial pacemaker.

modified chest leads Placement of the standard limb leads of an ECG that are altered to mimic the precordial leads.

monomorphic ventricular tachycardia Ventricular tachycardia where the QRS complex has the same morphology or fixed shape.

multifocal atrial tachycardia A dysrhythmia that resembles wandering pacemaker but is associated with rates often in the 120 to 150 beats/minute range.

multifocal premature ventricular complex A premature ventricular complex that originates from multiple sites in the ventricles.

myocardial contractility The intrinsic ability of the heart to contract independent of preload and afterload.

myocarditis Inflammation of the heart muscle.

non-STEMI A myocardial infarction in which there is no ST-segment elevation.

P wave The first complex of the electrocardiogram, representing depolarization of the atria.

palpitations Irregular or forceful beating of the heart.

paroxysmal atrial tachycardia Atrial tachycardia that begins and ends abruptly.

paroxysmal nocturnal dyspnea An abnormal condition of the respiratory system characterized by sudden attacks of shortness of breath, profuse sweating, tachycardia, and wheezing that awaken a person from sleep; it often is associated with left ventricular failure and pulmonary edema.

paroxysmal supraventricular tachycardia An ectopic rhythm in excess of 100 beats per minute and usually faster than 170 beats per minute that begins abruptly with a premature atrial or junctional beat and is supported by an atrioventricular nodal reentry mechanism or by an atrioventricular reentry involving an accessory pathway.

P-R interval The time that elapses between the beginning of the P wave and the beginning of the QRS complex in the electrocardiogram.

pericarditis Inflammation of the pericardium.

peripheral vascular resistance The total resistance against which blood must be pumped; also known as *afterload*.

point of maximum impulse The location or area where the apical pulse is palpated the strongest, often in the fifth intercostal space of the thorax just medial to the left midclavicular line.

polymorphic ventricular tachycardia Ventricular tachycardia where the QRS complex has varying morphology or shape.

posterior hemiblock Failure in conduction of the cardiac impulse in the posterior division of the left bundle branch.

potassium ion channels Protein-lined channels in the cell membrane that prevent sodium from passing into the cell.

precordial leads Unipolar chest leads used in 12-lead ECG monitoring that record the electrical activity of the heart in the horizontal plane.

precordial thump A technique to restore circulation in monitored unstable ventricular tachycardia.

preexcitation syndrome Anomalous or accelerated atrioventricular conduction associated with an abnormal conduction pathway between the atria and ventricles.

preload The volume of blood returning to the heart.

premature atrial complex A cardiac dysrhythmia characterized by an atrial beat occurring before the expected excitation and indicated on the electrocardiogram as an early P wave.

premature junctional complex A cardiac dysrhythmia that occurs during sinus rhythm earlier than the next expected sinus beat is caused by premature discharge of an ectopic focus in the atrioventricular junctional tissue.

premature ventricular complex A cardiac dysrhythmia characterized by a ventricular beat preceding the expected electrical impulse and indicated on the electrocardiogram as an early, wide QRS complex without a preceding related P wave.

proarrhythmia A new or worsened rhythm disturbance seemingly generated by antidysrhythmic therapy.

pulmonary edema The accumulation of extravascular fluid in lung tissues and alveoli.

pulse deficit A condition that exists when the radial pulse is less than the ventricular rate; it indicates a lack of peripheral perfusion.

pulseless electrical activity (PEA) The absence of a detectable pulse and the presence of some type of electrical activity other than ventricular tachycardia or ventricular fibrillation; also known as *electromechanical dissociation*.

Purkinje fibers Myocardial fibers that are a continuation of the bundle of His and that extend into the muscle walls of the ventricles.

QRS complex The principal deflection in the electrocardiogram, representing ventricular depolarization.

Q-T interval The time elapsing from the beginning of the QRS complex to the end of the T wave, representing the total duration of electrical activity of the ventricles.

R-on-T phenomenon The occurrence of a ventricular depolarization during a vulnerable period of relative refractoriness.

reentry The reactivation of tissue by a returning impulse; the sustaining mechanism in some cases of ventricular bigeminy or trigeminy, ventricular tachycardia, and paroxysmal supraventricular tachycardia.

refractory period The period after effective stimulation during which excitable tissue fails to respond to a stimulus of threshold intensity.

relative refractory period The portion of the action potential after the absolute refractory period during which another action potential can be produced with a greater than threshold stimulus strength.

repolarization The phase of the action potential in which the membrane potential moves from its maximum degree of depolarization toward the value of the resting membrane potential.

resting membrane potential The electrical charge difference inside a cell membrane measured relative to just outside the cell membrane.

return of spontaneous circulation (ROSC) Restoration of spontaneous circulation that provides evidence of more than an occasional gasp, occasional fleeting palpable pulse, or arterial waveform; the patient may or may not survive.

right axis deviation A pattern of electrical activity that occurs in the heart where there is a deviation of the axis to the right within the quadrant of +90 degrees and ±180 degrees.

right bundle branch A division in the bundle of His that provides pathways for impulse conduction.

right bundle branch block A conduction abnormality that occurs when transmission of the electrical impulse is delayed or not conducted along the right bundle branch.

right ventricular failure Failure of the right ventricle to serve as an effective forward pump; often results from left ventricular failure that produces elevated pressure in the pulmonary vascular system.

sinoatrial node An area of specialized heart tissue that generates the cardiac electrical impulse.

sinus arrest The failure of the sinus node causes short periods of cardiac standstill.

sinus bradycardia Decreased heart rate that results from slowing of the pacemaker rate of the SA node.

sinus dysrhythmia A cardiac rhythm disturbance that often is related to the respiratory cycle and to changes in intrathoracic pressure.

sinus tachycardia Increased heart rate that results from increase in the rate of the sinus node discharge.

sodium ion channels Protein-lined channels in the cell membrane that allow sodium to enter the cell during rapid depolarization.

ST segment The early part of repolarization in the electrocardiogram of the right and left ventricles.

standard limb leads Bipolar ECG leads that record the difference in electrical potential between the left arm (+), the right arm (−), and the left leg (−) electrodes.

Starling's law of the heart A rule that the force of the heartbeat is determined by the length of the fibers making up the myocardial walls.

STEMI A myocardial infarction in which there is ST-segment elevation.

stroke volume The volume of blood ejected from one ventricle in a single heartbeat.

sudden death A death that occurs within the first 2 hours after the onset of illness or injury.

supraventricular tachycardia A complex group of dysrhythmias that can be broadly defined as any tachycardia that directly or indirectly involves the atria or atrioventricular node (above the bundle of His).

syncope A brief lapse in consciousness caused by transient cerebral hypoxia.

synchronized cardioversion An electrical countershock used to terminate dysrhythmias other than ventricular fibrillation and pulseless ventricular tachycardia given after the peak of the R wave of the cardiac cycle.

systole Contraction of the atria and ventricles.

T wave A deflection in the electrocardiogram after the QRS complex, representing ventricular repolarization.

tachycardia A heart rate that exceeds 99 beats per minute.
third-degree atrioventricular block A condition that results from complete electrical block at or below the atrioventricular node; also known as *complete heart block*.
threshold potential The value of the membrane potential at which an action potential is produced as a result of depolarization in response to a stimulus.
torsades de pointes An unusual bidirectional ventricular tachycardia.
transcutaneous cardiac pacing (TCP) The delivery of repetitive electrical currents to the heart through an external artificial pacemaker; also known as *external cardiac pacing.*
Type I second-degree atrioventricular block A type of second-degree atrioventricular block that usually occurs at the level of the atrioventricular node; also known as *Wenckebach.*
Type II second-degree atrioventricular block A type of second-degree atrioventricular block that occurs when atrial impulses are not conducted to the ventricles.
U wave The gradual deviation from the T wave in the electrocardiogram, thought to represent the final stage of repolarization of the ventricles.
unifocal premature ventricular complex A premature ventricular complex that originates from a single ectopic pacemaker site.
unipolar leads Augmented limb leads that record the difference in electrical potential, using one electrode for a positive pole, but having no distinct negative pole.
unstable angina (UA) An acute coronary syndrome associated with a pattern of ischemic chest pain that has changed in its ease of onset, frequency, intensity, duration, or quality; also known as *preinfarction angina.*
unsynchronized cardioversion An electrical countershock used to terminate ventricular fibrillation and pulseless ventricular tachycardia, given without regard to where the shock occurs in the cardiac cycle.
Valsalva maneuver A vagal maneuver used to slow the heart and decrease the force of atrial contraction by stimulating postganglionic parasympathetic nerve fibers in the wall of the atria and specialized tissues of the sinoatrial and atrioventricular nodes via the vagus nerve.
valvular heart disease Any disease process that affects one or more valves of the heart: the mitral, aortic, tricuspid, or pulmonary valves.
vasovagal syncope A brief loss of consciousness that results from stimulation of the vagus nerve.
ventricular asystole Refers to the absence of all ventricular activity (cardiac standstill); may be the cause of cardiac arrest.
ventricular bigeminy A cardiac rhythm disturbance characterized by two ventricular beats in rapid succession followed by a longer interval.
ventricular escape complex A dysrhythmia that results when impulses from higher pacemakers fail to fire or to reach the ventricles; also known as *idioventricular rhythm*.
ventricular fibrillation (VF) A cardiac dysrhythmia marked by rapid, disorganized depolarization of the ventricular myocardium.
ventricular tachycardia (VT) A tachycardia that usually originates in the Purkinje fibers.
ventricular trigeminy A cardiac dysrhythmia characterized by three ventricular beats in rapid succession followed by a longer interval.
wandering pacemaker The passive transfer of pacemaker sites from the sinus node to other latent pacemaker sites in the atria and atrioventricular junction.
Wolff-Parkinson-White syndrome A syndrome of preexcitation of the ventricles of the heart; caused by an accessory pathway (bundle of Kent) that permits abnormal electrical communication from the atria to the ventricles.

Cardiovascular disease accounts for more than 500,000 deaths in the United States each year. About one half of the cases of sudden death from coronary disease take place outside the hospital and usually occur within 4 hours after onset of symptoms.[1] *A large number of these deaths can be prevented by rapid entry into the EMS system, prompt provision of cardiopulmonary resuscitation, and early defibrillation.*

CRITICAL THINKING
How many of your friends or family have had a heart attack or stroke? How has that illness affected their lives?

RISK FACTORS AND PREVENTION STRATEGIES FOR CARDIOVASCULAR DISEASE

Although death rates from myocardial infarction have declined over the past several decades, coronary artery disease with resultant sudden death is still a major cause of morbidity and mortality and the most prominent medical emergency in the United States today.[1] The decline in death rates is due largely to heightened public awareness, the increased availability of automated external defibrillators (AEDs), improved cardiovascular diagnosis and therapy, the use of cardiovascular drugs by individuals at high risk, improved revascularization techniques, and improved and more aggressive risk factor modification.

Risk Factors and Risk Factor Modifications

Factors that pose a high risk for cardiovascular disease include advanced age, male gender, diabetes, hypertension, hypercholesterolemia, hyperlipidemia, a family history of premature cardiovascular disease, and known coronary artery disease. The risk can be increased considerably if the person has additional risk factors, such as obesity, cigarette smoking, and a sedentary lifestyle (Box 22-1). Clearly, some risk factors cannot be changed. Other risk factors, however, can be changed or modified through the following:

- Cessation of smoking
- Medical management and control of blood pressure, diabetes, cholesterol, and lipid disorders
- Exercise
- Weight loss
- Diet
- Stress reduction

Modifying cardiovascular risk factors can slow the rate of development of arterial disease. It also can reduce the incidence of acute myocardial infarction, sudden death, renal failure, and stroke.

Prevention Strategies

Paramedics and other health care professionals can support and practice activities that help prevent the development of cardiovascular disease. These strategies include community educational programs about nutrition, cessation of smoking (smoking prevention for children), early recognition and management of hypertension and cardiac symptoms, and prompt intervention (including cardiopulmonary resuscitation [CPR] and early use of an AED). These and other prevention strategies may help reduce risk factors at a young age. They also may have the greatest impact on risk factor modification (see Chapter 3).

BOX 22-1 Risk Factors for Cardiovascular Disease

Risk Factors

Age
Carbohydrate intolerance
Cigarette smoking
Cocaine use
Diabetes
Family history
Hypercholesterolemia
Hyperlipidemia
Hypertension
Previous myocardial infarction

Possible Contributing Risk Factors

Obesity
Oral contraceptive use
Personality type
Poor diet
Psychosocial tensions
Sedentary lifestyle
Stress
Excess alcohol consumption

SECTION ONE
Anatomy and Physiology of the Heart

ANATOMY REVIEW

The anatomy of the heart is described and illustrated in Chapter 10. The following is a brief review.

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 182-188.

The human heart is a muscular organ with four chambers (Figure 22-1). It is cone shaped and about the size of a man's closed fist. It lies just to the left of the midline in the thorax. The heart is enclosed in a pericardial sac. This sac is lined with three parietal layers of serous membrane that form the wall of the heart. These three layers of tissue are the outer layer (epicardium); the middle layer (myocardium); and the inner layer (endocardium). The four chambers of the heart are the right atrium, right ventricle, left atrium, and left ventricle. The right atrium receives deoxygenated blood from the systemic veins. The left atrium receives oxygenated blood from the pulmonary veins. The heart has two types of valves that keep the blood flowing in the right direction. The valves between the atria and ventricles are the atrioventricular valves (also called *cuspid valves*); the valves at the bases of the large vessels leaving the ventricles are the semilunar valves. The right atrioventricular valve is the tricuspid valve. The left atrioventricular valve is the bicuspid (or mitral) valve. The valve between the right

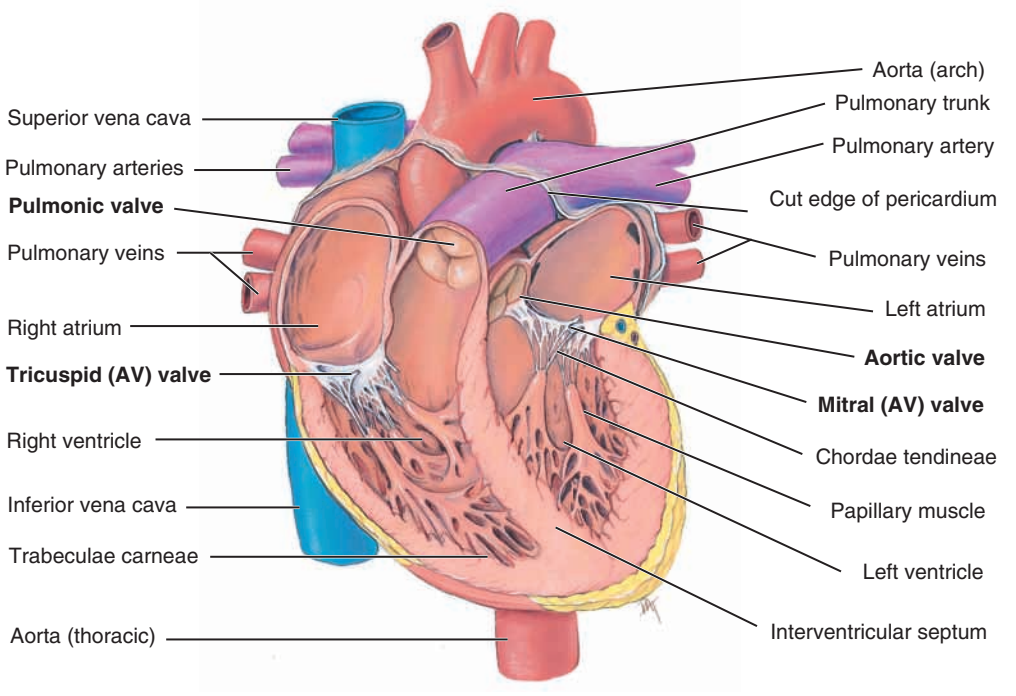

FIGURE 22-1 Internal view of the heart showing the four valves. (Applegate EM: *The anatomy and physiology learning system,* ed 3, St Louis, 2007, Saunders.)

ventricle and pulmonary trunk is the pulmonary semilunar valve. The valve between the left ventricle and the aorta is the aortic semilunar valve. When the ventricles contract, atrioventricular valves close to prevent blood from flowing back into the atria. When the ventricles relax, semilunar valves close to prevent blood from flowing back into the ventricles.

Blood Supply to the Heart

The coronary arteries are the sole suppliers of arterial blood to the heart. They deliver 200 to 250 mL of blood to the myocardium each minute during rest (Figure 22-2). The left coronary artery carries about 85% of the blood supply to the myocardium. The right coronary artery carries the rest. The coronary arteries begin just above the aortic valve where the aorta exits the heart. These arteries run along the epicardial surface. They divide into smaller vessels as they penetrate the myocardium and the endocardial (inner) surface.

The left main coronary artery supplies the left ventricle, the interventricular septum, and part of the right ventricle. Its two main branches are the left anterior descending artery and the circumflex artery. The right coronary artery supplies the right atrium and ventricle, part of the left ventricle, and the conduction system. Its two major branches are the right anterior descending branch and the marginal branch. In addition to the blood supply provided by these arteries, many connections (anastomoses) exist between arterioles to provide backup (collateral) circulation. These anastomoses play a key role in providing alternative routes of blood flow in the event one or more of the coronary vessels become blocked (Figure 22-3).

CRITICAL THINKING
Why is collateral circulation important?

Coronary capillaries allow for the exchange of nutrients and metabolic wastes. The capillaries merge to form coronary veins. These veins deliver most of the blood to the coronary sinus. The coronary sinus empties directly into the right atrium. The coronary sinus is the major vein draining the myocardium.

PHYSIOLOGY

The heart can be thought of as two pumps in one. One is a low-pressure pump (right atrium and right ventricle). This pump supplies blood to the lungs. The other is a high-pressure pump (left atrium and left ventricle). This pump supplies blood to the body. The right atrium receives venous blood from the systemic circulation and from the coronary veins. Most of this deoxygenated blood in the right atrium then passes to the right ventricle as the ventricle relaxes from the previous contraction. Once the right ventricle has received about 70% of its volume, the right atrium contracts. The blood remaining in the atrium is pushed into the ventricle. Contraction of the right ventricle pushes blood against the tricuspid valve (forcing it closed) and

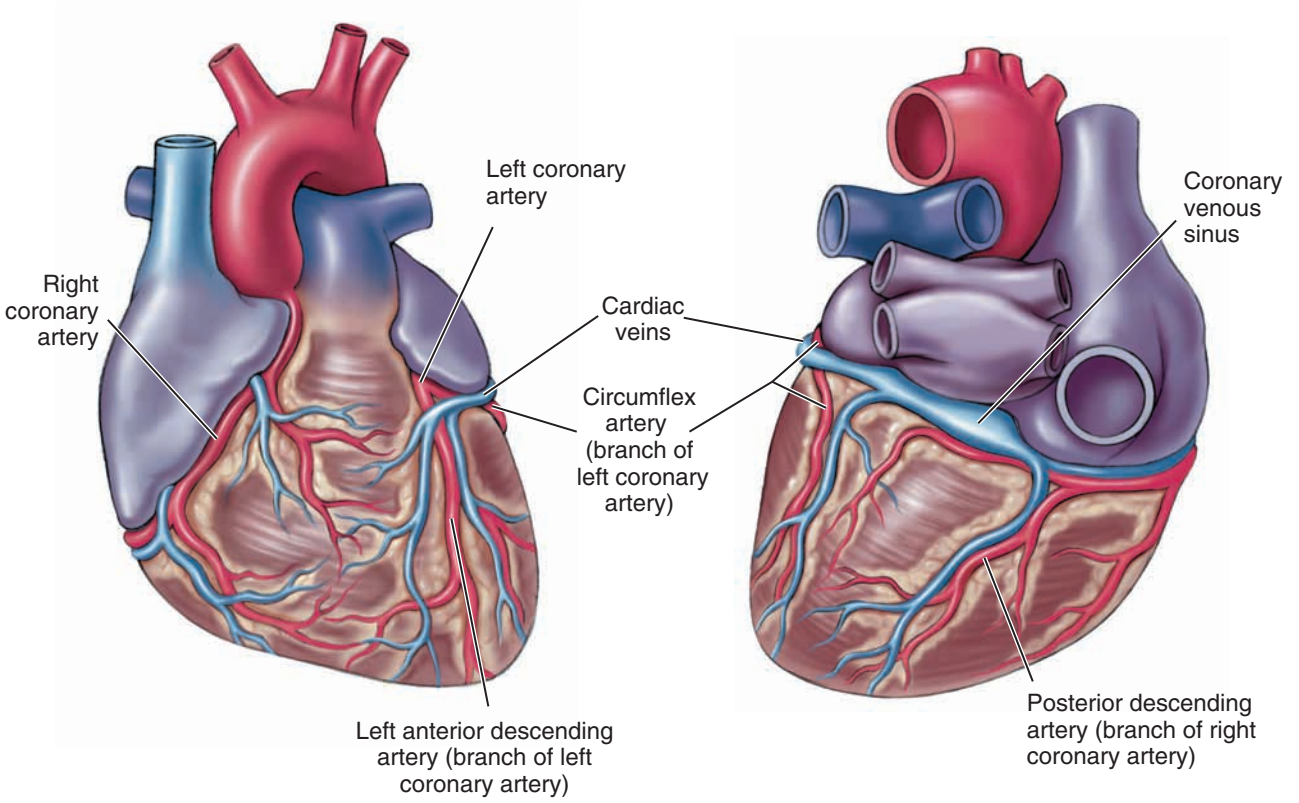

FIGURE 22-2 Blood supply to the myocardium: coronary blood vessels. (Herlihy B: *The human body in health and illness,* ed 3, St Louis, 2007, Saunders.)

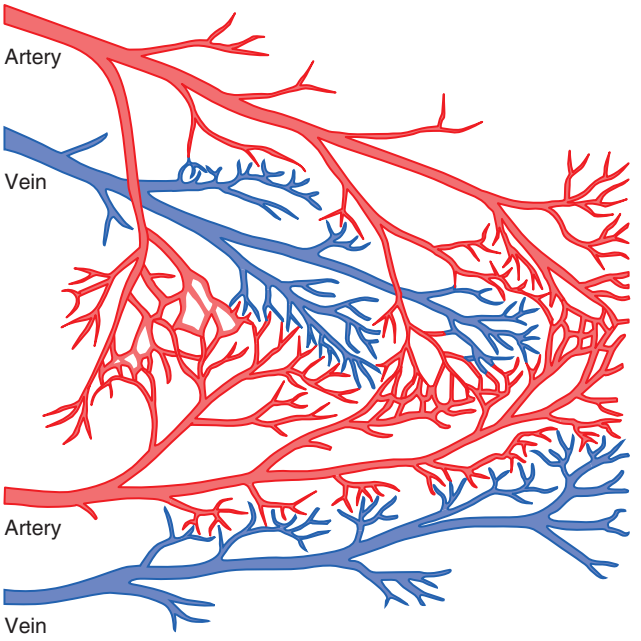

FIGURE 22-3 Minute anastomoses in the normal coronary arterial system. (Guyton AC, Hall JE: *Textbook of medical physiology,* ed 11, St Louis, 2007, Saunders.)

through the pulmonic valve (forcing it open). This allows the blood to enter the lungs via the pulmonary arteries. From the pulmonary arteries, the deoxygenated blood enters the capillaries in the lungs, where gas exchange takes place.

From the lungs the blood travels through four pulmonary veins back to the left atrium. The mitral valve opens, and blood flows to the left ventricle. Once the left ventricle has received about 70% of its volume, the left atrium contracts. The remaining blood 20% to 30% of the blood is pushed into the ventricles during atrial contraction (this is known as the **atrial kick**). The blood passing from the left atrium to the left ventricle opens the bicuspid valve when the ventricle relaxes to complete left ventricular filling. As the left ventricle contracts, blood is pushed against the bicuspid valve (closing it) and against the aortic valve (opening it). This allows blood to enter the aorta. From the aorta, blood is distributed first to the heart itself and then throughout the systemic arterial circulation.

NOTE

The atria work mainly as "primer pumps." Under most conditions, the ventricles can pump enough blood to maintain adequate blood flow to the body without the extra 30% of blood squeezed in by the atria. However, under stress, the heart may pump 300% to 400% more blood than during rest. In such conditions, the priming action of the atria becomes a key factor in maintaining pumping efficiency.

Cardiac Cycle

The pumping action of the heart is a product of rhythmic, alternate contraction **(systole)** and relaxation **(diastole)** of the atria and ventricles. (When *systole* and *diastole* are used without reference to specific chambers, they mean *ventricular* systole or diastole.) These heartbeats occur about 70 times a minute (every 0.8 second) in resting adults. These rhythmic contractions of the heart chambers are responsible for the movement of blood (Figure 22-4).

NOTE

The cardiac cycle has three phases: phase 1, ventricular filling (middle to late diastole); phase 2, ventricular systole; and phase 3, *isovolumetric relaxation* (early diastole).[2] In phase 2, ventricular systole, the atria relax and the ventricles begin contracting. Their walls close in on the blood in their chambers and ventricular pressure rises, closing the atrioventricular (AV) valve. Because, for a split second, the ventricles are completely closed chambers and blood volume in the chambers remains constant, this is called the *isovolumetric contraction* phase.

VENTRICULAR SYSTOLE AND DIASTOLE

As the ventricles begin to contract, ventricular pressure exceeds atrial pressure. This causes the atrioventricular valves to close. As the contraction proceeds, ventricular pressure continues to rise. Pressure rises until it exceeds that in the pulmonary artery on the right side of the heart and in the aorta on the left side. At that time, the pulmonary and aortic valves open. Blood then flows from the ventricles into those arteries **(ejection).**

After ventricular contraction, ventricular relaxation begins. Ventricular pressure falls rapidly. When the pressure falls below the pressure in the aorta or the pulmonary trunk, blood is forced back toward the ventricles. This closes the pulmonic and aortic valves. As the ventricular pressure drops below the atrial pressure, the tricuspid and mitral valves open. Blood then flows from the atria into the ventricles. Atrial systole occurs during ventricular diastole.

CRITICAL THINKING

What would happen if the valves were scarred and became stiff?

Stroke Volume

The **stroke volume** is the amount of blood ejected from the heart with each ventricular contraction. The stroke volume depends on three factors: **preload** (the volume of blood returning to the heart) (Box 22-2), **afterload** (the resistance against which the heart muscle must pump), and **myocardial contractility** (the performance of cardiac muscle).

BOX 22-2 Venous Return

Venous return is influenced by several factors, including the following[3]:

1. *Muscle contraction (skeletal muscle pump).* Rhythmical contraction of limb muscles, such as occurs during normal exercise (e.g., walking, running, swimming), promotes venous return by compressing and decompressing the veins.
2. *Respiratory cycle (thoracicoabdominal pump).* During respiratory inspiration, the negative pressure in the chest increases. This increase in pressure reduces right atrial pressure and increases venous return. Therefore, increasing the rate and depth of respiration increases cardiac output. Conversely, when negative pressure in the chest is reduced (e.g., from positive pressure ventilation, intermittent positive pressure breathing [IPPB], positive end-expiratory pressure [PEEP], continuous positive airway pressure [CPAP], and biphasic positive airway pressure [BiPAP]), venous return and cardiac output decrease.
3. *Decreased venous compliance.* Sympathetic activation of veins decreases venous compliance. This increases central venous pressure. It also promotes venous return by augmenting cardiac output through Starling's law of the heart. The result is an increase in the total blood flow through the circulatory system.
4. *Vena cava compression.* An increase in the resistance of the vena cava, such as occurs when the thoracic vena cava becomes compressed during a Valsalva maneuver or during late pregnancy, reduces return.
5. *Gravity.* The effects of gravity can reduce venous return. When a person stands from a supine position, cardiac output and arterial pressure decrease, because right atrial pressure falls. The flow through the entire systemic circulation falls, because the arterial pressure falls more than the right atrial pressure. Therefore, the pressure gradient driving flow throughout the entire circulatory system is decreased.

PRELOAD

During diastole, blood flows from the atria into the ventricles. The volume of blood returning to each ventricle is the **end-diastolic volume.** This volume normally reaches 120 to 130 mL. As the ventricles empty during systole, their volume decreases to 50 to 60 mL (end-systolic volume). Therefore, the amount of blood ejected during each cardiac cycle (stroke volume) in the average adult is about 70 mL.

In a patient with a healthy heart, the capacity to increase the stroke volume is great. The strong contraction of a heart during exercise, for example, can reduce the volume returning to each ventricle to as little as 10 to 30 mL. If large amounts of blood flow into the ventricles during diastole, their end-diastolic volume can be as much as 200 to 250 mL. In this way, the stroke volume can increase to more than double the normal amount. The ability of the heart to pump more strongly when it has a larger preload is explained by **Starling's law of the heart**.

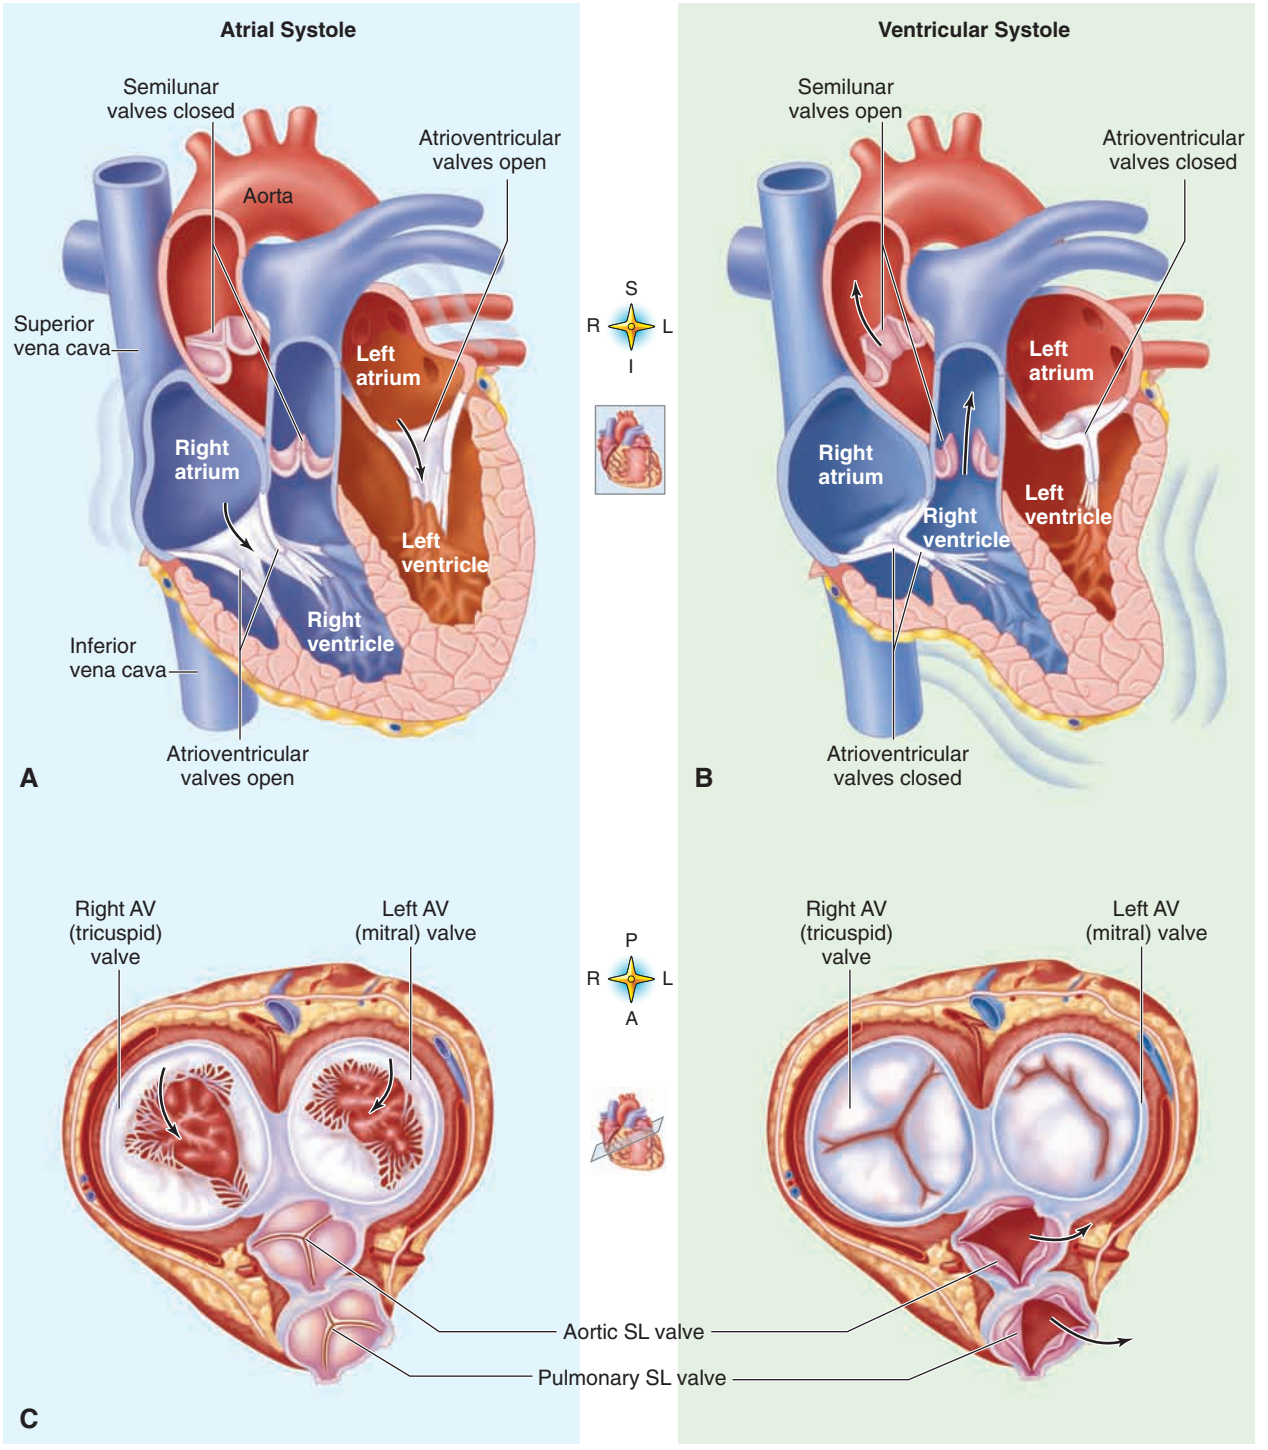

FIGURE 22-4 Heart action. **A**, During atrial systole (contraction), cardiac muscle in the atrial wall contracts, forcing blood through the atrioventricular valves and into the ventricles. **B**, During the ventricular systole that follows, the atrioventricular valves close and blood is forced out of the ventricles through the semilunar valves into the arteries. **C**, The pulmonary semilunar valves as seen from above (superior). (Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

CRITICAL THINKING
When you blow up a balloon, why does the balloon act like the heart muscle?

According to Starling's law (Figure 22-5), myocardial fibers contract more forcefully when they are stretched. (This ability of stretched muscle to contract with increased force is a quality of all striated muscle, not just cardiac muscle.) When the ventricles are filled with larger than normal volumes of blood (increased preload), they contract with greater than normal force to deliver all the blood to the systemic circulation.

The most important feature of the heart's ability to handle changes in venous blood return is that changes in arterial pressure have minimal effect on cardiac output. In other words, the heart can pump a small amount of blood or a large amount. The amount depends on the amount of venous return. The heart simply adapts, as long as the total amount of blood does not exceed the limit the heart can pump. Venous return is the most important factor in stroke volume; arterial pressure has a lesser effect in the form of afterload. Starling's law and its effect on stroke volume can be applied only to a certain limit of muscle fiber stretching. Beyond that limit, muscle fiber stretch actually diminishes the strength of contraction. At that point, the heart begins to fail.

NOTE
Preload is more important in determining cardiac output than afterload.

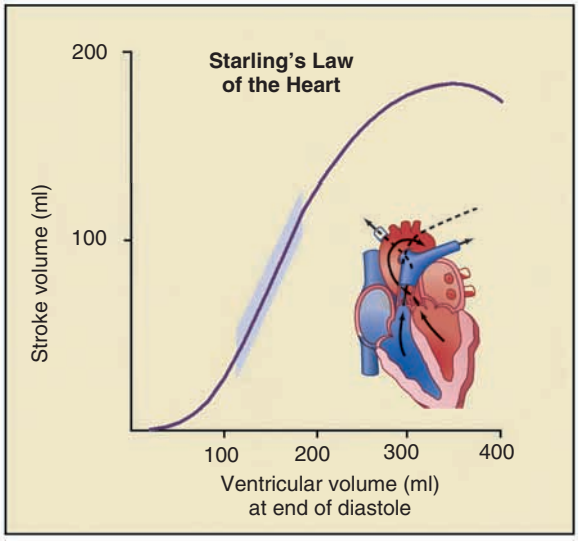

FIGURE 22-5 Starling's law of the heart. (Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 7, St Louis, 2007, Mosby.)

AFTERLOAD

Afterload is the pressure within the aorta before ventricular contraction. It is a result of **peripheral vascular resistance** (the total resistance against which blood must be pumped). The greater the afterload, the more difficult it is for the left ventricle to pump blood to the body. In addition, the amount of blood ejected with ventricular contraction (stroke volume) is reduced. (The decrease in stroke volume is due to the increased pressure in the aorta that the ventricular muscle must overcome to open the aortic valve and push blood through.) As afterload is reduced (e.g., by lowering blood pressure, vasodilators), stroke volume increases, provided there is enough blood in the system.

NOTE
Although the term *afterload* generally is used to refer to the left ventricle, it also can refer to the right ventricle. For example, pulmonary hypertension increases afterload and can cause right ventricular failure.

CRITICAL THINKING
What condition would increase the afterload?

MYOCARDIAL CONTRACTILITY

The unique function of the myocardial muscle fibers and the influence of the autonomic nervous system play a major role in the function of the heart. Ischemia or various drugs can decrease myocardial contractility. Ischemia can reduce the total number of working myocardial cells (this occurs in myocardial infarction). Hypoxia or beta blockers can decrease the ability of the myocardial cells to contract.

Cardiac Output

Cardiac output is the amount of blood pumped by the ventricles in 1 minute. It can be increased by increasing the heart rate, the stroke volume, or both. Cardiac output is calculated as follows:

$$\text{Cardiac output} = \text{Stroke volume} \times \text{Heart rate}$$

Peripheral vascular resistance changes cardiac output by affecting the stroke volume. Vasodilation of the arteries, for example, reduces afterload. This produces an increase in cardiac output. In contrast, vasoconstriction increases afterload. In turn, this tends to reduce cardiac output. However, the body responds to the decrease by constricting the venous circulation. This increases the amount of blood returning to the heart and causes the heart to contract more forcefully (Starling's law). These actions help maintain or increase cardiac output.

Nervous System Control of the Heart

In addition to the heart itself, the autonomic nervous system controls the behavior of the heart (described in Chapter 10). It greatly influences the heart rate,

conductivity, and contractility. The autonomic nervous system innervates the atria and ventricles. The atria are well supplied with large numbers of sympathetic and parasympathetic nerve fibers. The ventricles mainly are supplied by sympathetic nerves.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 171-177.

The parasympathetic nervous system is concerned mainly with vegetative functions (e.g., digestion and bowel and bladder function). In contrast, the sympathetic nervous system helps prepare the body to respond to stress. These sympathetic and parasympathetic control systems work in a checks-and-balance manner. They stimulate the heart to increase or decrease cardiac output according to the metabolic demands of the body.

CRITICAL THINKING
Consider how you regulate the hot and cold taps in a shower. How is the behavior of the autonomic nervous system similar?

PARASYMPATHETIC CONTROL

Parasympathetic control of the heart is accomplished through the vagus nerve. Control by these nerve fibers has a continuous restraining influence on the heart, primarily by reducing the heart rate and, to a lesser extent, contractility. The vagus nerve may be stimulated in several ways, such as the Valsalva maneuver, carotid sinus massage (described later in this chapter), pain, and distention of the urinary bladder. Acetylcholine is the chemical mediator of the parasympathetic nervous system.

Strong parasympathetic stimulation can decrease the heart rate to 20 or 30 beats/minute. Yet such stimulation generally has little effect on stroke volume. In fact, stroke volume may increase with a decreased heart rate. This occurs because the longer interval between heartbeats allows the heart to fill with a larger amount of blood and thus contract more forcefully (Starling's law).

SYMPATHETIC CONTROL

Sympathetic nerve fibers originate in the thoracic region of the spinal cord. They form groups of nerve fibers called *ganglia.* Their postganglionic fibers release the chemical norepinephrine. This chemical stimulates an increase in the heart rate *(positive chronotropic effect).* Norepinephrine also stimulates an increase in the force of muscle contraction *(positive inotropic effect).* Sympathetic stimulation of the heart causes the coronary arteries to dilate. It also causes constriction of peripheral vessels. These two effects, dilation and constriction, help increase the blood and oxygen supply to the heart. The cardiac effects of norepinephrine result from stimulation of alpha- and beta-adrenergic receptors.

LOOK AGAIN
See Chapter 13: Principles of Pharmacology and Emergency Medications, pp. 300-304.

NOTE
As described in Chapter 13, the term *inotropic* refers to the force of energy of muscular contractions; *chronotropic* refers to the regularity and rate of the heartbeat; and *dromotropic* refers to conduction velocity. The effects are classified as positive or negative. For example, a positive inotropic effect would increase the strength of contraction. However, a negative dromotropic effect would decrease the speed of conduction.

Strong sympathetic stimulation of the heart may increase the heart rate notably. When rates are significantly high (greater than 150 beats/minute), the time available for the heart to fill is decreased. This produces a decrease in stroke volume.

Hormonal Regulation of the Heart

Impulses from the sympathetic nerves are sent to the adrenal medulla at the same time they are sent to all blood vessels. In response, the adrenal medulla secretes the hormones epinephrine and norepinephrine into the circulating blood in response to increased physical activity, emotional excitement, or stress.

Epinephrine has basically the same effect on cardiac muscles as norepinephrine. Epinephrine increases the rate and force of contraction. In addition, it causes blood vessels to constrict in the skin, kidneys, gastrointestinal tract, and other organs (viscera). Epinephrine also causes dilation of skeletal and coronary blood vessels. Epinephrine from the adrenal glands takes longer to act on the heart than direct sympathetic innervation does. Yet the effect lasts longer. Norepinephrine causes constriction of peripheral blood vessels in most areas of the body and also stimulates cardiac muscle.

Role of Electrolytes

As are all other cells of the human body, myocardial cells are bathed in an electrolyte solution. The major electrolytes that affect cardiac function (described in the next section) are calcium, potassium, and sodium. Magnesium is a major intracellular cation that also plays an important role. Changes in electrolytes can affect depolarization, repolarization, and myocardial contractility.

CRITICAL THINKING
What drugs can alter the normal balance of electrolytes in the body?

SECTION TWO
Electrophysiology of the Heart

To provide appropriate care for patients with cardiac disease, the paramedic must understand the mechanical and electrical functions of the heart. Understanding why and how the electrical conduction system can malfunction is crucial. The paramedic also must understand the effect that lack of oxygen to the cells (myocardial ischemia) has on cardiac rhythms. Two basic groups of cells in the myocardium are vital for cardiac function. One group is the specialized cells of the electrical conduction system. These cells are responsible for the formation and conduction of electrical current. The second group is the working myocardial cells. These cells have the property of contractility. They do the actual pumping of blood.

ELECTRICAL ACTIVITY OF CARDIAC CELLS AND MEMBRANE POTENTIALS

As described in Chapter 11, ions are charged particles. These particles are positive or negative. The charge depends on the ability of the ion to accept or donate electrons. In solutions containing electrolytes, particles with unlike (opposite) charges attract each other, and the particles with like charges push away from each other. This results in a tendency to produce ion pairs. These ion pairs help keep the solution neutral.

LOOK AGAIN

See Chapter 11: General Principles of Pathophysiology, pp. 215-217.

Electrically charged particles may be thought of as small magnets. They require energy to pull them apart if they have opposite charges. They also require energy to push them together if they have like electrical charges. Therefore, separated particles with opposite charges have an electrical magnetic–like force of attraction. This gives them *potential energy* (Figure 22-6). The electrical charge creates a membrane potential between the inside and the outside of the cell. The electrical charge *(potential difference)* between the inside and outside of cells is expressed in millivolts (1 mV equals 0.001 volt). This potential energy is released when the cell membrane separating the ions becomes permeable.

Resting Membrane Potential

When the cell is in its resting state, the electrical charge difference is the **resting membrane potential**. The term *potential* is used in the electrical sense as a synonym for voltage. The inside of the cell is negative compared with the outside of the cell membrane. Also, the resting membrane potential is recorded from the inside of the cell. Therefore, the resting membrane potential is reported as a negative number (about –70 to –90 mV).

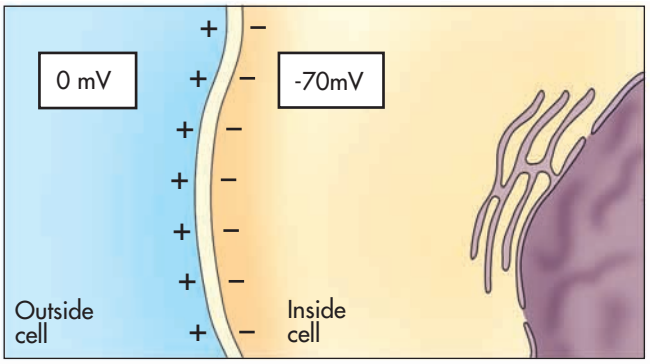

FIGURE 22-6 Electrical activity of cardiac cells and membrane potentials.

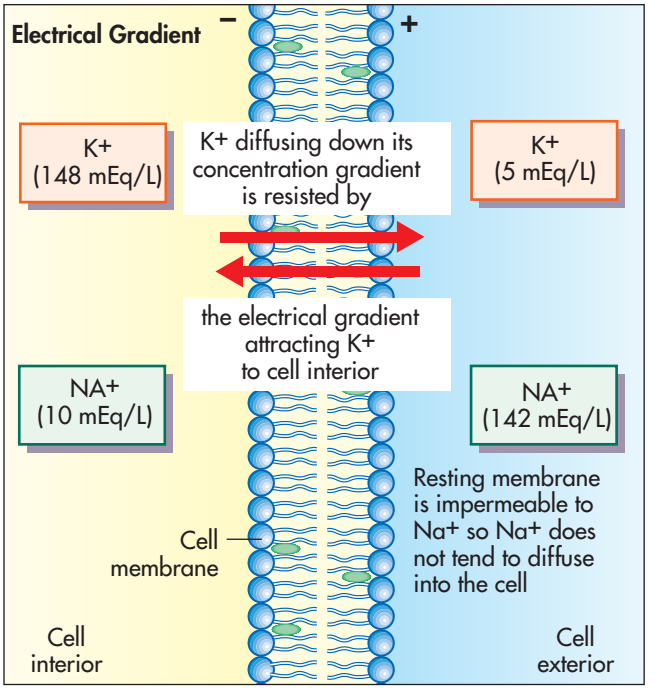

FIGURE 22-7 At equilibrium (resting conditions), the tendency for potassium ions to diffuse out of the cell is opposed by the potential difference (electrical gradient) across the cell membrane. Because the resting membrane is not permeable to sodium ions, sodium ions do not tend to diffuse into the cell.

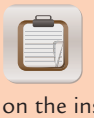
The resting membrane potential is a result of the balance between two opposing forces. One of these forces is the concentration gradient of ions (mainly potassium) across a permeable cell membrane. The other is the electrical forces produced by the separation of positively charged ions from their negative ion pair. The resting membrane potential mainly is established by the difference between the intracellular potassium ion level and the extracellular potassium ion level. The ratio of 148:5 produces a large chemical gradient for potassium ions to leave the cell. Yet the negative intracellular charge relative to the extracellular charge tends to keep potassium ions in the cell (Figure 22-7).

Sodium ions are positively charged ions on the outside of the cell. These ions have a chemical and electrical gradient. The gradients tend to cause sodium ions to move intracellularly, making the cell more positive on the inside compared with the outside.

Diffusion Through Ion Channels

The cell membrane is relatively permeable to potassium, somewhat less permeable to calcium chloride, and minimally permeable to sodium. The cell membrane appears to have individual protein-lined channels: **potassium ion channels** and **sodium ion channels.** These channels allow passage of a specific ion or group of ions. Permeability is influenced by electrical charge, size, and the proteins that open and close the channels *(gating proteins)*.

Potassium ion channels are smaller than sodium ion channels. They therefore prevent sodium from passing into the cell. Potassium ions are small enough to pass through sodium ion channels, but the cell favors sodium ions entering the cell during rapid depolarization. Rapid depolarization (the rapid entry of sodium ions into cells) creates a local area of current known as the *action potential*. After one patch of membrane is depolarized, the electrical charge spreads along the cell surface. This opens more channels (Figure 22-8).



NOTE

Depolarization occurs when the resting membrane potential changes from being more negatively charged on the inside of the cell to being more positively charged on the inside of the cell.

The contribution of unpaired ions to the resting membrane potential depends on two factors. The first factor is the diffusion of ions through the membrane by way of the ion channels. This creates an imbalance of charges. The second factor is the active transport of ions through the membrane by way of the sodium-potassium exchange pump. This also creates an imbalance of charges.

CRITICAL THINKING

Which of these processes of electrolyte transfer requires energy to occur?

Sodium-Potassium Exchange Pump

The specialized sodium-potassium exchange pump actively pumps sodium ions out of the cell and potassium ions into the cell. Thus this pump separates the ions across the membrane against their concentration gradients. Potassium ions are transported into the cell. This increases their concentration in the cell. Sodium ions are transported out of the cell. This increases their concentration outside the cell (Figure 22-9).

The sodium-potassium exchange pump normally transports three sodium ions out for every two potassium ions taken in. Therefore, more positively charged ions are transferred outward than inward. This repolarizes the cell and returns it to its resting state. In the cell's resting state, the number of negative charges inside the cell is equal to the number of positive charges outside the cell.

NOTE

Repolarization occurs when charges inside the cell return to normal (become more negatively charged on the inside), allowing the cell to return to its normal resting state.

Pharmacological Actions

In cardiac muscle, sodium and calcium ions can enter the cell through two separate channel systems in the cell membrane. These are the fast channels and the slow channels. Fast channels are sensitive to small changes in membrane potential. As the cell drifts toward threshold level (the point at which a cell depolarizes), fast sodium channels open. This results in a rush of sodium ions into the cell and rapid depolarization. The slow channel has selective permeability to calcium and to a lesser extent to sodium. Calcium plays an electrical role by contributing to the number of positive charges in the cell. Calcium also plays a contractile role. Calcium is the ion required for contraction of cardiac muscle.

An understanding of ion channels can help paramedics understand how the heart rate and contractility respond to drugs. For example, calcium channel blockers selectively block the slow channel. Examples of such drugs are ***verapamil*** and ***diltiazem.*** These drugs limit the movement of calcium ions into the cell without altering its voltage. Other examples, such as ***amiodarone*** (a type III antidysrhythmic), owe much of their antidysrhythmic effects to their ability to block the fast inward sodium channel.

CELL EXCITABILITY

Nerve and muscle cells are capable of producing action potentials. This is known as *excitability*. When these cells are stimulated, a series of changes in the resting membrane potential normally causes depolarization of a small region of the cell membrane. The stimulus may be strong enough to depolarize a cell membrane to a level called the **threshold potential**. If this is the case, an explosive series of permeability changes takes place. This causes an action potential to spread over the entire cell membrane.

Propagation of Action Potential

An action potential at any point on the cell membrane acts as a stimulus to adjacent regions of the cell membrane. Thus the excitation process, once started, is spread along

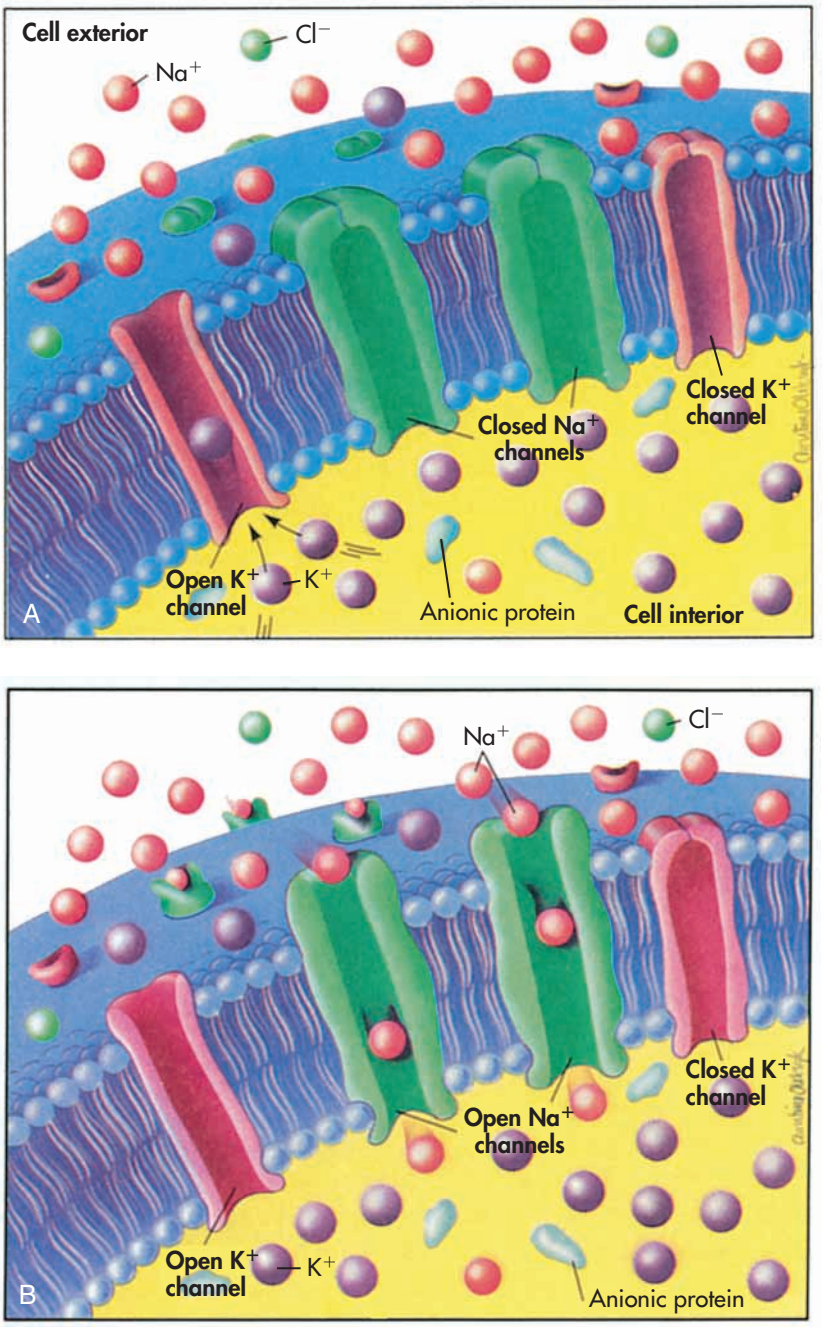


FIGURE 22-8 Effect of a stimulus that causes a voltage change across the cell membrane on the permeability of the cell membrane. **A,** Sodium channels remain closed in a resting (unstimulated) cell membrane. **B,** Depolarization of the cell membrane causes sodium channels to open. Sodium ions then diffuse down their concentration gradient into the cell, causing depolarization of the cell membrane.

the length of the cell and onto the next cell and so on. A stimulus strong enough to cause a cell to reach threshold and depolarize spreads quickly from one cell to another (this is the *all or none principle*). The cardiac action potential can be divided into five phases (phases 0 to 4) (Figure 22-10).

PHASE 0

Phase 0 is the rapid depolarization phase. It represents the rapid upstroke of the action potential. This occurs when the cell membrane reaches threshold potential. During this phase, the fast sodium channels open momentarily. In this moment, the sodium channels permit rapid entry of sodium

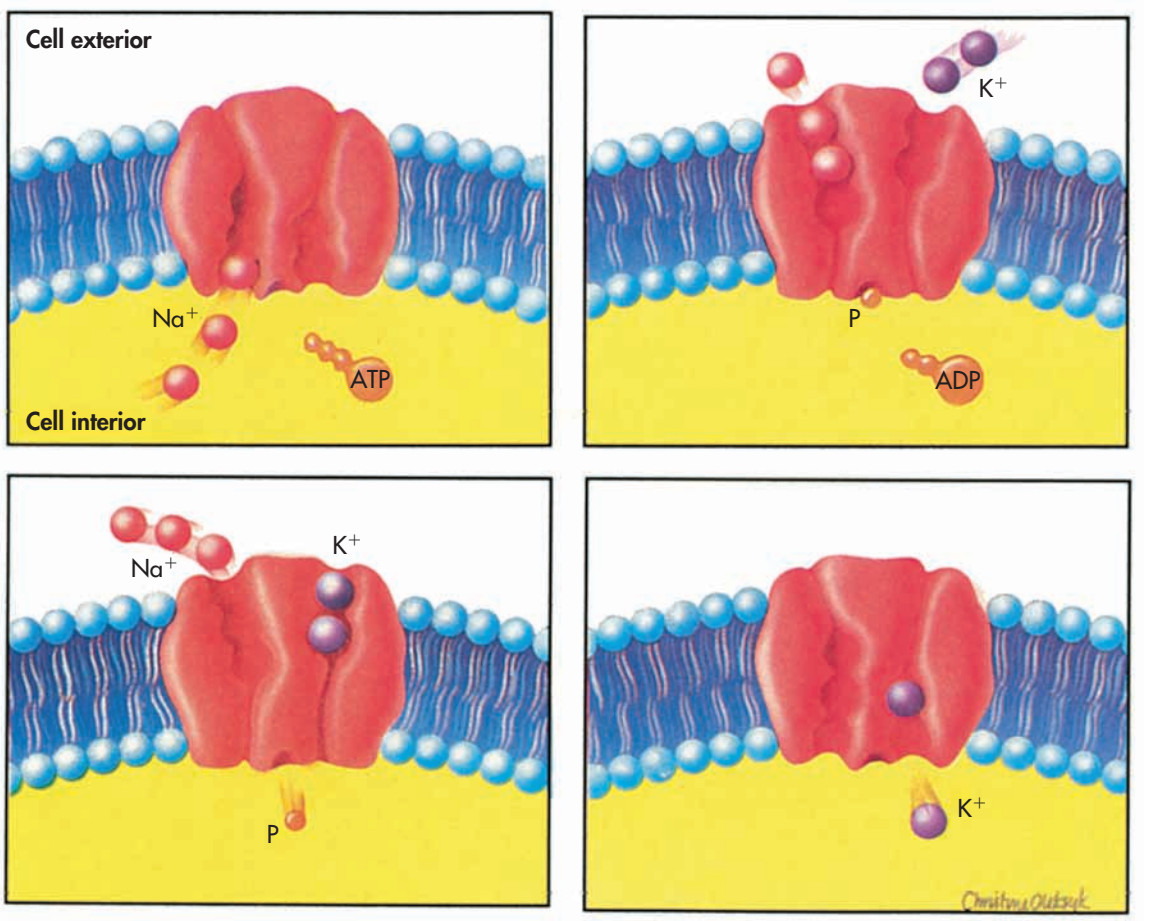

FIGURE 22-9 The sodium-potassium exchange pump actively transports sodium ions out of the cell across the cell membrane and potassium ions into the cell across the cell membrane. Adenosine triphosphate is used as the energy source. The pump can transport up to three sodium ions for every two potassium ions transported.

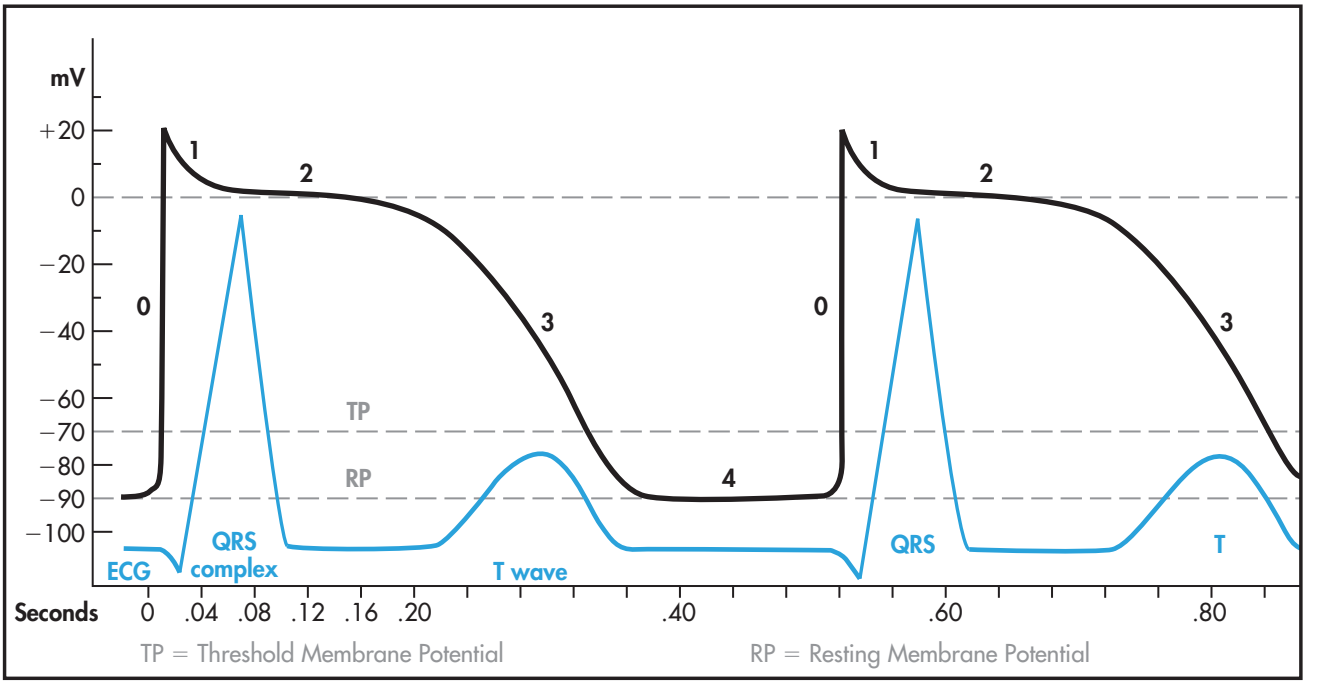

FIGURE 22-10 Cardiac action potential of myocardial cells.

into the cell. As the positively charged ions flow into the cell, the inside of the cell becomes positively charged compared with the outside, leading to muscular contraction.

PHASE 1

Phase 1 is the early rapid repolarization phase. During this phase, the fast sodium channels close, the flow of sodium into the cell stops, and potassium continues to be lost from the cell. This results in a decrease in the number of positive electrical charges inside the cell and a drop in the membrane potential. This returns the cell membrane to its resting permeability state.

PHASE 2

Phase 2 (the plateau phase) is the prolonged phase of repolarization of the action potential. During this phase, calcium enters the myocardial cells. This triggers a large secondary release of calcium from intracellular storage sites and initiates contraction. Calcium slowly enters the cell through the slow calcium channels. At the same time, potassium continues to leave the cell. The inward calcium current maintains the cell in a prolonged depolarization state. This allows time for completion of one muscle contraction before another depolarization begins. This phase also stimulates the release of intracellular stores of calcium and aids in the contraction process.

PHASE 3

Phase 3 is the terminal phase of rapid repolarization. It results in the inside of the cell becoming negatively charged. The membrane potential also returns to its resting state. This phase is initiated by closing of the slow calcium channels and by an increase in permeability with an outflow of potassium. Repolarization is completed by the end of this phase.

PHASE 4

Phase 4 represents the period between action potentials, when the membrane has returned to its resting membrane potential. During this phase, the inside of the cell is negatively charged with respect to the outside. However, the cell still has an excess of sodium inside and an excess of potassium outside. This activates the sodium-potassium exchange pump. The excess sodium is transported out of the cell, and the potassium is transported back into the cell. During phase 4, pacemaker cells have a slow depolarization from their most negative membrane potential to a level at which threshold is reached, and phase 0 begins all over again.

Refractory Period of Cardiac Muscle

As does all excitable tissue, cardiac muscle has a **refractory period**, or resting period, in which cells are incapable of repeating a particular action. The refractory period can be further defined in two ways:

- The **absolute refractory period,** in which the cardiac muscle cell cannot respond to any stimulation, regardless of how long the stimulus is applied
- The **relative refractory period,** in which the cardiac muscle cell is more difficult than normal to excite, but the cell still can be stimulated

The refractory period ensures that the cardiac muscle is fully relaxed before another contraction begins. The refractory period of the ventricles lasts about as long as that of the action potential. The refractory period of the atrial muscle is much shorter than that of the ventricles. This allows the rate of atrial contraction to be much faster than that of the ventricles. If the depolarization phase of cardiac muscle is prolonged, the refractory period also is prolonged (Figure 22-11).

CRITICAL THINKING

How are the relative and absolute refractory periods of the heart similar to the flushing mechanism of your toilet?

ELECTRICAL CONDUCTION SYSTEM OF THE HEART

The conduction system of the heart is composed of two nodes and a conducting branch (Figure 22-12). The two nodes are located in the walls of the right atrium. They are named according to their location. The **sinoatrial node** (SA node) is medial to the opening of the superior vena cava. The **atrioventricular node** (AV node) is medial to the right atrioventricular valve. The AV node and the **bundle of His** form the **atrioventricular junction.** The AV junction serves as the only electrical link between the atria and ventricles in a normal heart. The bundle of His passes

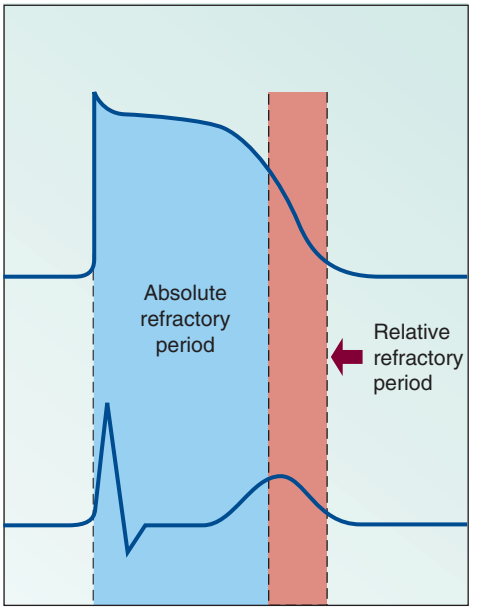

FIGURE 22-11 Absolute and relative refractory periods correlated with the cardiac muscle's action potential and with an ECG tracing. (Urden LD, Stacy KM, Lough ME: *Critical care nursing: diagnosis and management,* ed 6, St Louis, 2009, Mosby.)

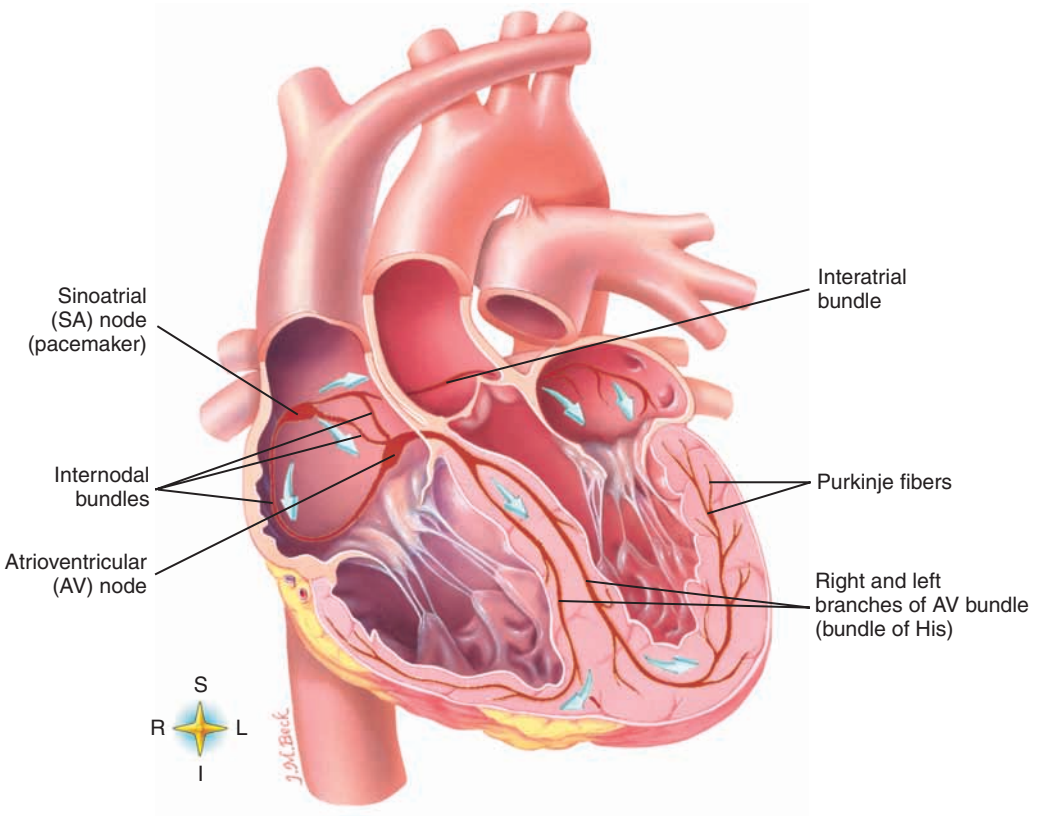

FIGURE 22-12 Conduction system of the heart. Impulses *(arrows)* travel across the wall of the right atrium from the sinoatrial node to the atrioventricular node. The atrioventricular bundle extends from the atrioventricular node through the fibrous skeleton and into the intervertebral septum, where it divides into right and left bundle branches. The bundle branches descend to the apex of the ventricle and then branch repeatedly for distribution throughout the ventricular walls.

through a small opening in the heart and reaches the **interventricular septum.** There the bundle of His divides into the **right bundle branch** and the **left bundle branch.** The left bundle branch then subdivides into the anterior-superior and posterior-inferior fascicles. These structures provide pathways for impulse conduction. A third fascicle of the left bundle branch also innervates the interventricular septum and the base of the heart.

The right and left bundle branches extend beneath the endocardium on either side of the septum to the apical portions of the right and left ventricles. The bundle branches subdivide into smaller branches. The smallest branches are called **Purkinje fibers.** The terminal Purkinje fibers spread electrical impulses from cell to cell through the myocardial fibers. This results in contraction of the heart muscle. The rapid conduction along these fibers causes depolarization of all right and left ventricular cells. These cells contract at more or less the same time, ensuring a single, coordinated contraction.

Pacemaker Activity

In skeletal and most smooth muscle, the individual cells contract only in response to hormones or nerve impulses from the central nervous system. However, unlike most other muscle cells, cardiac fibers have specialized cells known as *pacemaker cells*. These cells can generate electrical impulses spontaneously (**automaticity**). Pacemaker cells can depolarize in a repetitive manner. This rhythmic activity occurs because these tissues do not have a stable resting membrane potential (RMP). Instead, the RMP gradually decreases from its maximum repolarization potential. This continues until the RMP reaches a critical threshold, leading to depolarization. Sometimes the SA node may fail to generate an electrical impulse. If this occurs, other pacemaker cells take over. These pacemaker cells are capable of spontaneous depolarization and subsequent spread of an action potential. However, their rate is usually slower.

Sequence of Excitation in Cardiac Muscle

Under normal conditions, the chief pacemaker of the heart is the SA node. This is because the SA node reaches its threshold for depolarization more quickly than other pacemaker cells. The rapid rate of the SA node normally prevents the discharge of slower pacemakers from becoming dominant. If impulses from the SA node do not develop

normally, however, the next pacemaker to reach its threshold level would take over the pacemaker duties.

Because of automaticity, cardiac cells can act as a "fail-safe" means of initiating electrical impulses. The backup cells *(intrinsic pacemakers)* are arranged in cascade fashion: the farther from the SA node, the slower the intrinsic firing rate. In order, the location of cells with pacemaker capabilities and the rates of spontaneous discharge are the SA node (60 to 100 discharges/minute); AV junctional tissue (40 to 60 discharges/minute); and the ventricles, including the bundle branches and Purkinje fibers (20 to 40 discharges/minute) (Figure 22-13).

From the SA node the excitation spreads throughout the right atrium. This is made possible through four conduction tracks that make up the atrial conduction system: the AV node, *Bachmann's bundle* (in the left atrium), *Wenckebach's tract* (in the middle internodal tract), and *Thorel's tract* (in the posterior internodal tract). Through these tracts, impulses travel directly from the right to the left atrium and to the base of the right atrium. This results in virtually simultaneous contraction of the two atria. About 0.04 second is required for the impulse of the SA node to spread to the AV node. From there, propagation of the action potentials in the AV node is slow compared with the rate in the rest of the conducting system. As a result, a delay of 0.11 second occurs from the time the action potentials reach the AV node until they pass to the AV bundle. The total delay of 0.15 second allows atrial contraction to be completed before ventricular contraction begins.

After leaving the AV node, the impulse picks up speed. It travels rapidly through the bundle of His and the left and right bundle branches. The action potential passes quickly through the individual Purkinje fibers. The impulse ends in near simultaneous stimulation and contraction of the left and right ventricles. Ventricular contraction begins at the apex. Once stimulated, the special arrangement of muscle layers in the wall of the heart produces a wringing action that proceeds toward the base of the heart.

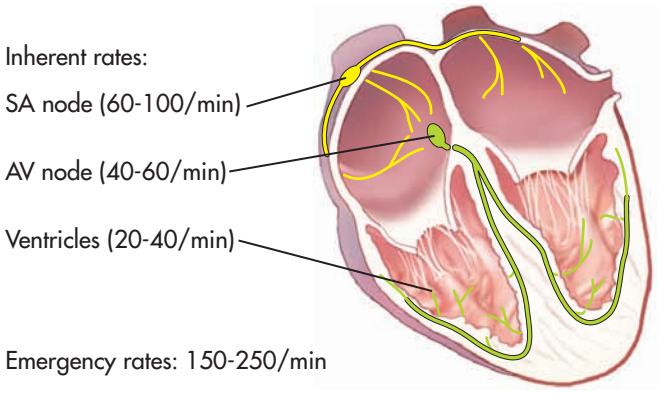

FIGURE 22-13 Intrinsic pacemakers in the atria, atrioventricular node, and ventricles can discharge at their own inherent rate when normal pacemaking fails.

Autonomic Nervous System Effects on Pacemaker Cells

The effects of autonomic nervous system stimulation on the heart rate are mediated by acetylcholine and norepinephrine. Acetylcholine causes the cell membrane of the SA node to become more permeable to potassium ions. This delays the pacemaker in reaching threshold and thus reduces the heart rate. Parasympathetic effects also may result from stimulation of the cardiac branch of the vagus nerve, causing the heart rate to slow. An example of vagal stimulation is carotid sinus massage, described later in this chapter. Excessive vagal stimulation may result in **asystole** (the absence of electrical and mechanical activity in the heart). This is why asystole sometimes is referred to as the "ultimate bradycardia."

CRITICAL THINKING
What else can cause vagal stimulation?

Norepinephrine increases the heart rate by increasing the rate of depolarization. The result is an increase in the pacemaker discharge rate in the SA node. Norepinephrine increases the flow of potassium and calcium ions into the cell during depolarization of the action potential. As a result, sympathetic stimulation leads to an increase in the heart rate. The force of cardiac contractions also increases.

Mechanisms of Ectopic Electrical Impulse Formation

When the heart contracts as a result of stimulation by cells other than those in the SA node, the contraction is known as an ectopic beat. These isolated events sometimes are called *premature beats* because they occur early in the cycle, before the SA node normally would discharge. The new pacemaker is called an **ectopic focus**. Depending on the location of the ectopic focus, these premature complexes or contractions may be of atrial origin (premature atrial contractions [PACs]), junctional origin (**premature junctional complexes [PJCs]**), or ventricular origin (premature ventricular contractions [PVCs]). The ectopic focus may be intermittent or may be sustained and may assume the pacemaker duties of the heart (i.e., the pacemaker site that fires the fastest controls the heart).

The two basic ways ectopic impulses are generated are by enhanced automaticity and reentry.

NOTE
An *ectopic beat* should not be confused with *aberrant conduction* (aberrancy). An ectopic beat is one that originates in the wrong part of the heart (away from normal). Aberrancy is abnormal conduction; that is, cardiac conduction through pathways that do not normally conduct impulses (particularly through ventricular tissue). **Aberration** can result from a number of causes, including premature atrial complexes, blocks in the bundle branches, and electrolyte abnormalities.

ENHANCED AUTOMATICITY

Enhanced automaticity is caused by an acceleration in depolarization. This commonly results from an abnormally high leakage of sodium ions into the cells, causing the cells to reach threshold prematurely. As a result, the rate of electrical impulse formation in potential pacemakers increases beyond their inherent rate.

Enhanced automaticity is responsible for **dysrhythmias** (abnormal rhythms) in Purkinje fibers and other myocardial cells. This condition may occur after the release of excess catecholamines (i.e., norepinephrine and epinephrine) or as result of digitalis toxicity, hypoxia, hypercapnia, myocardial ischemia or infarction, increased venous return (preload), hypokalemia or other electrolyte abnormalities, or ***atropine*** administration.

REENTRY

Reentry is the reactivation of myocardial tissue for the second or subsequent time by the same impulse (Figure 22-14). Reentry occurs when the progression of an electrical impulse is delayed or blocked (or both) in one or more segments of the electrical conduction system of the heart. A delayed or blocked impulse can enter cardiac cells that have just become repolarized. Reentry may produce single or repetitive ectopic beats. Reentry dysrhythmias can occur in the SA node, atria, AV junction, bundle branches, or Purkinje fibers. Reentry is the most common mechanism for producing ectopic beats, including cases of PVCs, ventricular tachycardia, ventricular fibrillation, atrial fibrillation, atrial flutter, and paroxysmal supraventricular tachycardia. These and other dysrhythmias are described later in the chapter.

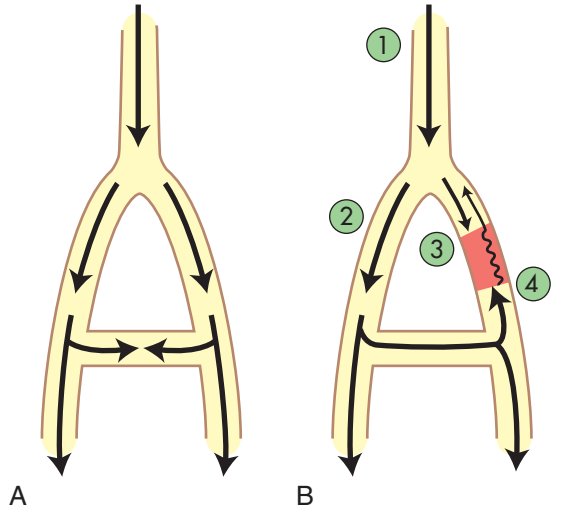

FIGURE 22-14 Reentry in terminal Purkinje fibers. **A,** Conduction through normal Purkinje fibers. The conduction velocity is uniform. **B,** Conduction through a severely depressed segment of terminal Purkinje fibers. The impulse *(1)* travels normally through normal tissue *(2)* and is blocked at the severely depressed tissue *(3)* but returns, with delay, through this tissue from the opposite direction *(4)*.

The reentry mechanism requires that at some point, conduction through the heart must take parallel pathways. Each pathway has different conduction speeds and refractory characteristics. A premature impulse, for example, may find one branch of a conducting pathway still refractory from the passage of the last normal impulse. If this occurs, the impulse may pass (somewhat slowly) along a parallel conducting pathway. By the time the impulse reaches the previously blocked pathway, the blocked pathway may have had time to recover its ability to conduct. If the two parallel paths connect at an area of excitable myocardial tissue, the depolarization process from the slower path may enter the now repolarized tissue. This can give rise to a new impulse spawned from the original impulse. Common causes of delayed or blocked electrical impulses include myocardial ischemia, certain drugs, and hyperkalemia.

SECTION THREE
Electrocardiogram Monitoring

An **electrocardiogram** (ECG) is a graphic representation of the electrical activity of the heart. It is produced by the electrical events in the atria and ventricles and is an important diagnostic tool. This graphic reading can help identify a number of cardiac abnormalities. These include abnormal heart rates and rhythms, abnormal conduction pathways, hypertrophy or atrophy of portions of the heart, and the approximate location of ischemic or infarcted cardiac muscle.

Evaluation of the ECG requires a systematic approach. The paramedic analyzes the electrocardiogram and then relates it to the clinical assessment of the patient. The ECG tracing is only a reflection of the electrical activity of the heart. It does not provide information on mechanical events such as force of contraction or blood pressure.

CRITICAL THINKING
Aside from blood pressure, how do you evaluate the mechanical activity of the heart?

BASIC CONCEPTS OF ELECTROCARDIOGRAM MONITORING

The summation of all the action potentials transmitted through the heart during the cardiac cycle can be measured on the surface of the body. This measurement is obtained by applying electrodes connected to an ECG machine to the patient's skin. The voltage changes are fed to the machine, amplified, and displayed visually on the oscilloscope screen, graphically on ECG paper, or both. The voltage may be positive (seen as an upward deflection on the ECG tracing);

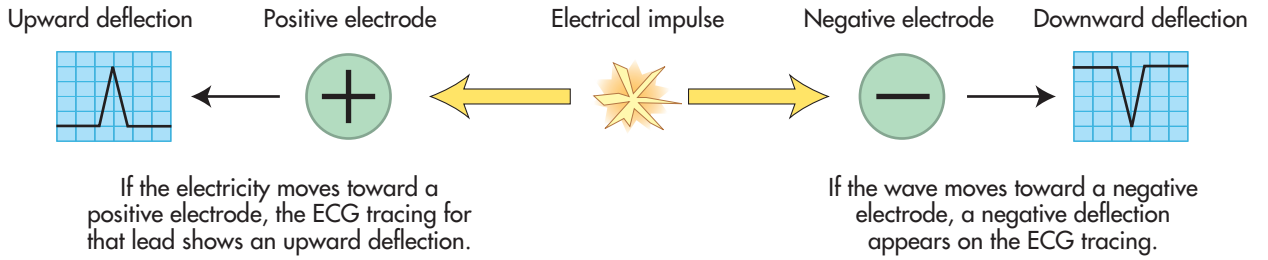

FIGURE 22-15 Rule of electrical flow.

negative (seen as a downward deflection on the ECG tracing); or isoelectric, when no electrical current is detected (seen as a straight baseline on the ECG tracing) (Figure 22-15).

Electrocardiograph Leads

Electrocardiograph machines offer many views of the electrical activity of the heart. They do this by monitoring voltage changes between the electrodes *(leads)* applied to the body. A modern ECG views the electrical activity of the heart from 12 leads: three standard limb leads; three augmented limb leads, and six precordial (chest) leads. The standard limb leads are I, II, III. The augmented limb leads are aV_R, aV_L, and aV_F. The precordial leads are V_1 through V_6. Each lead assesses the electrical activity of the heart from a slightly different view and produces different ECG tracings (Table 22-1).

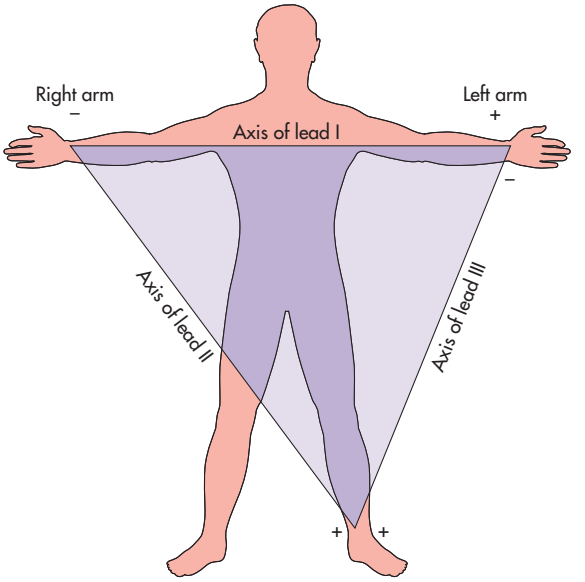

FIGURE 22-16 Leads I, II, and III make up the standard limb leads. An imaginary line joining the positive and negative electrodes of a lead is called the *axis* of the lead. The axes of these three limb leads form an equilateral triangle with the heart at the center (Einthoven's triangle).

NOTE

The various views of electrical activity of the heart provided by the ECG are always from the perspective of the positive electrode. If the net force of electrical activity moves toward the positive electrode, the waveform seen on the ECG is "up." If the net force of electrical activity moves away from the positive electrode, the waveform seen on the ECG is "down."

STANDARD LIMB LEADS

Standard limb leads are **bipolar leads.** That means they use two electrodes of opposite polarity (one pole is positive, the other, negative) to form the lead. Standard limb leads record the difference in electrical potential between the left arm (+), the right arm (–), and the left leg (–) electrodes. Lead I records the difference in electrical potential between the left arm (+) and right arm (–) electrodes. Lead II records the difference in electrical potential between the left leg (+) and right arm (–) electrodes. Lead III records the difference in electrical potential between the left leg (+) and left arm (–) electrodes. Imaginary lines *(axes)* join the positive and negative electrodes of each lead, forming a straight line between the positive and negative poles. These lines form an equilateral triangle with the heart at the center *(Einthoven's triangle)* (Figure 22-16).

The electrodes of the standard bipolar leads are placed on the following areas of the body:

TABLE 22-1 Comparison of Various Leads

Leads	Type	Polarity
I, II, III	Limb leads	Bipolar
aV_R, aV_L, aV_F	Limb leads	Unipolar
V_1-V_6	Chest leads	Unipolar

From Phalen T: *The 12-lead ECG in acute myocardial infarction,* St Louis, 1996, Mosby.

Lead	Positive electrode	Negative electrode
I	Left arm	Right arm
II	Left leg	Right arm
III	Left leg	Left arm

AUGMENTED LIMB LEADS

As do standard limb leads, **augmented limb leads** record the difference in electrical potential. However, unlike the standard limb leads, which are bipolar leads, the augmented

limb leads are **unipolar leads.** This means that they have one electrode for a positive pole, but they have no distinct negative pole. The negative pole of the augmented limb leads is made by combining two of the negative electrodes. (Augmented limb leads use three electrodes to provide their view of the heart.) Augmented limb leads "augment," or magnify, the voltage of the positive lead (which usually is small). This increases the size of the complexes seen on the ECG. Augmented limb leads use the same set of electrodes as the standard limb leads and are placed on the following areas of the body:

Lead	Positive electrode	Negative electrode
aV_L	Left arm	Right arm, left leg
aV_R	Right arm	Left arm, left leg
aV_F	Left leg	Right arm, left arm

The aV_R, aV_L, and aV_F leads intersect at angles different from those of the standard limb leads and produce three other intersecting lines of reference. When these lines of reference are combined with the lines of reference of standard limb leads, they form six lines of reference known as the **hexaxial reference system** (Figure 22-17). The hexaxial reference system is important for advanced ECG interpretation, described later in this chapter.

CRITICAL THINKING

Why is aV_R seldom used in ECG analysis? What view of the heart does it provide?

PRECORDIAL LEADS

The six **precordial leads,** or *chest leads,* are unipolar leads that record the electrical activity of the heart in the horizontal plane. These leads, which are used in 12-lead ECG monitoring, measure the amplitude of the heart's electrical current. The precordial leads are projected through the anterior chest wall (through the AV node) toward the patient's back. The projection of the leads separates the body into upper and lower halves, providing the transverse or horizontal plane (Figure 22-18). The electrodes on the patient's chest are considered positive, but they are considered negative posteriorly (i.e., the patient's chest is positive; the patient's back is negative). The chest leads are numbered V_1 to V_6.

When properly positioned on the chest, the chest leads surround the heart from the right to left side (Figure 22-19). Leads V_1 and V_2 are positioned over the right side of the heart and look at the septum; V_5 and V_6 over the left side of the heart and look at the lateral wall of the

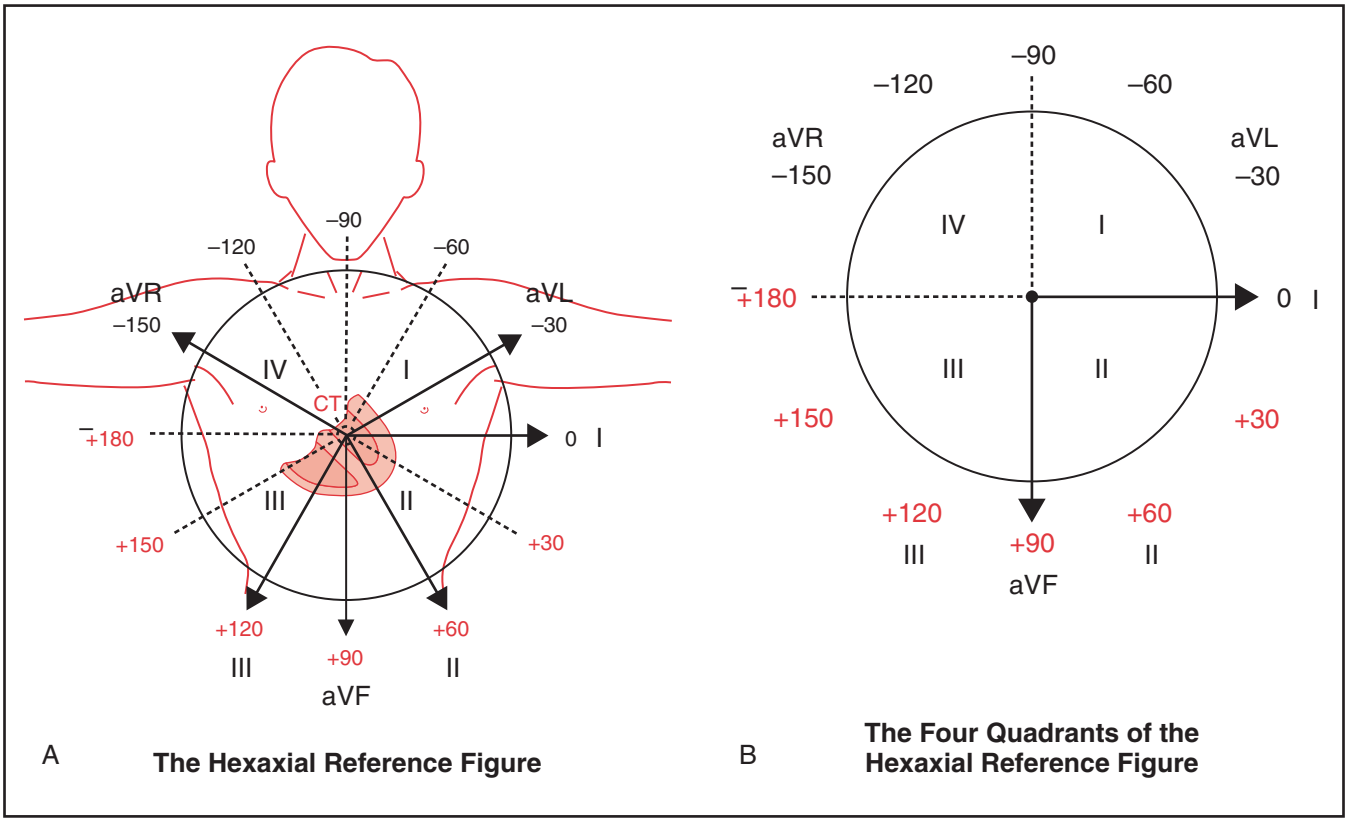

FIGURE 22-17 **A,** The hexaxial reference figure. **B,** The four quadrants of the hexaxial reference figure. (Wesley K: *Huszar's basic dysrhythmias and acute coronary syndromes: interpretation and management,* ed 4, St Louis, 2010, Mosby.)

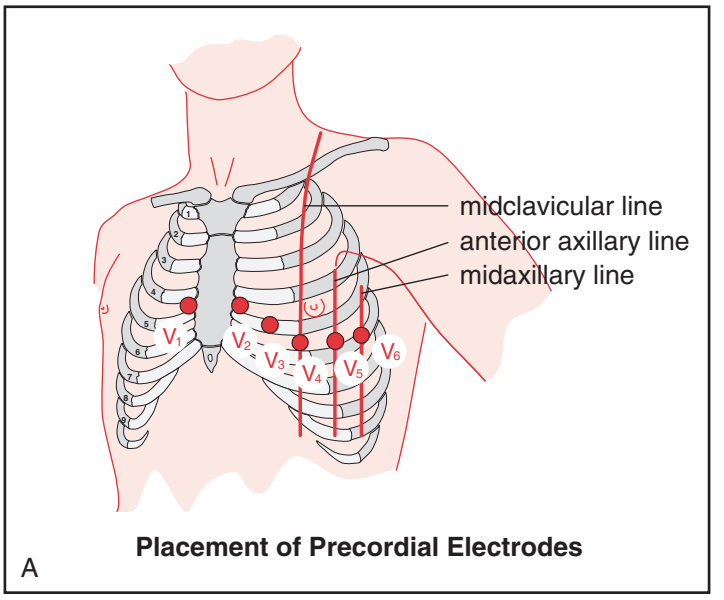

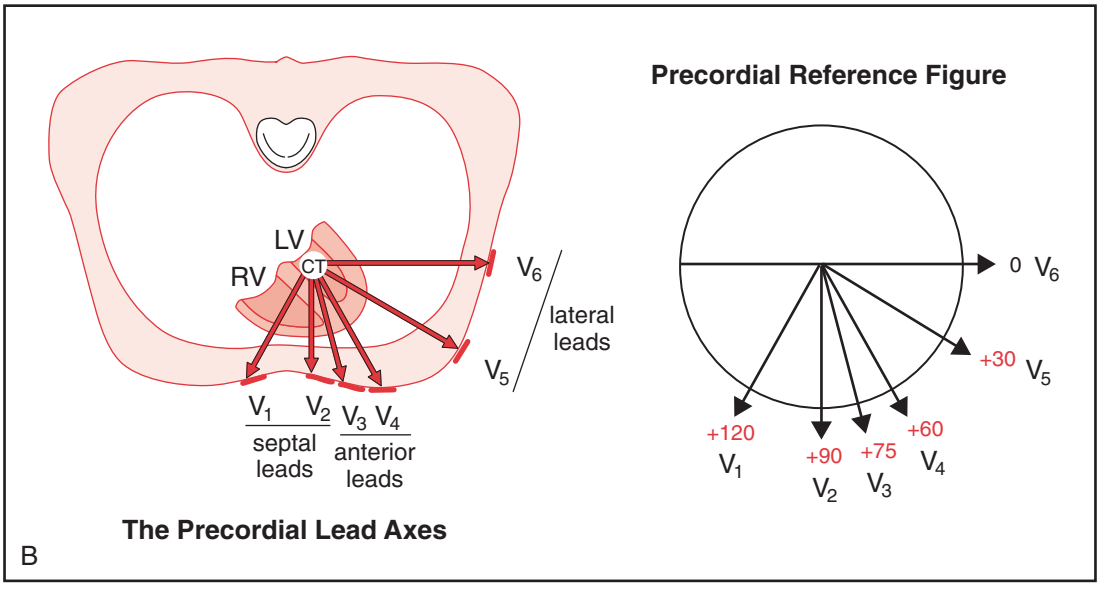

FIGURE 22-18 **A,** Placement of the precordial electrodes. **B,** Precordial lead axes and reference figure. (Wesley K: *Huszar's basic dysrhythmias and acute coronary syndromes: interpretation and management,* ed 4, St Louis, 2010, Mosby.)

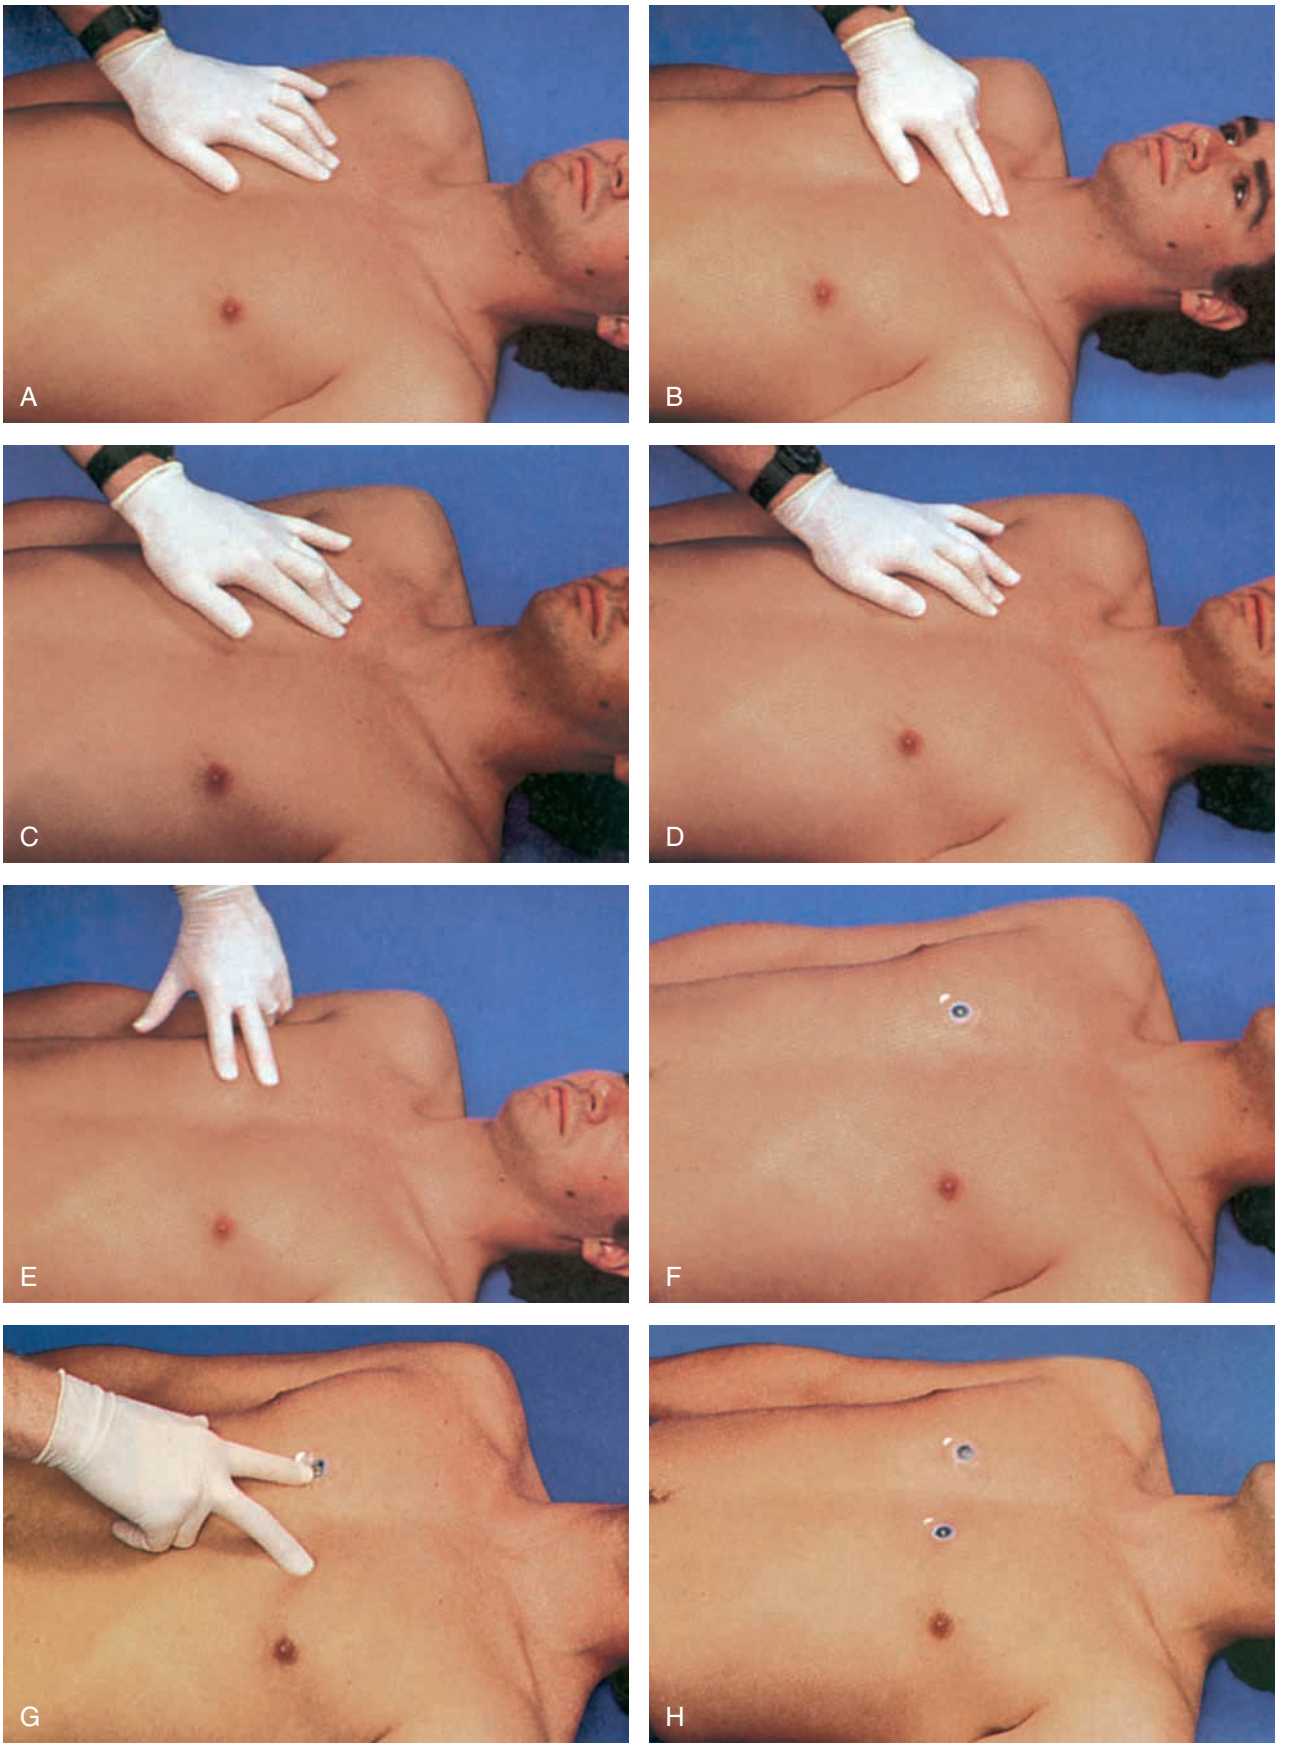
left ventricle; and V_3 and V_4 over the interventricular septum (right and left ventricle, AV bundle, and right and left bundle branches). These leads look at the anterior wall of the left ventricle.

The precordial leads are placed on the chest in reference to the thoracic landmarks. Proper placement of the chest leads at specific intercostal spaces is essential for an accurate reading. The following is one method of locating the appropriate intercostal spaces[4] (Figure 22-19):

1. Locate the jugular notch and move downward until the sternal angle is found.
2. Follow the articulation to the right sternal border to locate the second rib. Just below the second rib is the second intercostal space.
3. Move down two intercostal spaces and position the V_1 electrode in the fourth intercostal space, just to the right of the patient's sternum.
4. Move across the sternum to the corresponding intercostal space and position V_2 to the left of the patient's sternum.
5. From V_2, palpate down one intercostal space and follow the fifth intercostal space to the midclavicular line to place the V_4 electrode.
6. Place lead V_3 midway between V_2 and V_4.
7. Place V_5 in the anterior axillary line in a straight line with V_4 (where the arm joins the chest).
8. Place V_6 in the midaxillary line, level with V_4 and V_5. (It may be more convenient to place V_6 first and then



Continued on next page

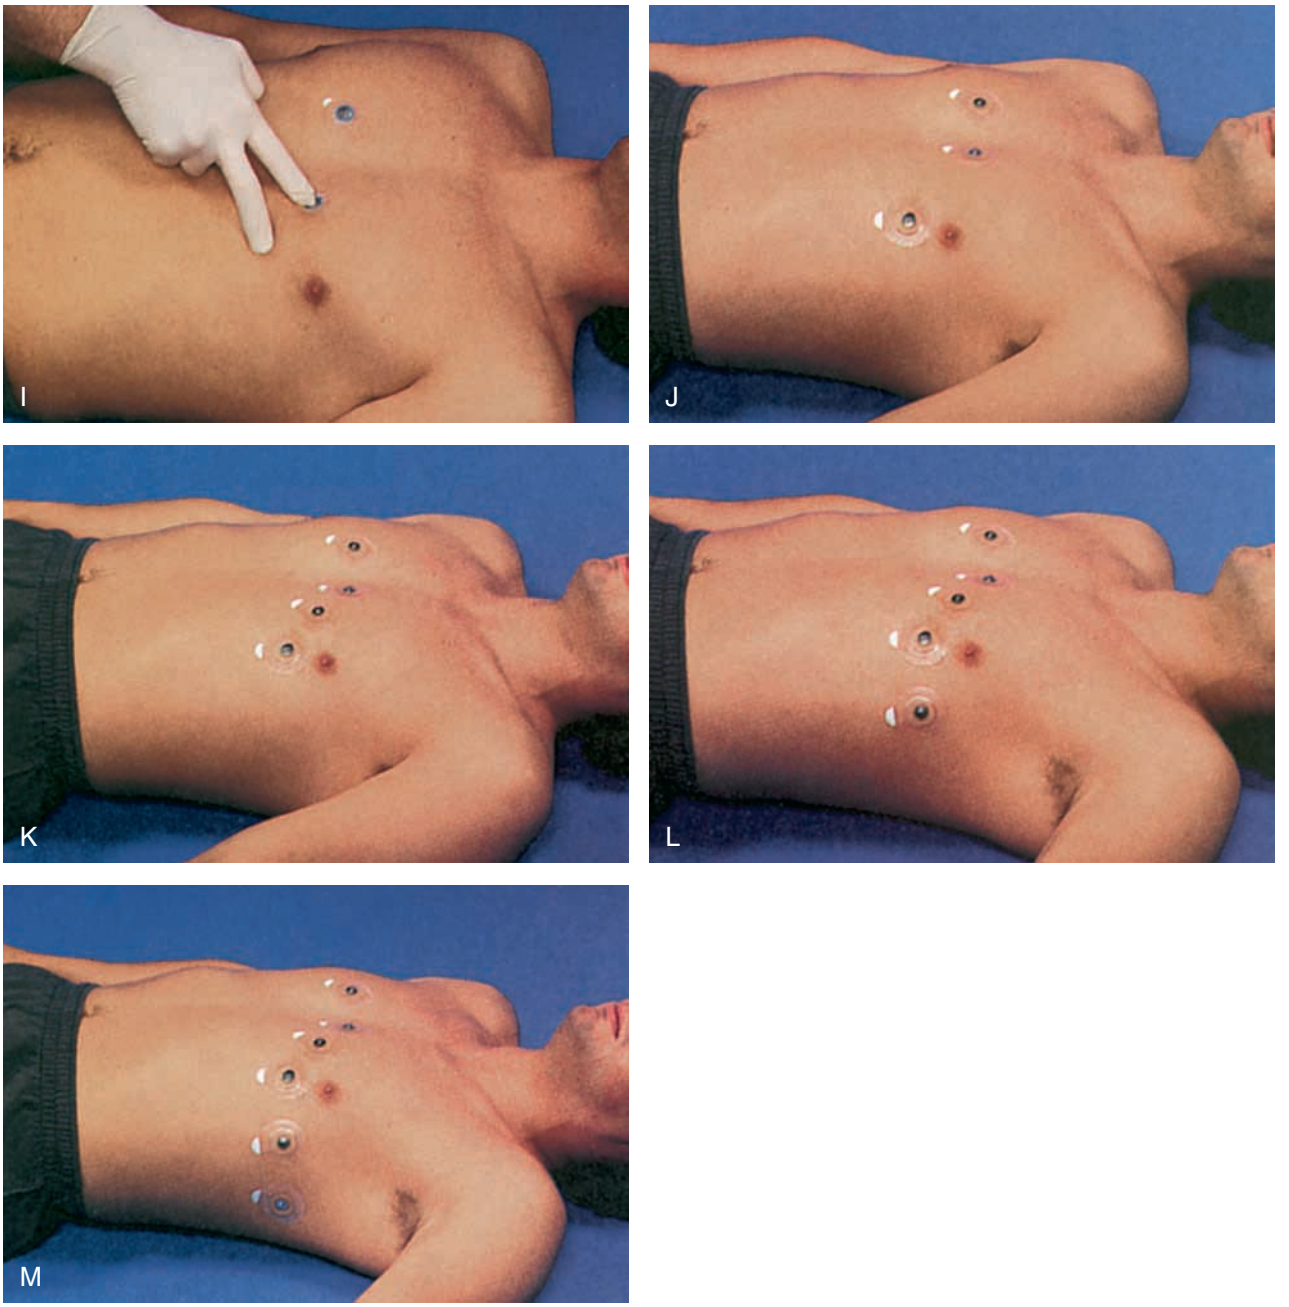


FIGURE 22-19 Proper chest lead placement.
A ■ Locate the jugular notch.
B ■ Palpate for the angle of Louis.
C ■ Follow the angle of Louis to the patient's right until it articulates with the second rib.
D ■ Locate the second intercostal space (immediately below the second rib).
E ■ From the second intercostal space, the third and fourth intercostal spaces can be found.
F ■ Lead V_1 is positioned in the fourth intercostal space just to the right of the sternum.
G ■ From the V_1 position, find the corresponding intercostal space on the left side of the sternum.
H ■ Place the V_2 electrode in the fourth intercostal space just to the left of the sternum.
I ■ From the V_2 position, locate the fifth intercostal space and follow it to the midclavicular line.
J ■ Position the V_4 electrode in the fifth intercostal space in the midclavicular line.
K ■ Lead V_3 is positioned halfway between V_2 and V_4.
L ■ Lead V_5 is positioned in the anterior axillary line, level with V_4.
M ■ Lead V_6 is positioned in the midaxillary line, level with V_4.

V_5.) For women, place the V_4 to V_6 electrodes under the left breast to avoid any errors in the ECG tracing that may occur from breast tissue. Lift the breast away using the back of the hand (Figure 22-19).

CRITICAL THINKING

Consider that your patient is female. You are performing a 12-lead ECG tracing. What measures can you take to reduce her potential discomfort or embarrassment?

DID YOU KNOW?

Modified Lead Recording

Placement of the limb leads can be altered to mimic the precordial leads (V_1 to V_6). These leads are referred to as **modified chest leads** and become MCL_1 to MCL_6. Modified chest leads are useful for monitoring cardiac activity in the prehospital setting when 12-lead machines are not available (e.g., equipment failure, mass disasters). These leads may help distinguish between supraventricular tachycardia and ventricular tachycardia. They also can help detect conduction blocks in the bundle branches (described later in this chapter).

When MCL_1 is viewed, the positive electrode is placed in the V_1 position. (This is the fourth intercostal space, just to the right of the patient's sternum.) The negative electrode is placed anteriorly, just below the lateral end of the left clavicle. Electrical activity in MCL_6 is observed by placing the positive electrode on the left midaxillary line at the level of the fifth intercostal space (as for lead V_6). The negative electrode is placed anteriorly, just below the left shoulder (see Figure 22-20).

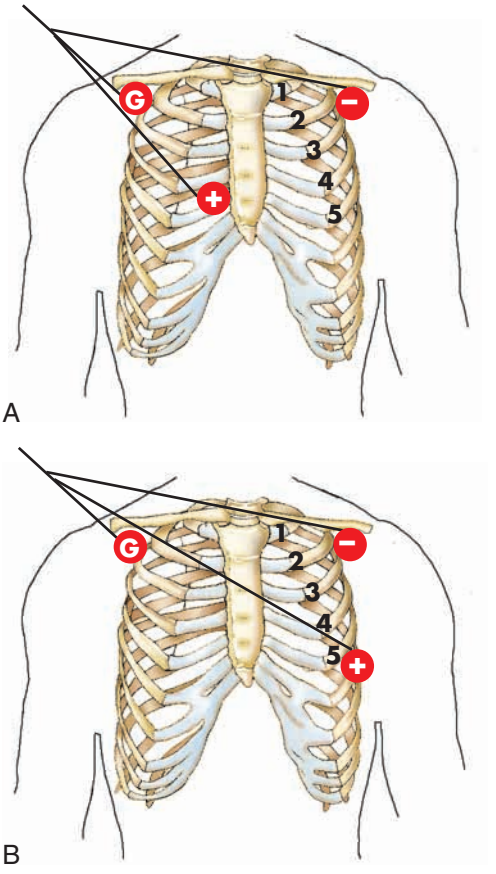

FIGURE 22-20 Monitor lead placement for MCL_1 **(A)** and MCL_6 **(B).** (Goldberger A: *Treatment of cardiac emergencies,* ed 5, St Louis, 1990, Mosby.)

Routine Electrocardiogram Monitoring

Routine monitoring of cardiac rhythm in the prehospital setting, emergency department (ED), or coronary care unit usually is obtained in lead II or MCL_1. These are the best leads to monitor for dysrhythmias because of their ability to display P waves (atrial depolarization) on the ECG tracing. A good deal of information can be gathered from a single monitoring lead, and in many cases cardiac monitoring by a single lead is sufficient. For example, monitoring a single lead can determine how fast the heart is beating and how regular the heartbeat is. The paramedic also can determine how long conduction lasts in different parts of the heart. Single-lead monitoring does have limitations and may fail to reveal various cardiac abnormalities. In most EMS systems that provide advanced life support, the 12-lead ECG is the standard for monitoring patients with chest pain of cardiac origin.

CRITICAL THINKING

What effect does improper lead placement have on the view of the heart and the analysis of the ECG tracing?

Application of Monitoring Electrodes

The most commonly used electrodes for continuous ECG monitoring are pregelled, stick-on disks. These disks can be applied easily to the chest wall. The paramedic should observe the following guidelines to minimize artifacts in the signal and to make effective contact between the electrode and the skin:

CRITICAL THINKING

Why should alcohol or benzoin not be used under defibrillator pads?

1. Choose an appropriate area of skin, avoiding large muscle masses and large amounts of hair, which may prevent the electrode from lying flat against the skin.
2. Cleanse the area with alcohol to remove dirt and body oil. When attaching electrodes to the extremities, use the inner surfaces of the arms and legs. If necessary, trim excess body hair before placing the electrodes. If the patient is extremely diaphoretic, use tincture of benzoin to help secure application or use diaphoretic electrodes.

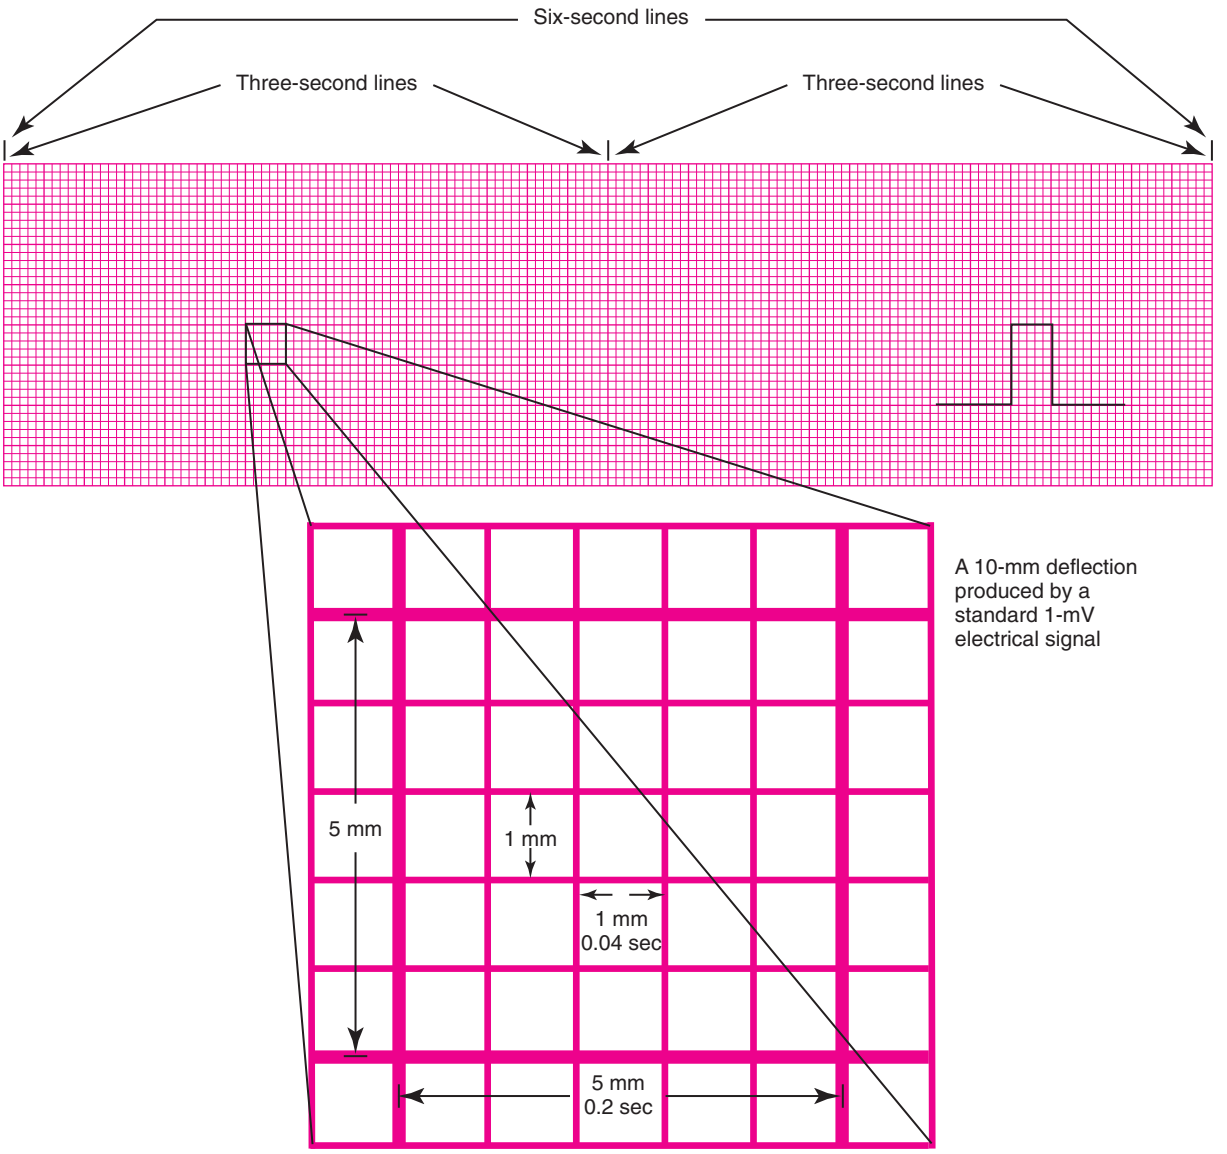

FIGURE 22-21 Electrocardiogram graph paper.

3. Attach the electrodes to the prepared site.
4. Attach the ECG cables to the electrodes. Most cables are marked for right arm, left arm, and left leg application.
5. Turn on the ECG monitor and obtain a baseline tracing.

If the signal is poor, the paramedic should recheck the cable connections and the effectiveness of the patient's skin contact with the electrodes. Other common causes of a poor signal include body hair, dried conductive gel, poor electrode placement, and diaphoresis.

Electrocardiogram Graph Paper

The paper used in recording electrocardiograms is standardized to allow comparative analysis of an ECG wave. The graph paper is divided into squares 1 mm in height and width. The paper is divided further by darker lines every fifth square vertically and horizontally. Each large square is 5 mm high and 5 mm wide (Figure 22-21).

As the graph paper moves past the needle or pen of the ECG machine, it measures time and amplitude. Time is measured on the horizontal plane (side to side). When the ECG is recorded at the standard paper speed of 25 mm/second, each small square is equal to 1 mm (0.04 second) and each large square (the dark vertical lines) is equal to 5 mm (0.20 second). These squares measure the time it takes an electrical impulse to pass through a specific part of the heart.

Amplitude is measured on the vertical axis (top to bottom) of the graph paper. Each small square of the graph paper is equal to 0.1 mV. Each large square (five small squares) is equal to 0.5 mV. The sensitivity of the 12-lead ECG machine is standardized. When properly calibrated, a 1 mV electrical signal produces a 10 mm deflection (two

large squares) on the ECG tracing. ECG machines equipped with calibration buttons should have a calibration curve placed at the beginning of the first tracing (generally a 1 mV burst, represented by a 10 mm "block" wave).

Time-interval markings are denoted by short vertical lines and usually are located on the top of the ECG graph paper. When the ECG is recorded at the standard paper speed of 25 mm/second, the distance between each short vertical line is 75 mm (3 seconds). Each 3-second interval contains 15 large squares (0.2 second multiplied by 15 squares equals 3 seconds). These markings are used as a method of heart rate calculation (i.e., counting the number of QRS complexes in 6 seconds and multiplying by 10).

RELATIONSHIP OF THE ELECTROCARDIOGRAM TO ELECTRICAL ACTIVITY

Each waveform seen on the oscilloscope or recorded on the ECG graph paper represents the conduction of an electrical impulse through a certain part of the heart. All waveforms begin and end at the isoelectric line. This line represents the absence of electrical activity in cardiac tissue. A deflection above the baseline is positive. It indicates an electrical flow toward the positive electrode. A deflection below the baseline is negative. It indicates an electrical flow away from the positive electrode.

The normal electrocardiogram consists of a P wave, QRS complex, and T wave. A U wave sometimes may be seen after the T wave. The **U wave** is thought to represent repolarization of the Purkinje fibers. It may also be associated with electrolyte abnormalities. If present, the U wave usually is a positive deflection. Other key parts of the ECG that should be evaluated include the P-R interval, ST segment, and Q-T interval. The combination of these waves represents a single heartbeat, or one complete cardiac cycle (Figure 22-22). The electrical events of the cardiac cycle are followed by their mechanical counterparts. The descriptions of ECG waveform components refer to those that would be seen in lead II monitoring (Box 22-3).

NOTE

A *segment* on an ECG is the region between two waves. For example, the PR segment begins at the end of the P wave and ends at the onset of the QRS complex (see Figure 22-23). An *interval* on an ECG includes one segment and one or more waves. For example, the P-R interval starts at the beginning of the P wave and ends at the onset of the QRS complex (see Figure 22-24).

P Wave

The **P wave** is the first positive (upward) deflection on the ECG. It represents atrial depolarization. It usually is rounded and precedes the QRS complex. The P wave begins with the first positive deflection from the baseline and ends at the point where the wave returns to the baseline. The duration of the P wave normally is 0.10 second or less, and its amplitude is 0.5 to 2.5 mm. The P wave usually is followed by a QRS complex. However, if conduction disturbances are present, a QRS complex does not always follow each P wave.

BOX 22-3 ECG Waves and Mechanical Counterparts

P wave: Atrial depolarization
QRS complex: Ventricular depolarization
T wave: Ventricular repolarization

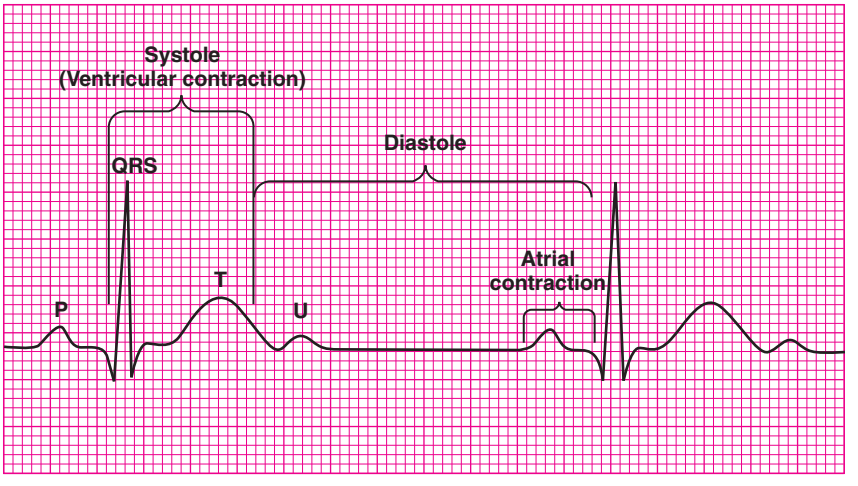

FIGURE 22-22 Summary of the electrical basis of the electrocardiogram.

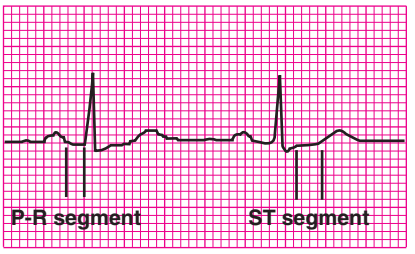

FIGURE 22-23 P-R segment and ST segment.

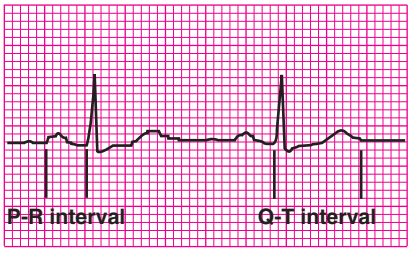

FIGURE 22-24 P-R interval and Q-T interval.

P-R Interval

The **P-R interval** is the time required for an electrical impulse to be conducted through the atria and the AV node up to the instant of ventricular depolarization. The P-R interval is measured from the beginning of the P wave to the beginning of the next deflection on the baseline (the onset of the QRS complex). The normal P-R interval is 0.12 to 0.20 second (three to five small squares on the graph paper). The P-R interval depends on the heart rate and the conduction characteristics of the AV node. When the heart rate is fast, the P-R interval normally is shorter than when the heart rate is slow. A normal P-R interval indicates that the electrical impulse has been conducted through the atria, AV node, and bundle of His normally and without delay.

QRS Complex

The **QRS complex** generally is composed of three individual waves: the Q, R, and S waves. The QRS complex begins at the point where the first wave of the complex deviates from the baseline. It ends where the last wave of the complex begins to flatten at, above, or below the baseline. The direction of the Q wave may be predominantly positive (upright), predominantly negative (inverted), or biphasic (partly positive, partly negative). A normal QRS complex is narrow and sharply pointed (when conduction is normal). Its duration generally is 0.08 to 0.10 second (two to two-and-a-half small squares on the graph paper) or less, and its amplitude normally varies from less than 5 mm to more than 15 mm.

The Q wave is the first negative (downward) deflection of the QRS complex on the ECG. However, it may not be present in all leads. The Q wave represents depolarization of the interventricular septum or a pathological change. The R wave is the first positive deflection after the P wave. Subsequent positive deflections in the QRS complex that extend above the baseline and that are taller than the first R wave are called *R prime (R′), R double prime (R″)*, and so on. The S wave is the negative deflection that follows the R wave. Subsequent negative deflections are called *S prime (S′), S double prime (S″)*, and so on. Although only one Q wave may be seen in the QRS complex, more than one R wave and more than one S wave may be present. The R and S waves represent the sum of electrical forces resulting from depolarization of the right and left ventricles (Figure 22-25).

CRITICAL THINKING

What is the importance of a QRS complex duration of 0.12 second?

The QRS complex follows the P wave. The QRS complex marks the approximate beginning of mechanical contraction of the ventricles, which continues through the onset of the T wave. The QRS complex represents ventricular depolarization. This includes the conduction of an electrical impulse from the AV node through the bundle of His, Purkinje fibers, and the right and left bundle branches. This impulse results in ventricular depolarization.

ST Segment

The **ST segment** represents the early phase of repolarization of the right and left ventricles. It immediately follows the QRS complex and ends with the onset of the T wave. The point at which it takes off from the QRS complex is called the *J point*. In a normal ECG, the ST segment begins at baseline and has a slight upward slope.

The position of the ST segment commonly is judged as normal or abnormal using the baseline of the P-R or T-P interval as a reference. Deviations above this baseline are referred to as *ST segment elevation*. Deviations below baseline are referred to as *ST segment depression* (Figure 22-26). Certain conditions can cause depression or elevation of the P-R interval, affecting the reference for ST segment abnormalities. Usually the baseline from the end of the T wave to the beginning of the P wave maintains its isoelectric position and can be used as a reference. Abnormal ST segments may be seen in infarction, ischemia, and pericarditis; after digitalis administration; and in other disease states.

T Wave

The **T wave** represents repolarization of the ventricular myocardial cells. The wave occurs during the last part of ventricular contraction. The T wave is identified as the first deviation from the ST segment and ends where the T wave returns to the baseline (Figure 22-27). This wave may be above or below the isoelectric line. The T wave usually is slightly rounded and slightly asymmetrical. Deep and symmetrically inverted T waves may indicate cardiac ischemia.

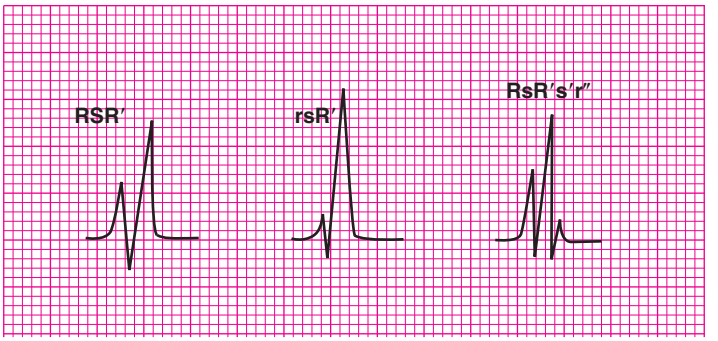

FIGURE 22-25 QRS complexes with more than one positive or negative deflection.

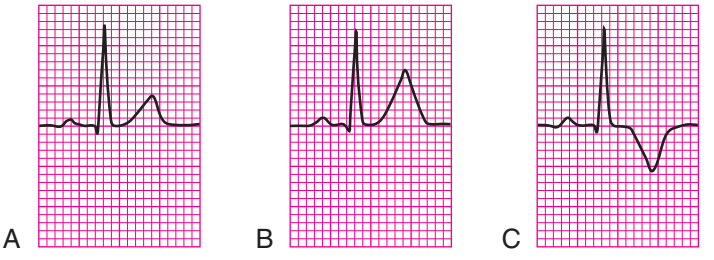

FIGURE 22-27 T waves. (Modified from Wesley K: *Huszar's basic dysrhythmias and acute coronary syndromes,* ed 4, St Louis, 2010, Mosby.)

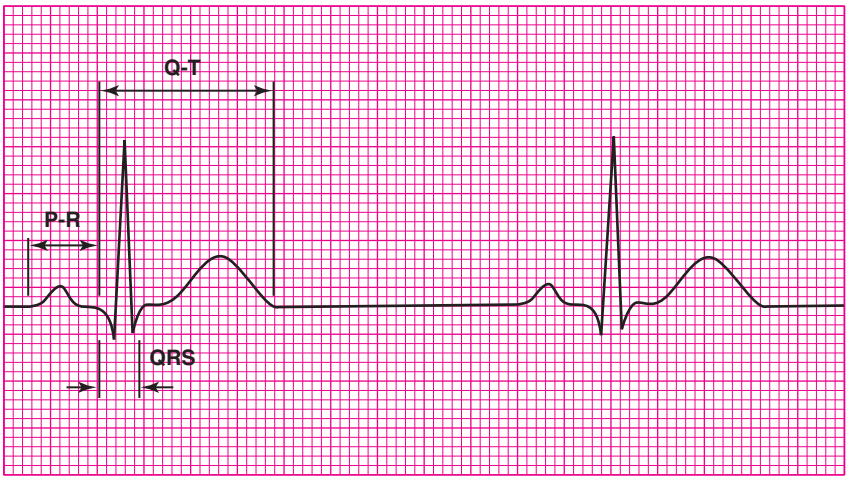

FIGURE 22-28 P-R, Q-T, and QRS intervals.

A T wave elevated more than half the height of the QRS complex *(peaked T wave)* may indicate new onset of ischemia of the myocardium or hyperkalemia.

Q-T Interval

The **Q-T interval** is measured from the beginning of the QRS complex to the end of the T wave (Figure 22-28). It represents the time from the beginning of ventricular depolarization until the end of ventricular repolarization. During the initial phase of the Q-T interval, the heart is completely unable to respond to electrical stimuli. (This is the absolute refractory period described earlier.) During the latter portion of this interval (from the peak of the T wave onward), the heart may be able to respond to premature stimuli (the relative refractory period). During this period, premature impulses may depolarize the heart. Commonly prescribed medications that may prolong the Q-T interval include quinidine, ***procainamide, amiodarone,*** and disopyramide. These antidysrhythmics, by virtue of their effect on the Q-T interval, may lead to potentially lethal dysrhythmias, including ventricular tachycardia, ventricular fibrillation, and an unusual bidirectional ventricular dysrhythmia called *torsades de pointes* (described later in this chapter).

NOTE
The duration of the Q-T interval depends on the heart rate. This interval usually is somewhat less than half of the preceding R-R interval. In general, a Q-T interval less than half the R-R interval is normal; one that is greater than half is abnormal; and one that is about half is considered borderline. Regardless of the heart rate, a Q-T interval greater than 0.45 second is considered abnormal.[5]

ARTIFACTS

Artifacts are marks on the ECG display or tracing caused by activities other than the electrical activity of the heart (Figure 22-29). Common causes of artifacts are improper grounding of the ECG machine, patient movement, loss of electrode contact with the patient's skin, patient shivering or tremors, and external chest compression. Two types of artifacts deserve special mention. One is alternating current interference *(60-cycle interference)*. The other one is *biotelemetry-related interference*.

Alternating current interference may occur in a poorly grounded ECG machine. Interference also may occur when an ECG is obtained near high-tension wires, transformers, and some household appliances. This results in a thick baseline made up of 60-cycle waves. The P waves may not be discernible because of the interference, but the QRS complex usually is visible. Alternating current interference also may result if the patient or the lead cable touches a metal object, such as a bed rail. Placing a blanket between the metal object and the patient may correct the interference.

Biotelemetry-related interference may occur when biotelemetry ECG signals are poorly received. This may result from weak batteries or from ECG transmission in areas with poor signaling conditions. Interference also may result if the transmitter is located a distance away from a base station receiver. Biotelemetry-related interference may produce sharp spikes and waves with a jagged appearance.

SECTION FOUR
Electrocardiogram Interpretation

STEPS IN RHYTHM ANALYSIS

Evaluation of an ECG requires a systematic approach to analyzing a given rhythm. Numerous methods can be used for rhythm interpretation. This text uses a method that first looks at the QRS complex (the most important observation in life-threatening dysrhythmias); then the P waves and the relationship between the P waves and the QRS complex; the rate; the rhythm; and finally the P-R interval. Regardless of

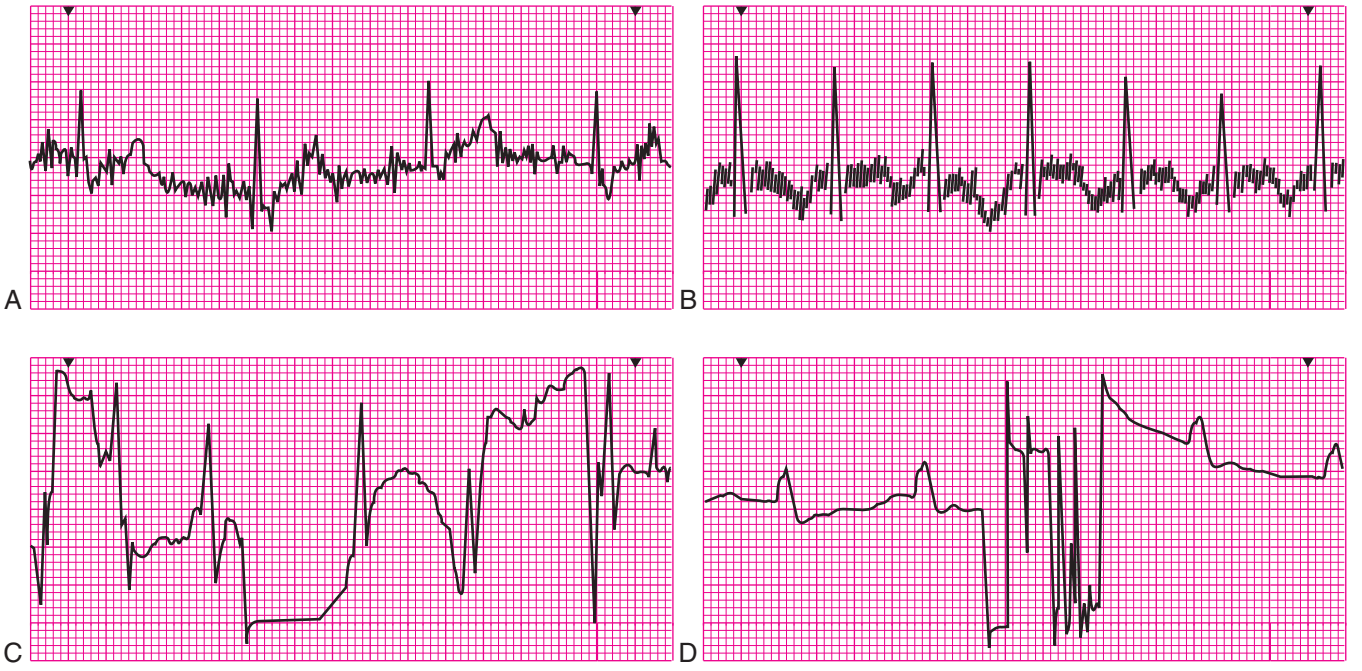

FIGURE 22-29 Artifacts. **A,** Muscle tremors. **B,** Alternating current (60 cycle) interference. **C,** Loose electrodes. **D,** Biotelemetry.

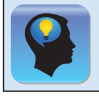
the method chosen to analyze a given rhythm, the paramedic should use a consistent format. This section of the text discusses rhythm interpretation as it pertains to standard three-lead ECG monitoring. Evaluation of 12-lead ECG monitoring is presented later in this chapter.

Five questions the paramedic must ask in any rhythm analysis to detect the presence of or potential for life-threatening rhythm disturbances are as follows:

1. Is the patient sick?
2. What is the heart rate?
3. Are there normal-looking QRS complexes?
4. Are there normal-looking P waves?
5. What is the relationship between the P waves and the QRS complexes?



CRITICAL THINKING
What does the ECG tell you about perfusion?

Step 1: Analyze the QRS Complex

The paramedic should analyze the QRS complex for regularity and width. QRS complexes less than or equal to 0.10 second wide (less than three small squares) are supraventricular in origin. These complexes are normal. Complexes equal to or greater than 0.12 second wide may indicate a conduction abnormality in the ventricles. They also may indicate that the focus originates in the ventricles and is abnormal (Figure 22-30). When evaluating an abnormal QRS width, the paramedic should identify the lead with the widest QRS complex, because a portion of the QRS complex may be hidden or difficult to see in some leads.

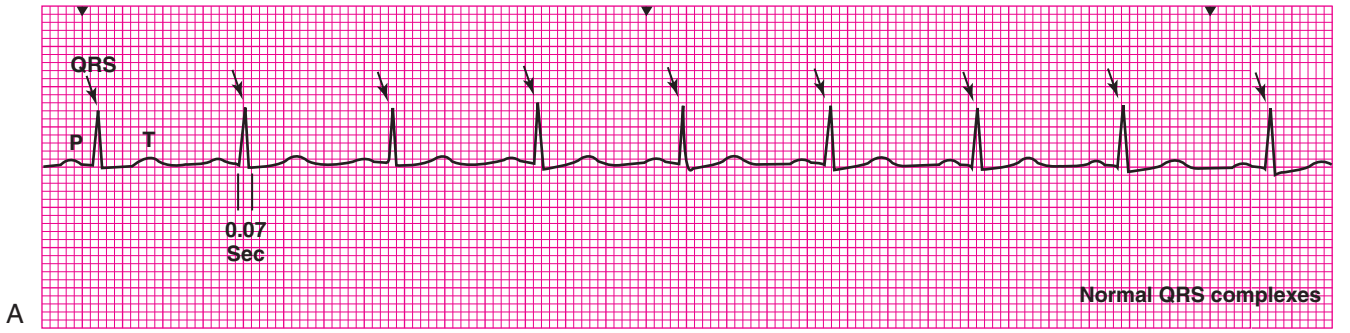
Step 2: Analyze the P Waves

The normal P wave in lead II is positive. It is smoothly rounded and usually precedes each QRS complex, indicating that the pacemaker originates in the SA node (Figure 22-31). Therefore, the paramedic should observe the following five components when evaluating P waves:

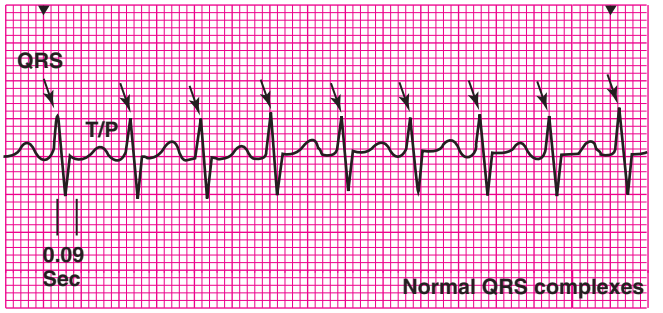
1. Are P waves present?
2. Are the P waves occurring at regular intervals?
3. Is there one P wave for each QRS complex, and is there a QRS complex after each P wave?
4. Are the P waves upright or inverted?
5. Do they all look alike? (P waves that look alike and are regular are likely from the same pacemaker.)

Step 3: Analyze the Rate

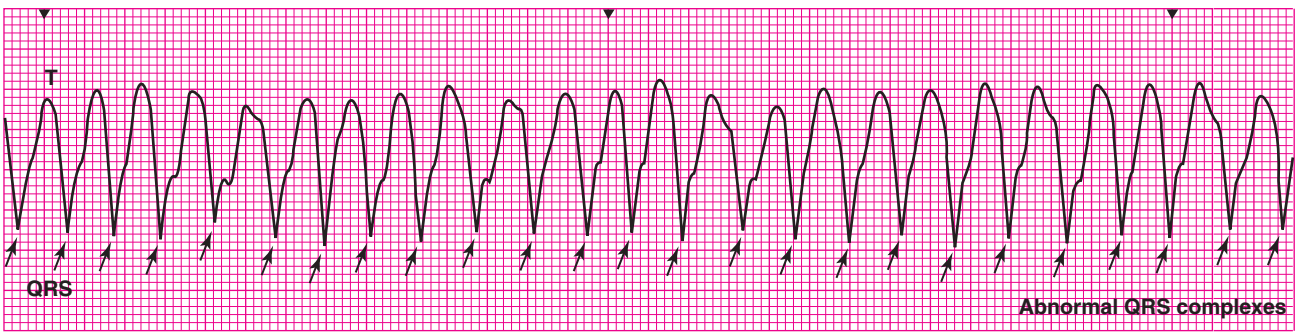
The heart rate can be analyzed in a number of ways. The methods for calculating the heart rate presented in this text are heart rate calculator rulers, the triplicate method, the R-R method, and the 6-second count method. The heart rate is determined by analyzing the ventricular rate (the QRS complex). The normal adult heart rate is 60 to 99 beats/minute. A ventricular rate less than 60 beats/minute is considered **bradycardia;** a rate equal to or greater than 100 beats/minute is considered **tachycardia.**



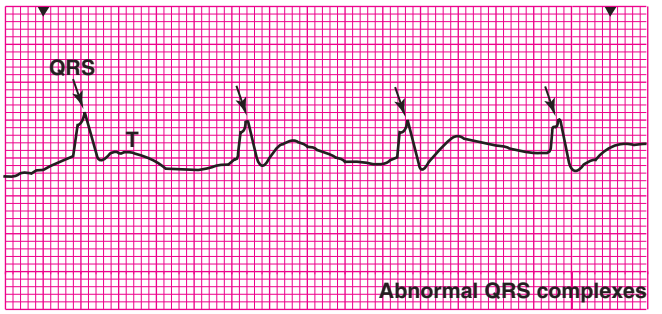
A



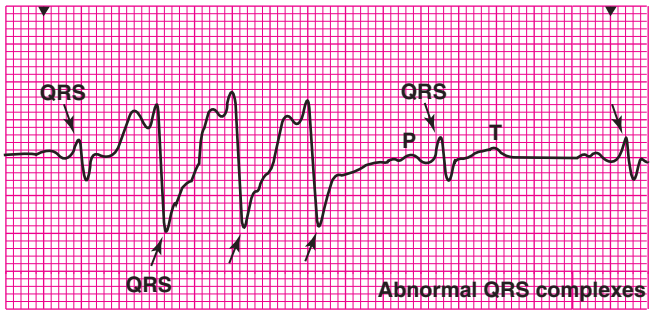
B



C



D



E

FIGURE 22-30 **A** and **B,** Normal QRS complexes. **C** to **E,** Abnormal QRS complexes.

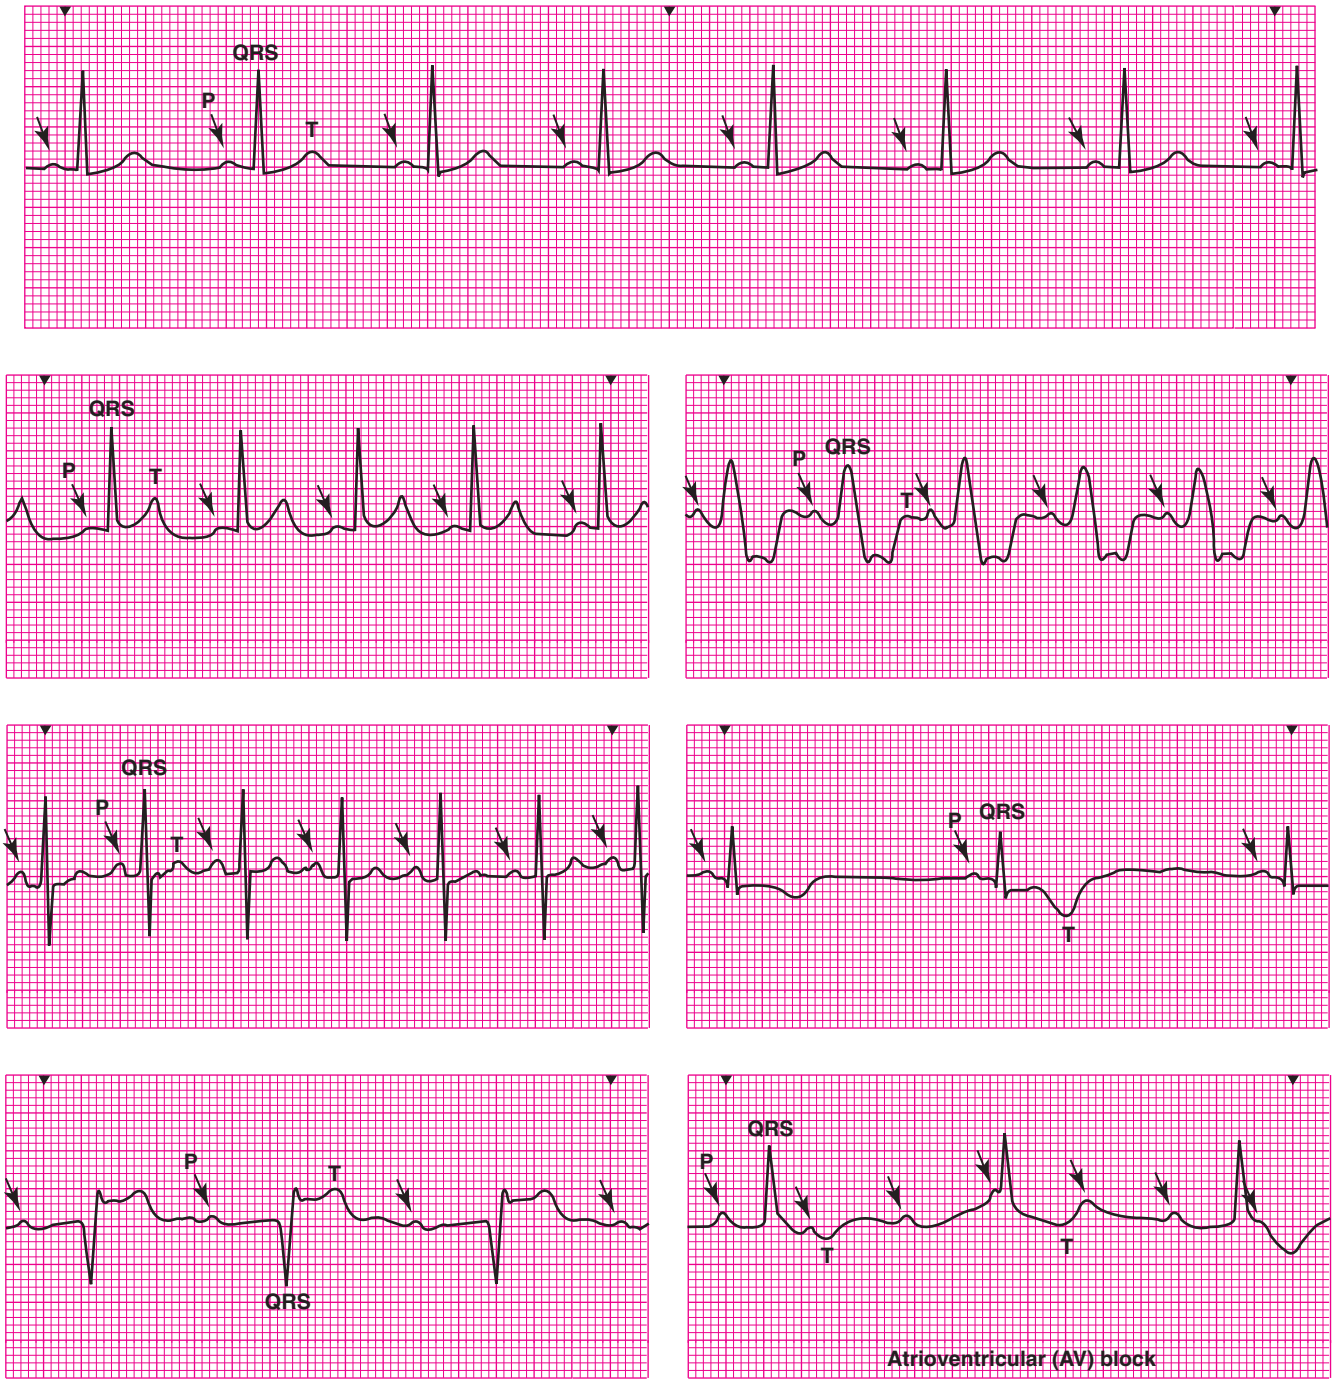


FIGURE 22-31 Normal P waves.

NOTE

In patients with healthy hearts, the atrial and ventricular rates are the same. This is because of the near simultaneous depolarization of the four chambers. If the atrial and ventricular rates are different (as may occur in certain dysrhythmias), the rates should be calculated separately.

HEART RATE CALCULATOR RULERS

Heart rate calculator rulers (Figure 22-32) are available from a number of manufacturers. The paramedic should follow the directions that come with the ruler. Heart rate calculator rulers are reasonably accurate if the rhythm is regular. However, the paramedic should not rely solely on a mechanical device or tool to determine the heart rate. Sometimes, a device or tool is not readily available.

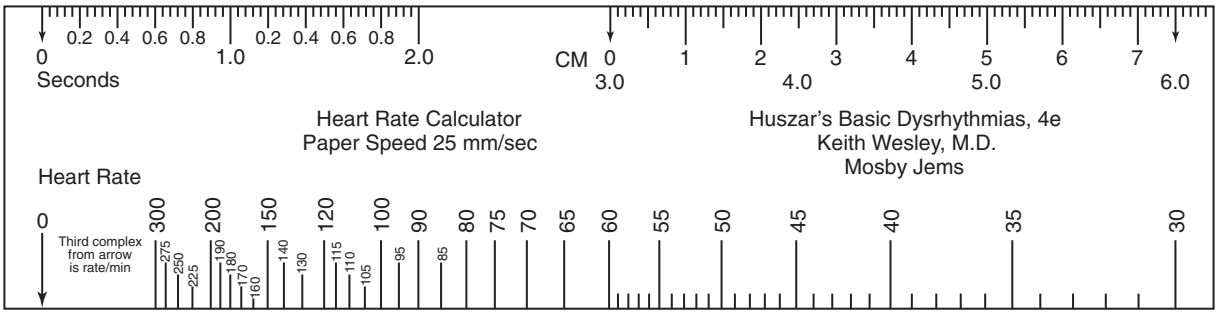

FIGURE 22-32 Heart rate calculator ruler.

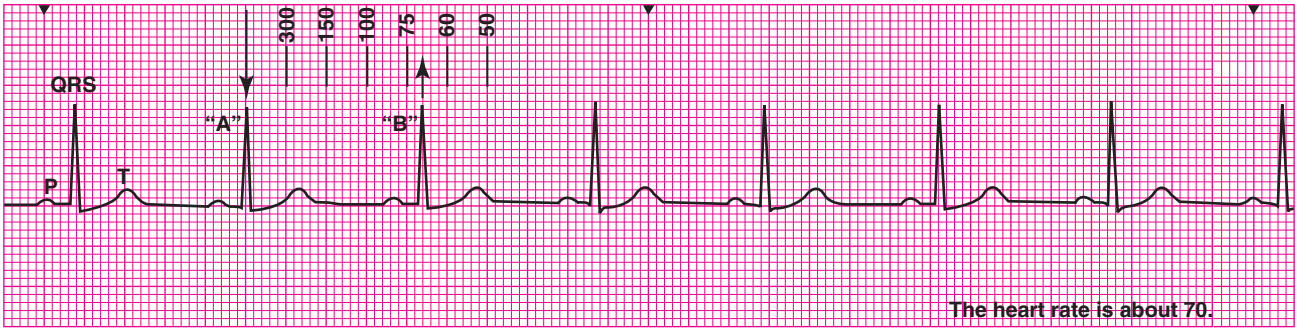

FIGURE 22-33 Triplicate method.

TRIPLICATE METHOD

The triplicate method of determining the heart rate (Figure 22-33) is accurate only under two circumstances: when the rhythm is regular and the heart rate is greater than 50 beats/minute. To use this method, the paramedic must memorize two sets of numbers: 300-150-100 and 75-60-50. These numbers are derived from the distance between the heavy black lines (each representing $\frac{1}{300}$ of a minute). Therefore, two $\frac{1}{300}$ minute units are equal to $\frac{2}{300}$ minute, which is equal to $\frac{1}{150}$ minute, or a heart rate of 150 beats/minute; three $\frac{1}{300}$ minute units are equal to $\frac{3}{300}$ minute, which is equal to $\frac{1}{100}$ minute, or a heart rate of 100 beats/minute. Using these triplicates, the paramedic can calculate heart rate as follows:

1. Select an R wave that lines up with a dark vertical line.
2. Number the next six dark vertical lines consecutively from left to right as 300-150-100 and 75-60-50.
3. Identify where the next R wave falls with reference to the six dark vertical lines. If the R wave falls on 75, the heart rate is 75 beats/minute. If the R wave falls halfway between 100 and 150, the heart rate is about 125 beats/minute.

R-R METHOD

The R-R method may be used several different ways to calculate the heart rate. As with the triplicate method, the rhythm must be regular to obtain an accurate reading. However, the R-R method works equally well for slow rates. The three methods are as follows:

Method 1. Measure the distance in seconds between the peaks of two consecutive R waves. Then divide this number into 60 to obtain the heart rate (Figure 22-34).

Method 2. Count the large squares between the peaks of two consecutive R waves. Divide this number into 300 to obtain the heart rate (Figure 22-35).

Method 3. Count the small squares between the peaks of two consecutive R waves. Divide this number into 1500 to obtain the heart rate (Figure 22-36).

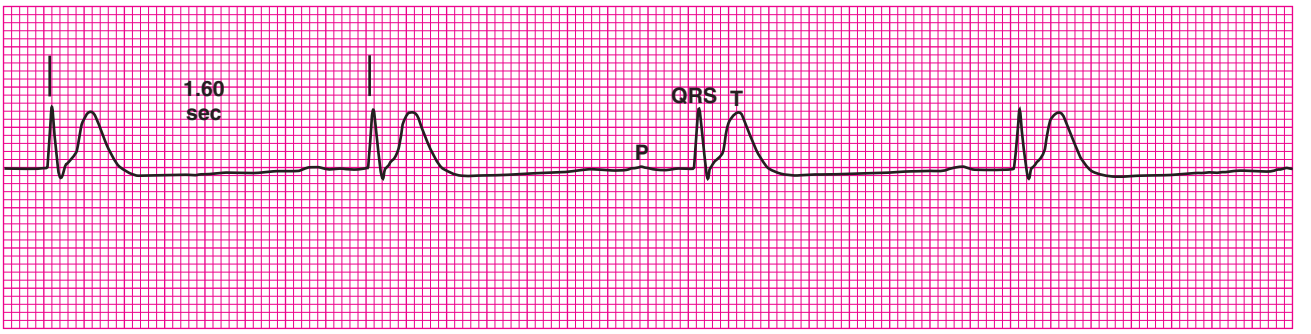
SIX-SECOND COUNT METHOD

The 6-second count method (Figure 22-37) is the least accurate method of determining the heart rate. However, it is useful for quickly obtaining an approximate rate in regular and irregular rhythms.

As previously stated, the short vertical lines at the top of most ECG graph paper are divided into 3-second intervals when run at a standard speed of 25 mm/second. Two of these intervals are equal to 6 seconds. The heart rate is calculated by counting the number of QRS complexes in a 6-second interval. This number is multiplied by 10.

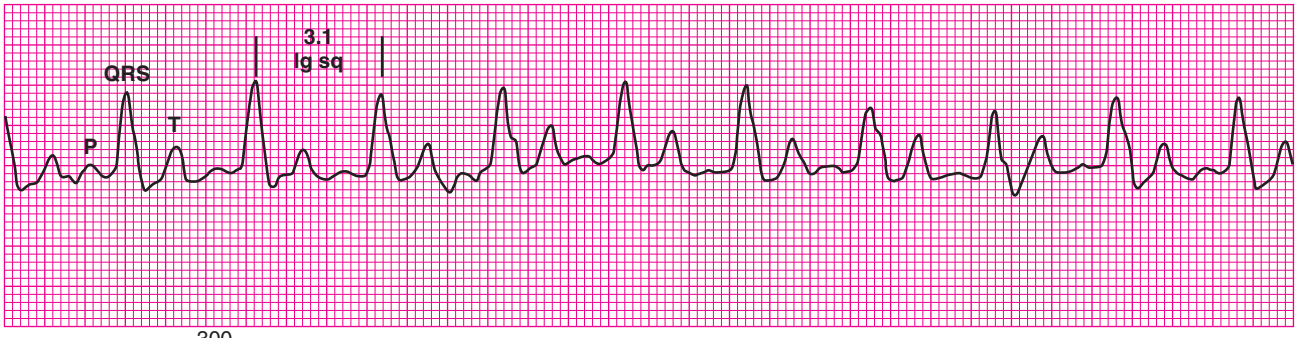
CRITICAL THINKING

Which of these rate calculation methods is fastest? Which is most accurate?



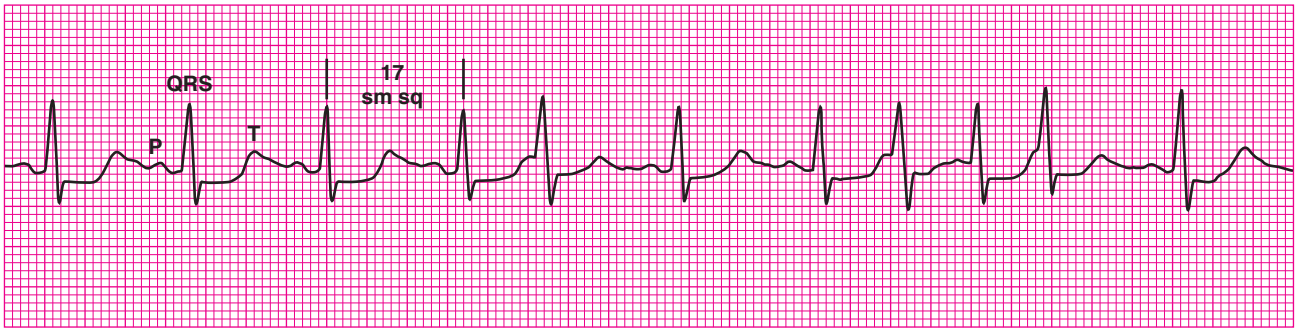
The heart rate $= \frac{60}{1.60 \text{ sec}} = 37.5$ or, rounded off, 38.

FIGURE 22-34 R-R interval, method 1.



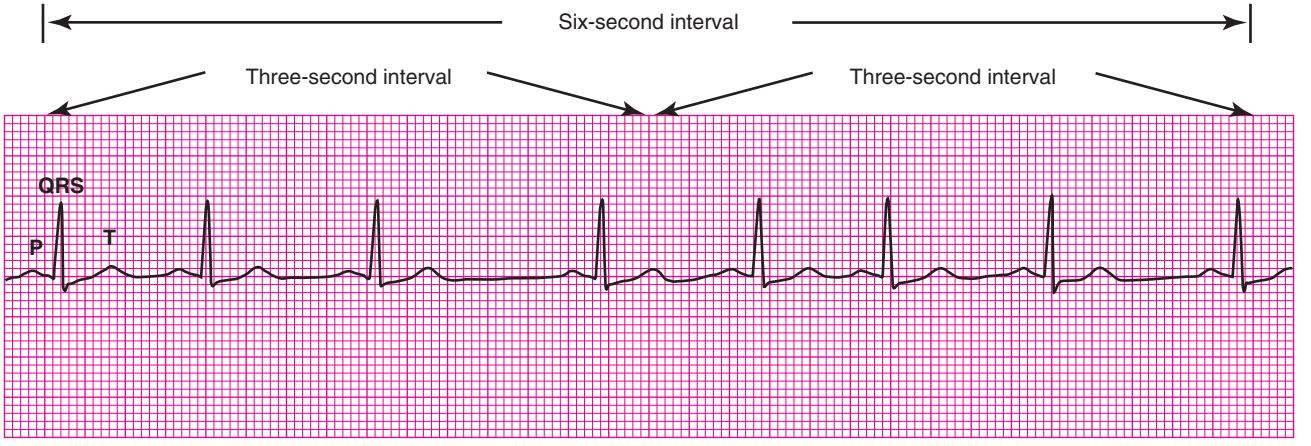
The heart rate $= \frac{300}{3.1 \text{ lg sq}} = 97.$

FIGURE 22-35 R-R interval, method 2.



The heart rate $= \frac{1{,}500}{17 \text{ sm sq}} = 88.$

FIGURE 22-36 R-R interval, method 3.



The heart rate is about 80. (Actual heart rate is 72.)

FIGURE 22-37 Six-second count method.

Step 4: Analyze the Rhythm

To analyze the ventricular rhythm, the paramedic should compare the R-R intervals on the ECG tracing in a systematic way from left to right. This measurement may be taken using ECG calipers or pen and paper. Using calipers, the paramedic should place one tip of the caliper on the peak of one R wave and adjust the other tip so that it rests on the peak of the adjacent R wave. The paramedic then uses the caliper to map the distance of the R-R interval to evaluate evenness and regularity. (P waves may be mapped for regularity in this same way.)

In the absence of calipers, the paramedic may use a similar method of evaluating the R-R interval by using pen and paper. The paramedic places the straight edge of the paper near the peaks of the R waves and marks off the distance between the two other consecutive R waves. The paramedic then compares this R-R interval with the other R-R intervals in the ECG tracing (Figure 22-38).

If the distances between the R waves are equal or vary by less than 0.16 second (four small squares), the rhythm is

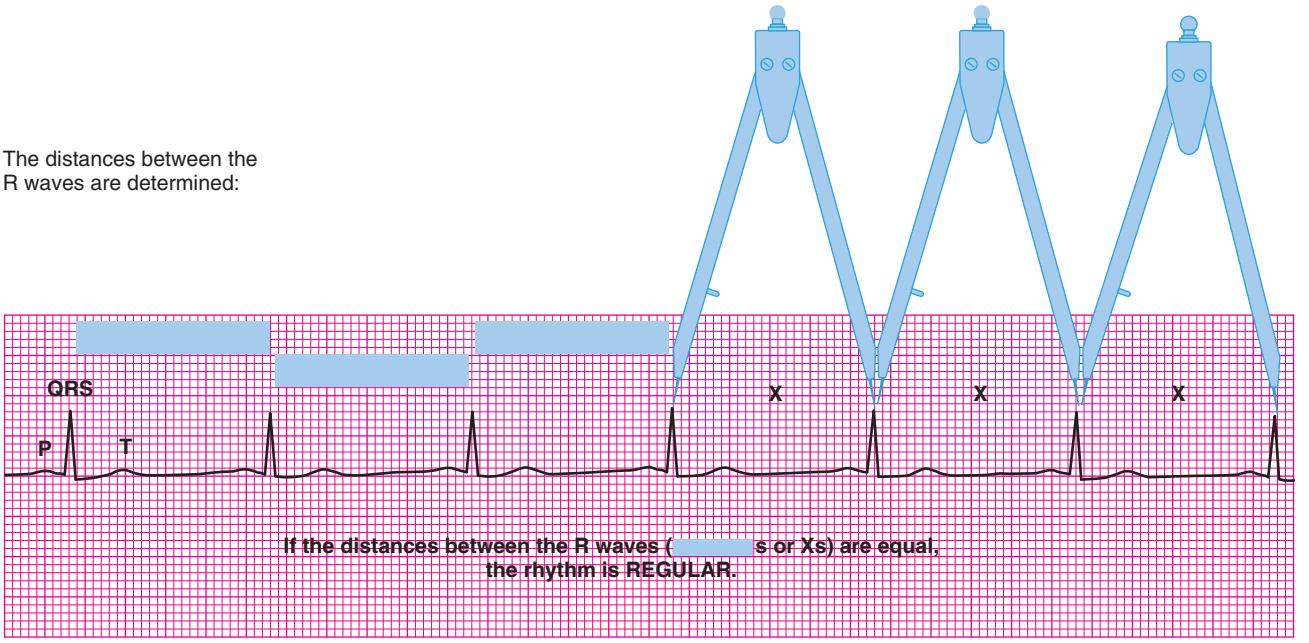


FIGURE 22-38 Determining the rhythm.

regular. If the shortest and longest R-R intervals vary by more than 0.16 second, the rhythm is irregular. Irregular rhythms may be classified further. They may be classified as *regularly irregular*. In this case, the irregularity has a pattern; it is also called "group beating." Irregular rhythms also may be *occasionally irregular*. In this case, only one or two R-R intervals are unequal. Finally, irregular rhythms may be *irregularly irregular*. In this case, the rhythm is totally irregular. No relationship is seen between the R-R intervals (Figure 22-39).

Step 5: Analyze the P-R Interval

The P-R interval indicates the time required for an electrical impulse to be conducted through the atria and AV node. The interval should be constant across the ECG tracing. A prolonged P-R interval (greater than 0.20 second) indicates a delay in the conduction of the impulse through the AV node or bundle of His. The delay is called an *atrioventricular (AV) block*. A short P-R interval (less than 0.12 second) indicates that the impulse progressed from the atria to the ventricles through pathways other than the AV node

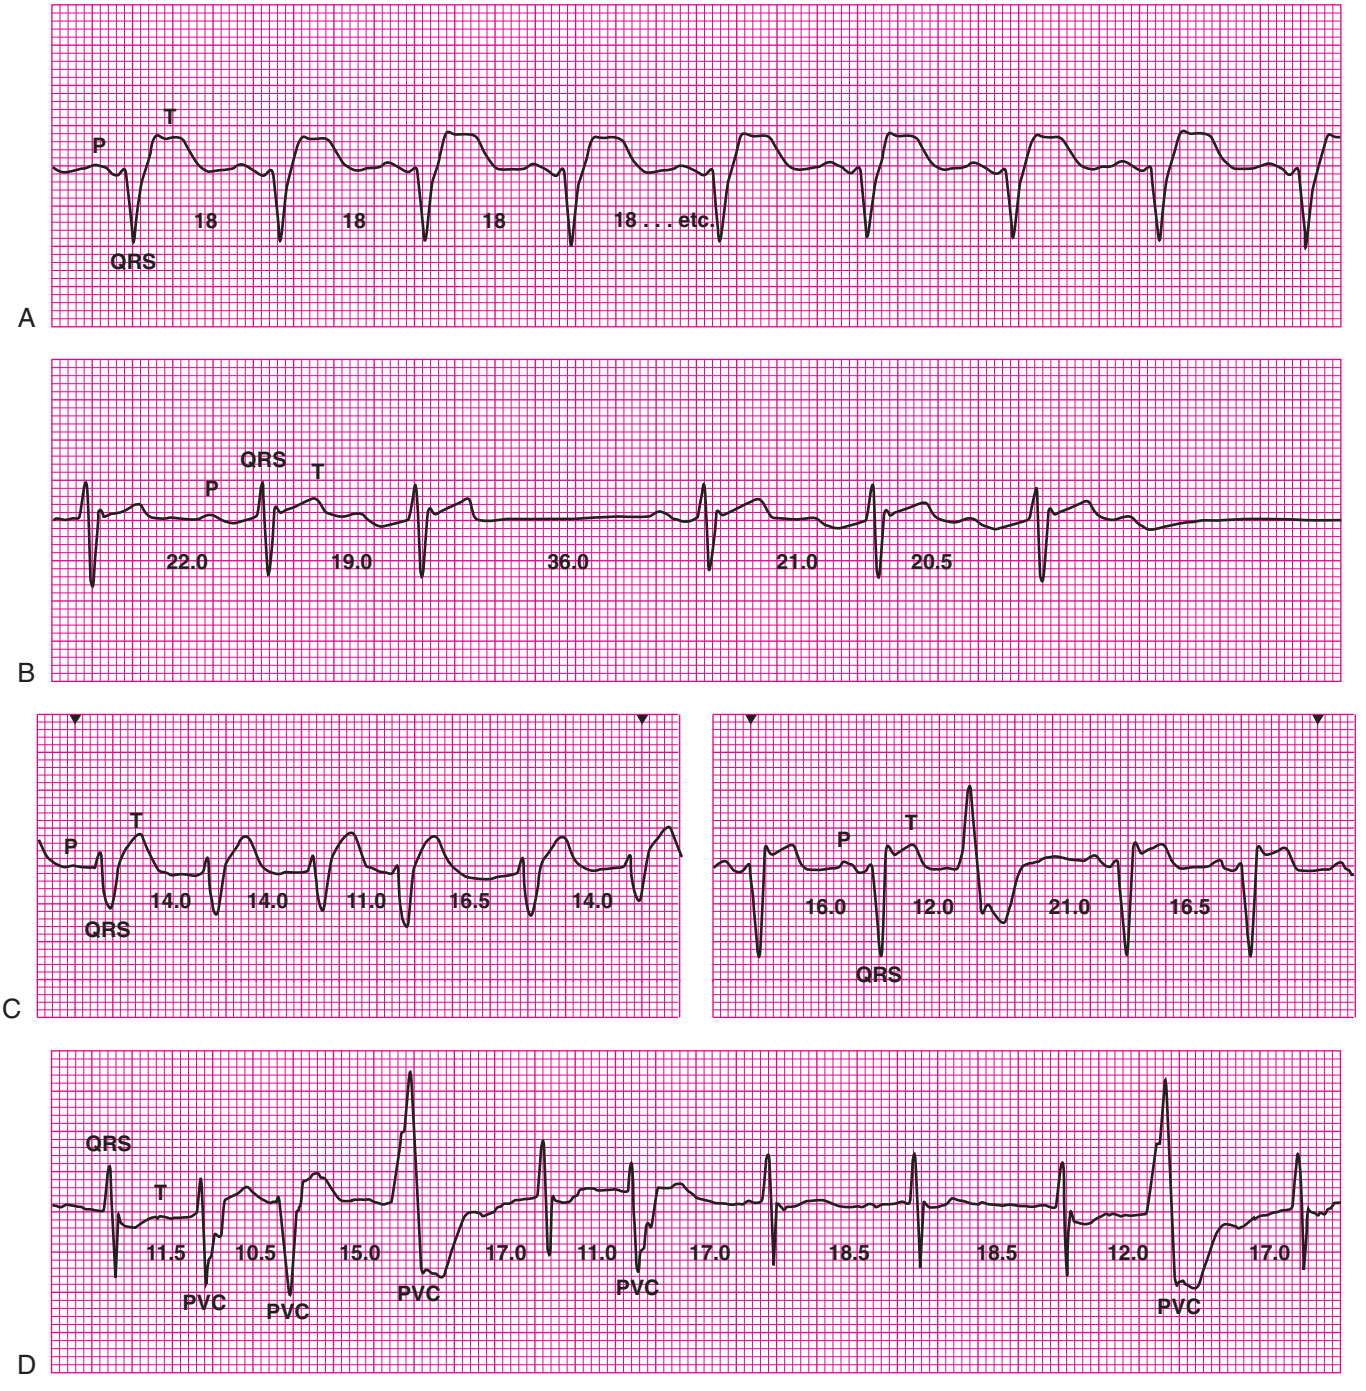

FIGURE 22-39 **A**, Regular rhythm. **B**, Regularly irregular rhythm. **C**, Occasionally irregular rhythm. **D**, Irregularly irregular rhythm.

(Figure 22-40). This is known as an *accessory pathway syndrome,* the most common of which is Wolff-Parkinson-White (WPW) syndrome.

NOTE

Wolff-Parkinson-White (WPW) syndrome is a genetic heart abnormality associated with early activation of the ventricles. In the presence of tachycardia, this preexcitation syndrome can be life threatening. (The syndrome is described later in this chapter.)

Analyzing a Rhythm Using the Five Steps

To review, the normal sequence of atrial and ventricular activation as it relates to the ECG tracing is as follows: Each P wave (atrial depolarization) is followed by a normal QRS complex (ventricular depolarization) and T wave (ventricular repolarization); all QRS complexes are preceded by P waves; the P-R interval is within normal limits, and the R-R interval is regular. The five steps in ECG rhythm interpretation can be applied to the rhythm in Figure 22-41.

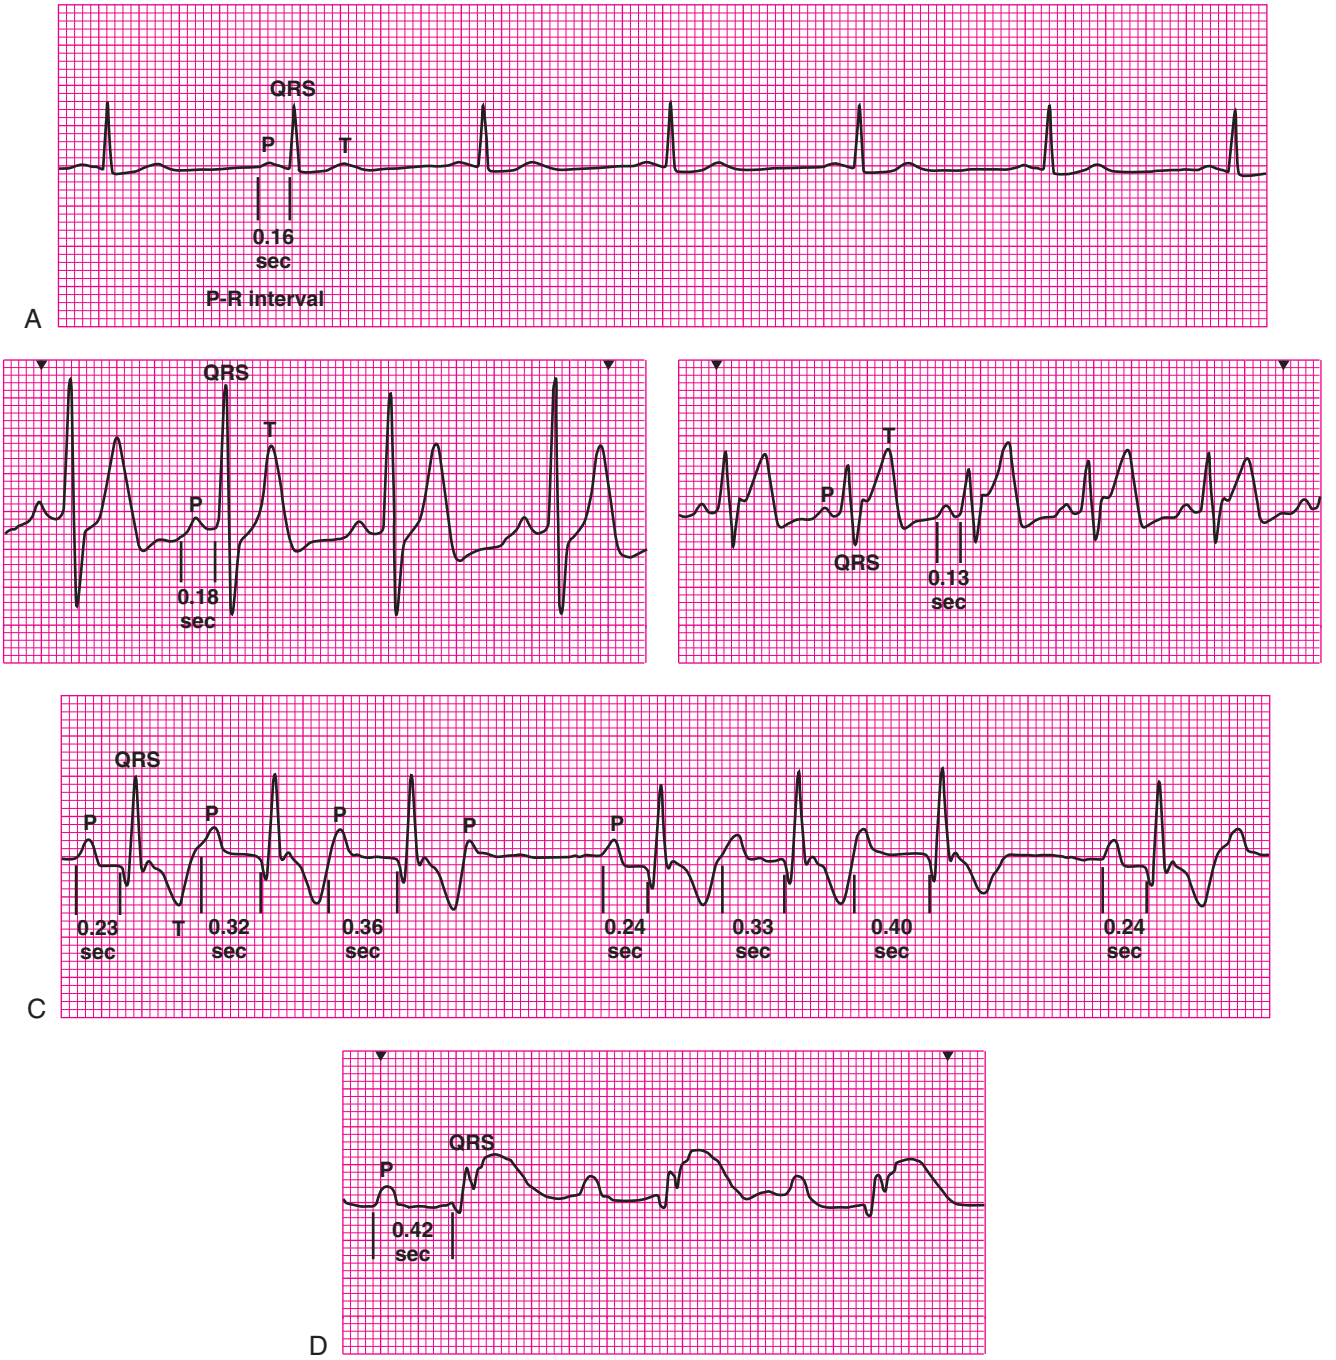

FIGURE 22-40 **A** and **B,** Normal P-R intervals. **C** and **D,** Abnormal P-R intervals.

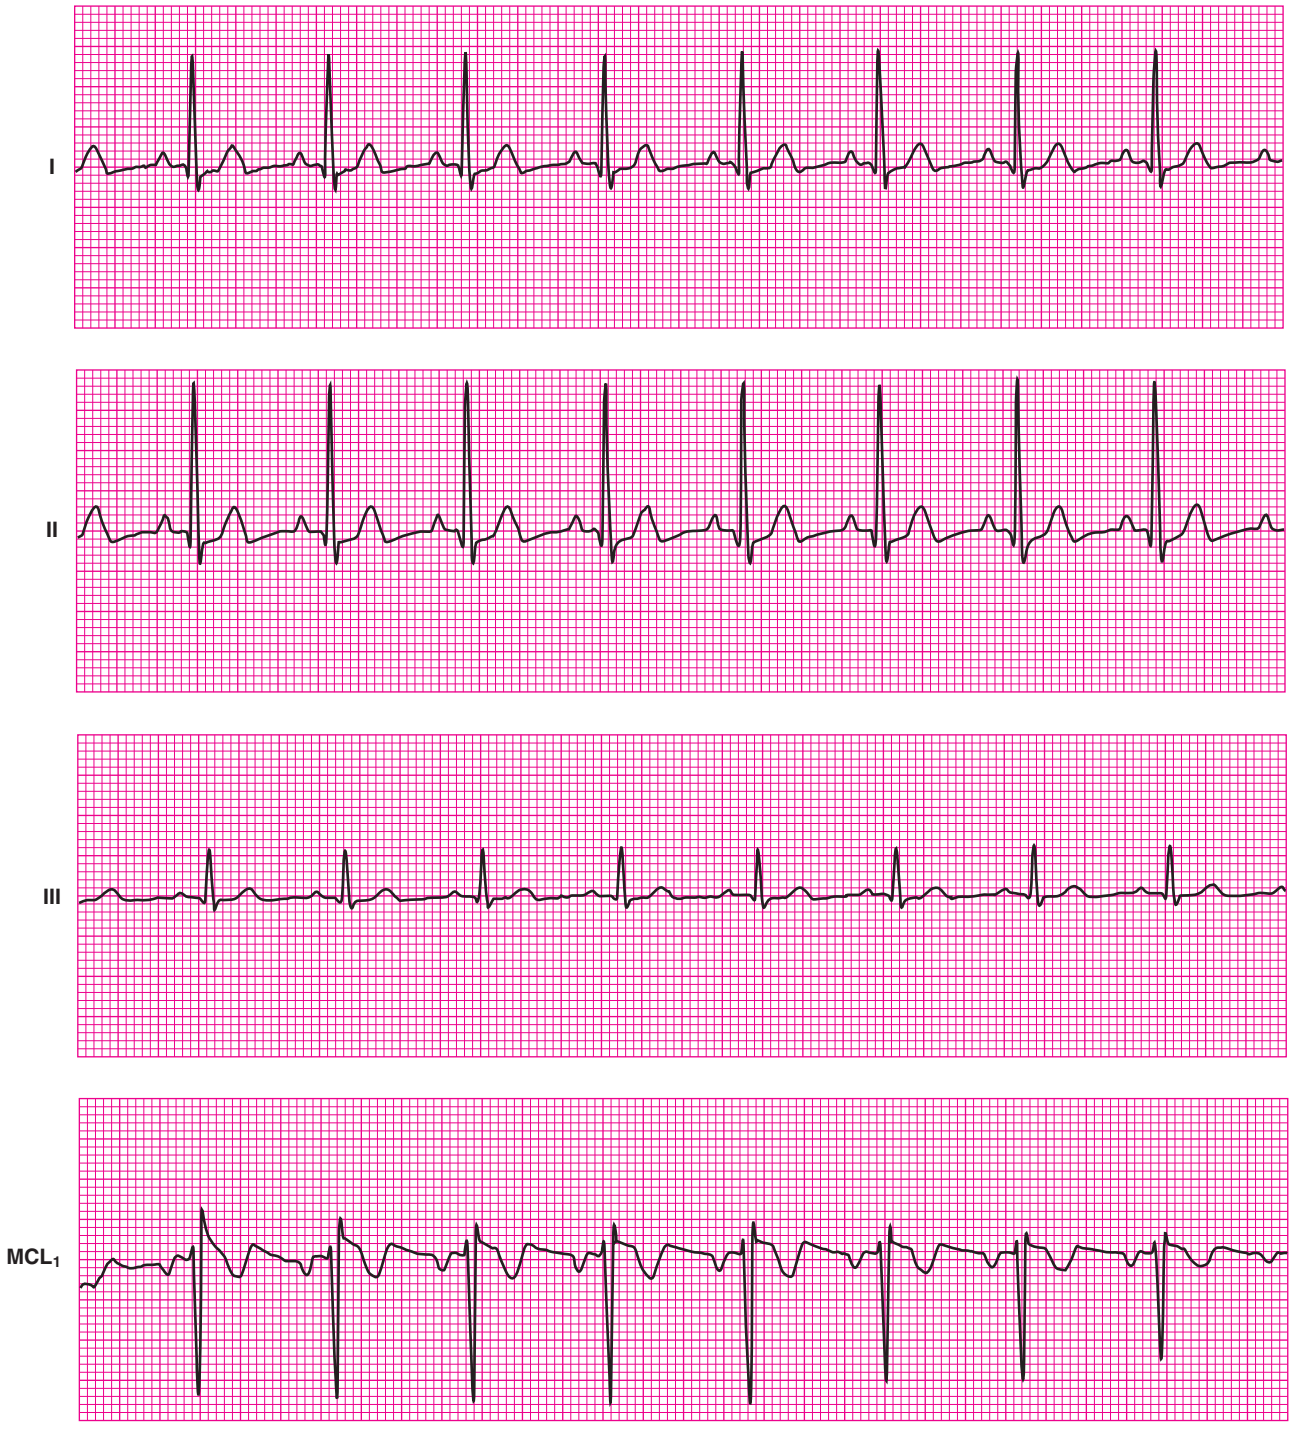

FIGURE 22-41 Normal sinus rhythm.

SECTION FIVE
Introduction to Dysrhythmias

Cardiac dysrhythmias can result from a number of physiological, pharmacological, and disease processes, including the following:

- Myocardial ischemia or necrosis
- Autonomic nervous system imbalance
- Distention of heart chambers
- Acid-base abnormalities
- Hypoxemia
- Electrolyte imbalance
- Drug effects or toxicity
- Electrical injury
- Hypothermia
- Central nervous system injury

In addition to these potential causes of dysrhythmias, some cardiac rhythm disturbances are normal, even in

patients who have healthy hearts. (For example, a patient may have sinus tachycardia from stress or anxiety.) *Regardless of the cause or type of dysrhythmia, management should focus on the patient and the underlying cause. Management should not focus merely on the dysrhythmia.*

NOTE
Special considerations regarding cardiac rhythm disturbances and resuscitation in infant and pediatric patients are addressed in Chapters 47 and 48.

CLASSIFICATION OF DYSRHYTHMIAS

Classification by Rate and Pacemaker Site

The classification of dysrhythmias can be based on a number of factors. These include changes in automaticity versus disturbances in conduction, cardiac arrest (lethal) rhythms and noncardiac arrest (nonlethal) rhythms, and site of origin. For learning purposes, this text classifies rhythms by rate and pacemaker site (e.g., ventricular tachycardia and sinus bradycardia) and includes the following five groups:

1. Dysrhythmias originating in the sinoatrial node
   a. Sinus bradycardia
   b. Sinus tachycardia
   c. Sinus dysrhythmia
   d. Sinus arrest
2. Dysrhythmias originating in the atria
   a. Wandering pacemaker
   b. Multifocal atrial tachycardia
   c. Premature atrial complex
   d. Paroxysmal supraventricular tachycardia
   e. Atrial flutter
   f. Atrial fibrillation
3. Dysrhythmias originating in the atrioventricular node and surrounding tissues
   a. Premature junctional complex
   b. Junctional escape complexes or rhythms
   c. Accelerated junctional rhythm
4. Dysrhythmias originating in the ventricles
   a. Ventricular escape complexes or rhythms
   b. Premature ventricular complex
   c. Ventricular tachycardia
   d. Ventricular fibrillation
   e. Asystole
   f. Artificial pacemaker rhythms
5. Dysrhythmias that are disorders of conduction
   a. Atrioventricular blocks
      (1) First-degree atrioventricular block
      (2) Second-degree atrioventricular block type I (or Wenckebach)
      (3) Second-degree atrioventricular block type II
      (4) Third-degree atrioventricular block
   b. Disturbances of ventricular conduction
   c. Pulseless electrical activity
   d. Preexcitation syndrome (WPW syndrome and Lown-Ganong-Levine syndrome)

NOTE
Broadly speaking, there are only four cardiac arrest rhythms: ventricular fibrillation, pulseless ventricular tachycardia, asystole, and assorted pulseless electrical activity rhythms. The two noncardiac arrest rhythms (precollapse or precardiac arrest rhythms) that are important to consider in prehospital care are those that are too slow (fewer than 60 beats/minute) and those that are too fast (more than 160 beats/minute).[1]

The text presents each dysrhythmia in lead II. For comparison, the same dysrhythmia also is shown as it would appear in leads I, III, and MCL_1. The text discusses how to recognize the dysrhythmia and the emergency treatment of patients with each dysrhythmia. All treatments in this chapter follow the recommendations of the American Heart Association (AHA). All treatments are referenced to the American Heart Association algorithms.

Use of Algorithms for Classification

Algorithms are lists used to summarize information. Some algorithms contain prehospital and in-hospital management recommendations. The following guidelines apply to the use of all algorithms:

1. First, manage the patient, not the monitor.
2. Algorithms for cardiac arrest presume that the condition under discussion continually persists; that the patient remains in cardiac arrest; and that cardiopulmonary resuscitation is always performed.
3. Apply different interventions when appropriate indications exist.
4. The algorithms are designed to outline the most common assessments and actions performed for the majority of patients, but they are not designed to be all-inclusive or restrictive.[6] The flow diagrams present treatments mostly in sequential order of priority. Next to a treatment or pharmacological agent may be a class recommendation (Box 22-4). The footnotes to the algorithm contain additional important information related to assessment, treatment, and evaluation.
5. Adequate airway, ventilation, oxygenation, chest compression, and defibrillation are more important than administration of medications. These measures take precedence over initiating an intravenous (IV) line or injecting pharmacological agents.
6. In the unlikely event that IV or intraosseous (IO) access is not available, some medications (naloxone, atropine, ***vasopressin, epinephrine,*** and ***lidocaine*** [N-A-V-E-L]), can be administered via an endotracheal (ET)

BOX 22-4 Classification of Recommendations for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care

Class I	Benefit significantly outweighs any possible harm. High-level prospective studies support the treatment. Treatment should be performed/administered.
Class IIa	Benefit outweighs risk. Weight of evidence supports the treatment. Treatment is considered acceptable and useful.
Class IIb	Benefit equals or is greater than the risk. Evidence documented only short-term benefit, or lower level evidence supported its use. Therapy may be considered.
Class III	Risk is greater than benefit. Therapy is not indicated. Not proven to be helpful. May harm the patient.

Modified from the American Heart Association: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care, *Circulation*. 112 (24)(Suppl):IV1-203, updated 2010.

tube. For adults, the endotracheal dose is 2 to 2½ times the IV dose. The ET tube route is the least preferred method of drug administration.

7. As a rule, intravenous medications are administered rapidly, by the bolus method in cases of cardiac arrest.
8. After each intravenous medication, a 20 to 30 mL bolus of IV fluid should be given. Also, the extremity should be elevated immediately. This enhances the delivery of drugs to the central circulation. This delivery may take 1 to 2 minutes.
9. Last, manage the patient, not the monitor.

DYSRHYTHMIAS ORIGINATING IN THE SINOATRIAL NODE

Most sinus dysrhythmias result from increases or decreases in vagal tone (parasympathetic nervous system). The SA node generally receives sufficient inhibitory parasympathetic impulses from the vagus nerve to keep the SA node in the normal rate of 60 to 100 beats/minute. However, if vagus nerve activity increases, the heart rate slows and sinus bradycardia results. If the vagus nerve is slowed or blocked, the heart rate increases and sinus tachycardia results. Dysrhythmias that originate in the SA node include sinus bradycardia, sinus tachycardia, sinus dysrhythmia, and sinus arrest. ECG features common to all SA node dysrhythmias include the following:

- Normal duration of QRS complex (in the absence of bundle branch block)
- Upright P waves in lead II
- Similar appearance of all P waves
- Normal duration of P-R interval (in the absence of atrioventricular block)

Sinus Bradycardia

DESCRIPTION

Sinus bradycardia results from slowing of the pacemaker rate of the SA node (Figure 22-42).

ETIOLOGY

Possible causes of sinus bradycardia include the following:

- Intrinsic sinus node disease
- Increased parasympathetic vagal tone
- Hypothermia
- Hypoxia
- Drug effects (e.g., digitalis, beta blockers, and calcium channel blockers)
- Myocardial infarction

RULES FOR INTERPRETATION (LEAD II MONITORING)

Sinus bradycardia has the following characteristics on the ECG:

QRS complex: Less than 0.12 second, provided no ventricular conduction disturbance is present
P waves: Normal and upright; one P wave before each QRS complex
Rate: Less than 60 beats/minute
Rhythm: Regular
P-R interval: 0.12 to 0.20 second and constant (normal), provided no atrioventricular block is present

CLINICAL SIGNIFICANCE

A decreased rate may compromise cardiac output. It may result in hypotension or other signs of shock, angina pectoris, or central nervous system symptoms (e.g.,

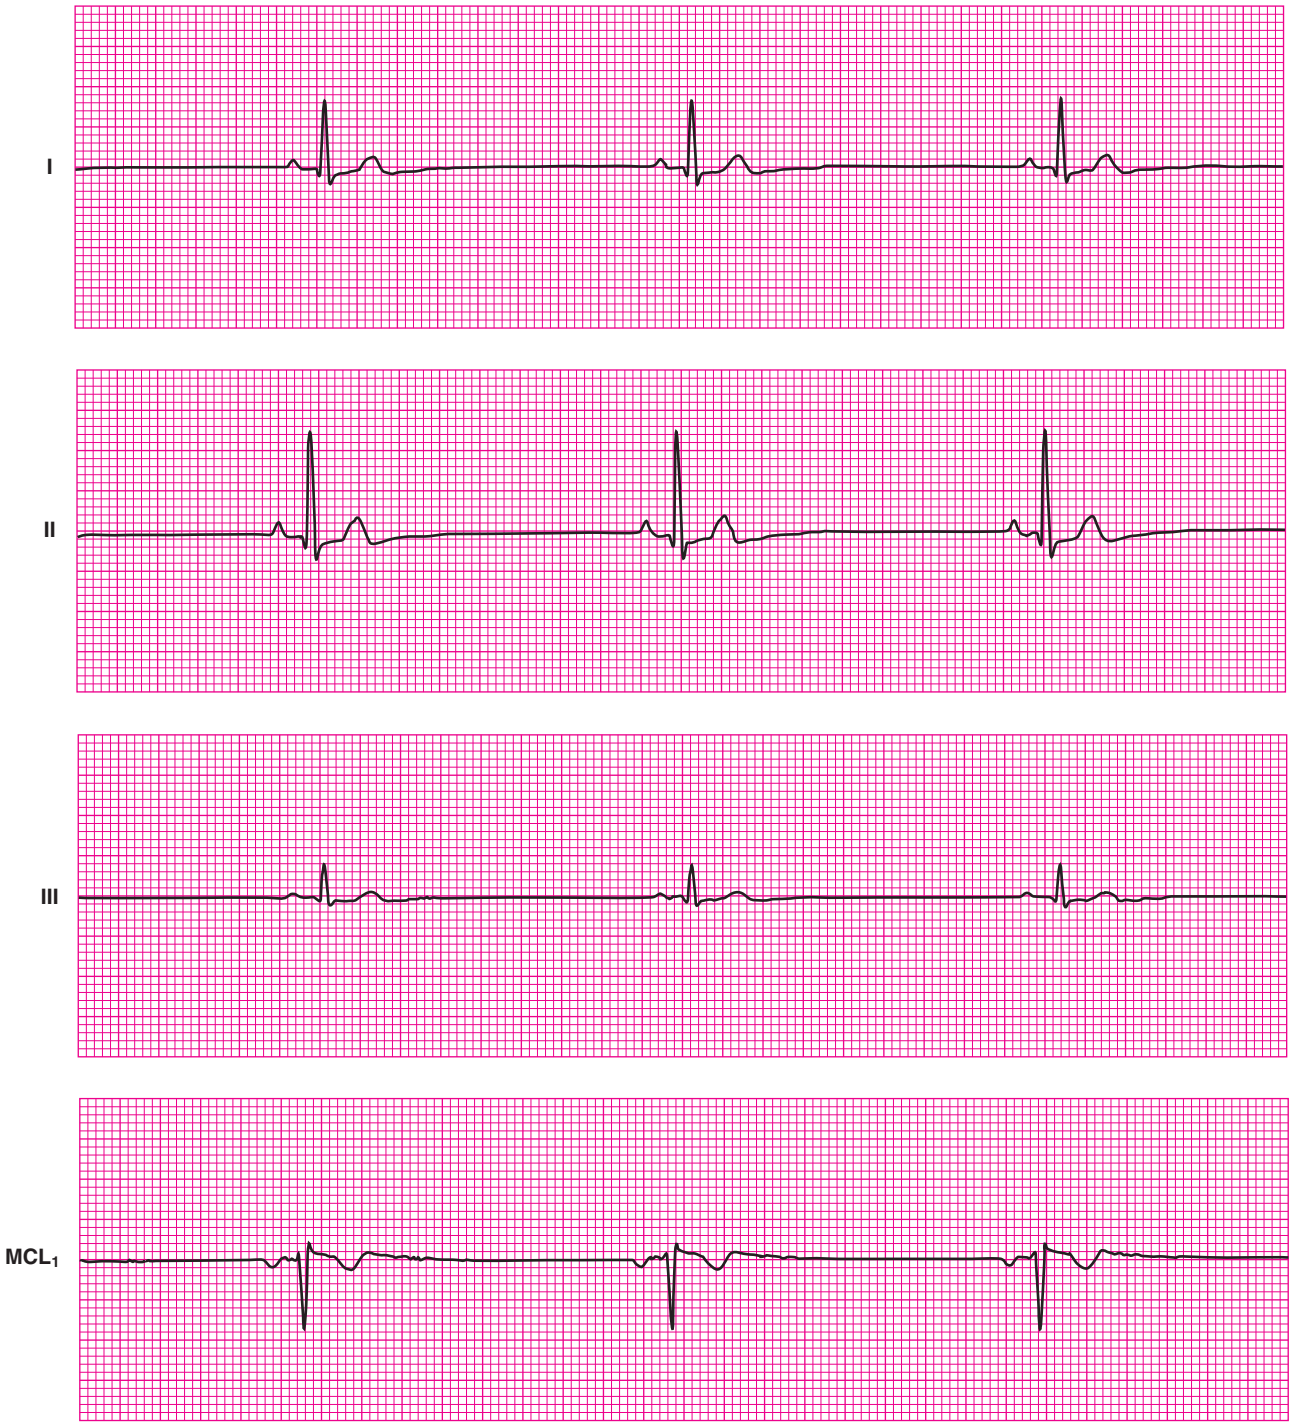

FIGURE 22-42 Sinus bradycardia.

lightheadedness, vertigo, and syncope). Sinus bradycardia can result from nausea and vomiting. The dysrhythmia is associated with overstimulation of the vagus nerve that can result in fainting (vasovagal syncope). However, sinus bradycardia may be beneficial. It may reduce myocardial oxygen consumption during myocardial infarction, provided the patient is well perfused. Sinus bradycardia also may occur after the application of carotid sinus pressure (carotid sinus massage, described later in this chapter). This dysrhythmia is common during sleep and in well-conditioned athletes.

CRITICAL THINKING

Take a poll of your classmates. How many have a resting heart rate of 60 beats/minute?

MANAGEMENT

Prehospital intervention usually is unnecessary unless hypotension, altered mental status caused by inadequate perfusion, acute heart failure, or ventricular irritability is present. (These are more common with rates below 50 beats/minute.) Management of symptomatic bradycardia is aimed at increasing the heart rate to improve cardiac output. Inotropic support also may be required (Figure 22-43). Treatment options for symptomatic bradycardia include oxygen, ventilation if indicated, ***atropine,*** transcutaneous pacing (the use of an external artificial pacemaker, described later in this chapter), a ***dopamine*** infusion, or an ***epinephrine*** infusion. Transcutaneous pacing is considered a class IIa intervention for symptomatic bradycardias unresponsive to atropine. Immediate pacing might be considered in unstable patients with high-degree AV block when IV access is not available.[1] Pacing is indicated for symptomatic bradycardias related to a conduction delay or block at or below the His-Purkinje level (infranodal).

NOTE

Blocks in electrical conduction may be classified as *nodal* or *infranodal*. A nodal block is one that occurs in the AV node. An infranodal block is one that occurs below the AV node. A *complete heart block* is one in which all electrical signals are blocked from the upper to lower chambers. (See conduction disorders later in this chapter.)

Atropine is administered intravenously for symptomatic bradycardia,. Administration may be repeated every 3 to 5 minutes as needed. The frequency of ***atropine*** administration is based on the patient's condition. ***Atropine*** should be administered at shorter intervals (every 3 minutes) for severely unstable patients.

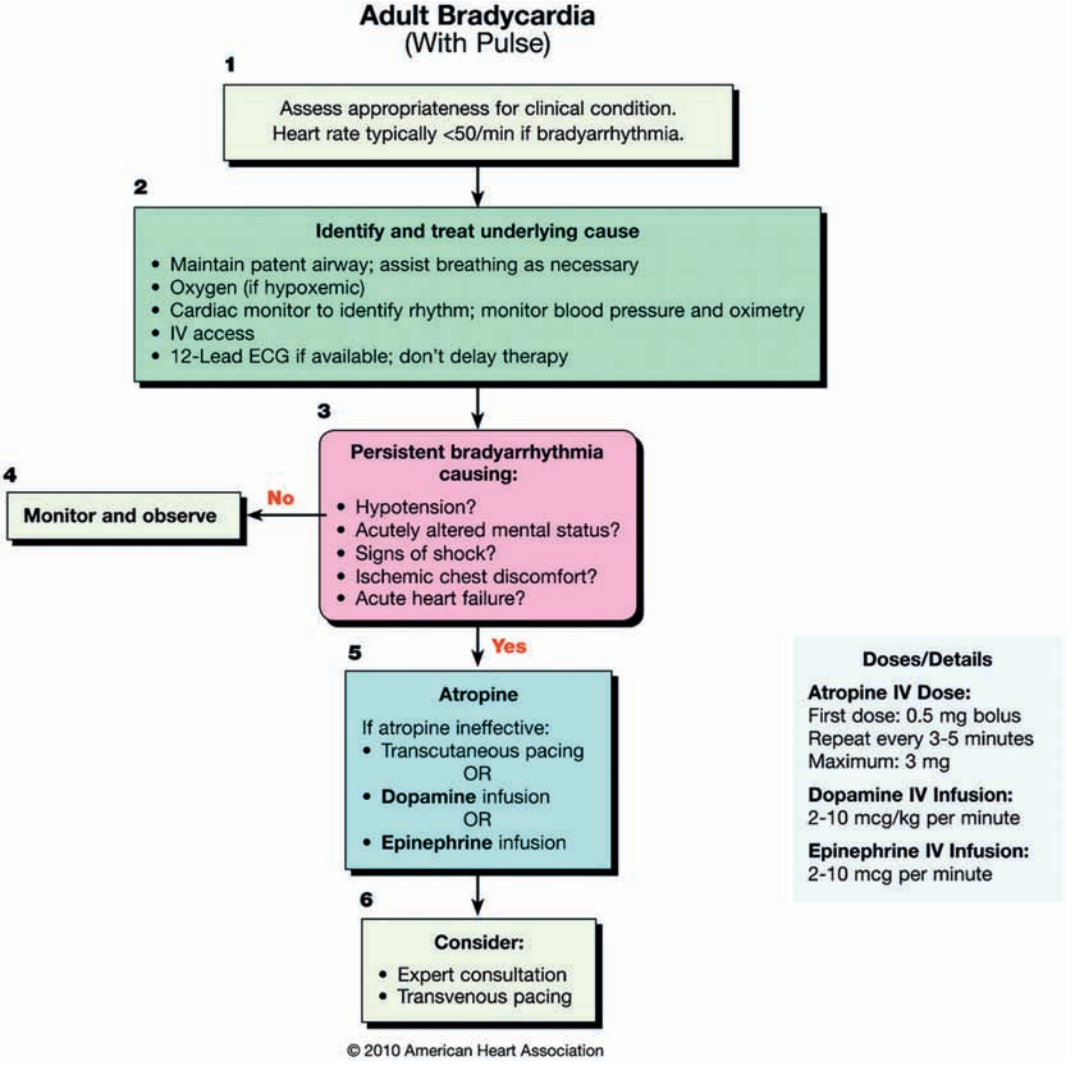

FIGURE 22-43 Bradycardia algorithm. (Reprinted with permission, American Heart Association Guidelines For CPR and ECC, *Circulation 122* [suppl 3]:S685-S919, American Heart Association, Inc, 2010.)

NOTE

Atropine should be used with caution in a patient with an acute myocardial infarction. The drug can increase the heart rate, increasing myocardial oxygen demand. This in turn can worsen ischemia or increase the size of the infarction. ***Atropine*** may be beneficial for the treatment of nodal blocks. The drug should be avoided for infranodal blocks and complete heart block with a wide QRS complex, because it may worsen the rhythm.

If symptoms persist after ***atropine*** administration, a pressor infusion such as ***dopamine*** or epinephrine may be needed (Box 22-5). Evaluate the need for fluid bolus infusion in hypotensive bradycardic patients before pressor infusion begins.[1]

An ***epinephrine*** infusion can be used for symptomatic bradycardia (Box 22-6). Generally, this is given after ***atropine*** and transcutaneous pacing fail to improve the patient's condition. However, an ***epinephrine*** infusion may be administered earlier if the patient displays severe symptoms and is deteriorating quickly.

Sinus Tachycardia

DESCRIPTION

Sinus tachycardia results from an increase in the rate of sinus node discharge (Figure 22-44).

CRITICAL THINKING

What effect does the excitement and commotion of the arrival of your ambulance likely have on the heart rate and blood pressure of a conscious, alert patient?

ETIOLOGY

Sinus tachycardia is common and may result from multiple factors, including the following:

- Exercise
- Fever
- Anxiety
- Ingestion of caffeine or alcohol
- Smoking
- Hypovolemia
- Hyperthyroidism
- Anemia
- Congestive heart failure
- Administration of ***atropine*** or any vagolytic or sympathomimetic drug (e.g., cocaine, phencyclidine, ***epinephrine***)

RULES FOR INTERPRETATION (LEAD II MONITORING)

Sinus tachycardia has the following characteristics on the ECG:

QRS complex: Less than 0.12 second, provided no ventricular conduction disturbance is present

BOX 22-5 Dopamine Infusion

- Low-dose dopamine: 1 to 5 mcg/kg/minute. A low dose of dopamine produces a dopaminergic effect that increases renal, mesenteric, and cerebrovascular vessel dilation. The benefit of low-dose dopamine is controversial.
- Moderate-dose dopamine: 5 to 10 mcg/kg/minute. At moderate doses, dopamine improves contractility, cardiac output, and blood pressure through alpha$_1$- and beta$_1$-receptor stimulation.
- High-dose dopamine: 10 to 20 mcg/kg/minute. Higher doses of dopamine have an alpha-adrenergic effect producing peripheral arterial and venous vasoconstriction. (See Chapter 14 for the calculation of dopamine infusions.)

BOX 22-6 Epinephrine Infusion

Epinephrine infusions are used for critically unstable patients with bradycardia who have not responded to atropine or pacing. An epinephrine infusion is prepared by mixing 1 mg of epinephrine 1:1000 into 500 mL of 5% dextrose in water or 0.9% normal saline. The concentration is 2 mcg/mL. The recommended rate of infusion is 2 to 10 mcg/minute.

P waves: Normal and upright; one before each QRS complex

Rate: Equal to or greater than 100 beats/minute

Rhythm: Regular

P-R interval: 0.12 to 0.20 second (normal), provided no atrioventricular conduction block is present

CLINICAL SIGNIFICANCE

Sinus tachycardia in healthy individuals generally is a benign rhythm disturbance. If tachycardia is associated with myocardial infarction, however, it may increase the oxygen requirements of the heart, increase myocardial ischemia, and predispose the patient to more serious rhythm disturbances.

MANAGEMENT

Sinus tachycardia usually does not require treatment. When the underlying cause is removed, the tachycardia usually resolves gradually and spontaneously.

Sinus Dysrhythmia

DESCRIPTION

Sinus dysrhythmia is present when the difference between the longest and shortest R-R intervals is greater than 0.16 second (Figure 22-45).

ETIOLOGY

Sinus dysrhythmia usually is normal. It often is related to the respiratory cycle and to changes in intrathoracic pressure. These changes cause the heart rate to increase during inspiration and to decrease during expiration.

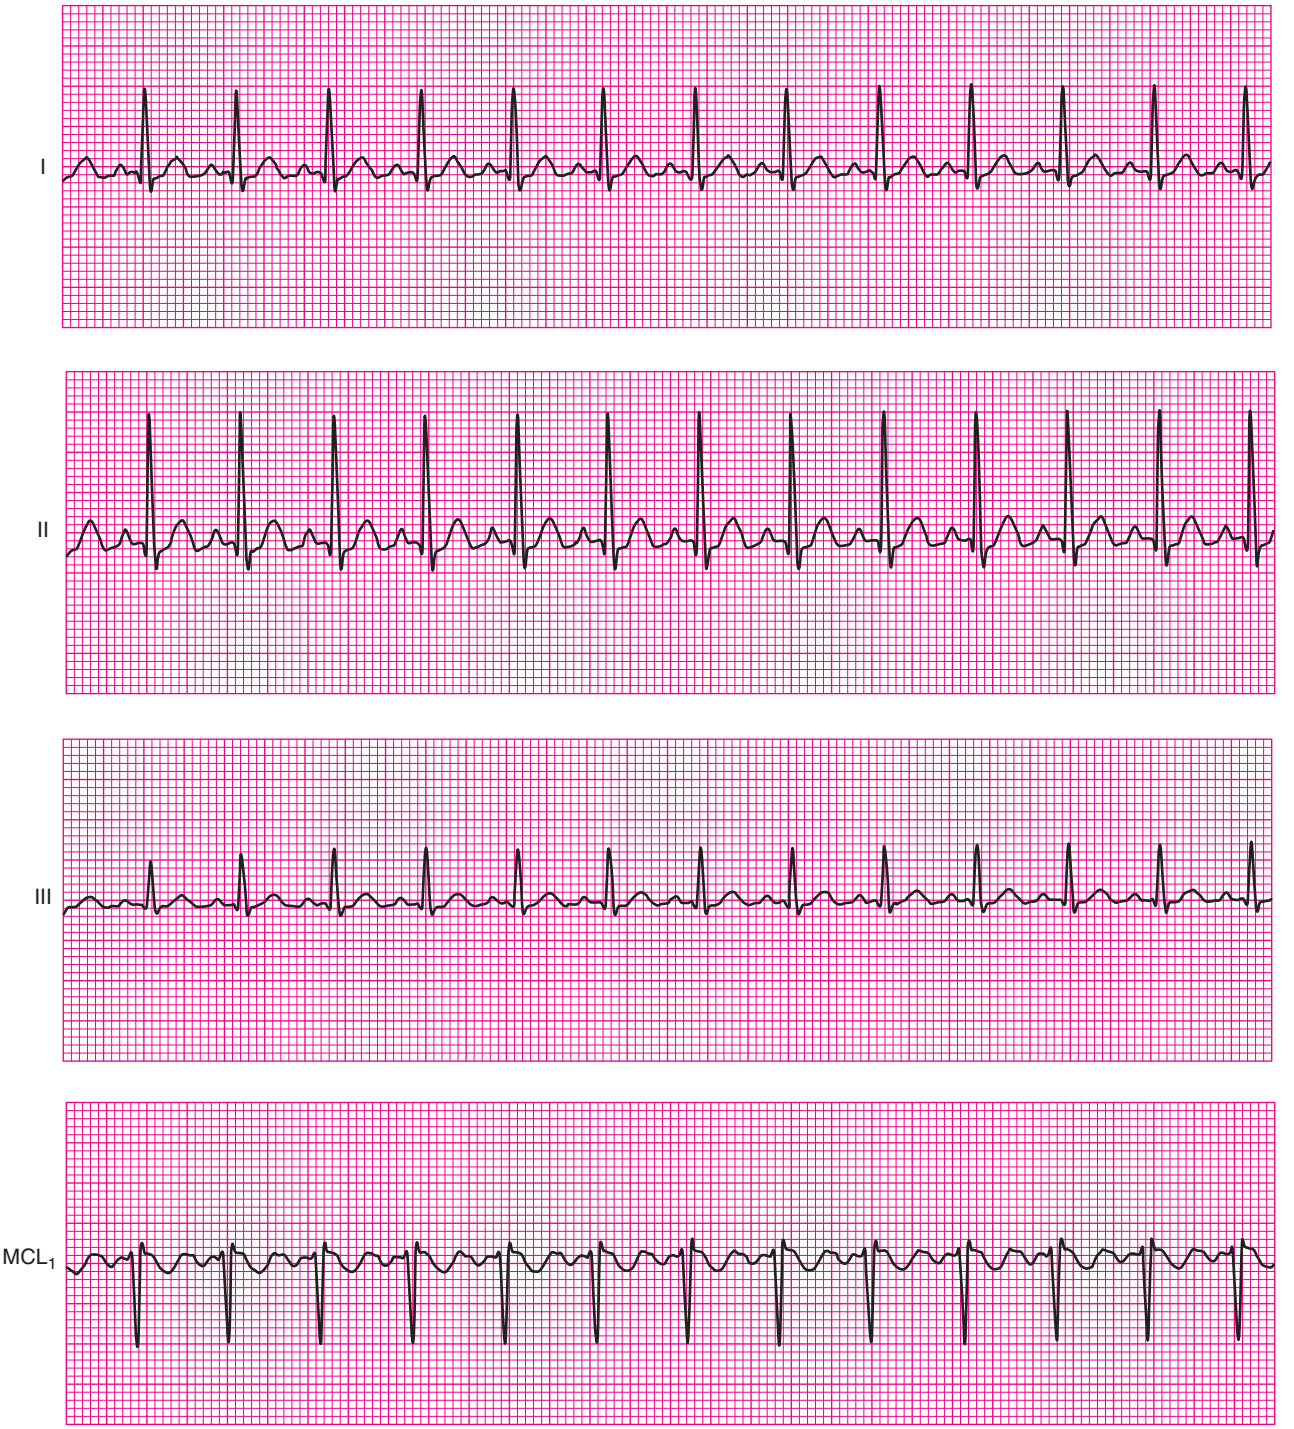

FIGURE 22-44 Sinus tachycardia.

Although sinus dysrhythmia sometimes occurs normally in healthy people, it is more common in patients with heart disease or myocardial infarction. It also is more common in patients receiving certain drugs, such as ***digoxin*** and ***morphine.***

RULES FOR INTERPRETATION (LEAD II MONITORING)

Sinus dysrhythmia has the following characteristics on the ECG:

QRS complex: Less than 0.12 second, provided no ventricular conduction disturbance is present

P waves: Normal and upright; one P wave before each QRS complex

Rate: Usually 60 to 99 beats/minute (varies with respiration)

Rhythm: Irregular (changes occur in cycles and usually follow the patient's respiratory pattern)

P-R interval: 0.12 to 0.20 second and constant (normal)

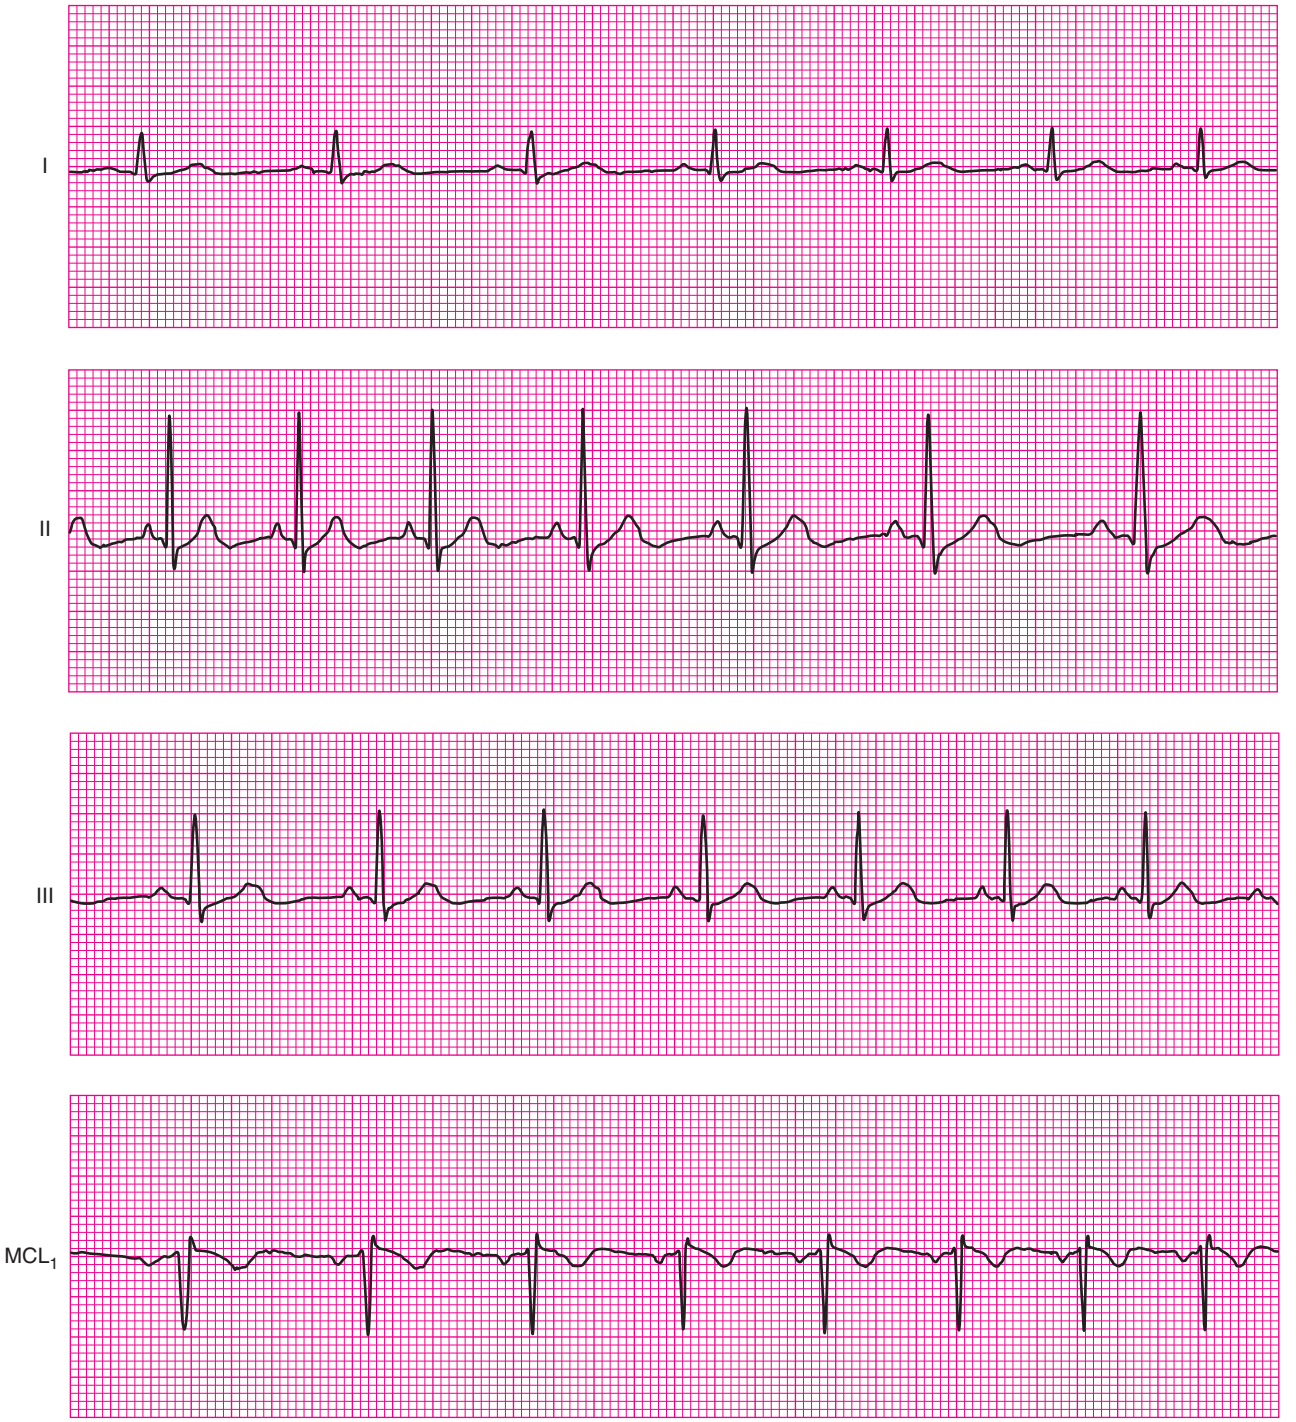

FIGURE 22-45 Sinus dysrhythmia.

CLINICAL SIGNIFICANCE

Sinus dysrhythmia is common in people of all ages. It may be associated with palpitations, dizziness, and syncope (rare).

MANAGEMENT

Sinus dysrhythmia usually is not a serious dysrhythmia. It seldom requires treatment.

Sinus Arrest

DESCRIPTION

Sinus arrest results from a depression in automaticity of the SA node (Figure 22-46). The failure of the sinus node causes short periods of cardiac standstill. This occurs until lower level pacemakers discharge (escape beats) or the sinus node resumes its normal function.

ETIOLOGY

Sinus arrest may be precipitated by an increase in parasympathetic tone on the SA node, hypoxia or ischemia, excessive administration of digitalis or ***propranolol,*** hyperkalemia, or damage to the SA node (acute myocardial infarction, degenerative fibrotic disease that affects the heart).

RULES FOR INTERPRETATION (LEAD II MONITORING)

Sinus arrest has the following characteristics on the ECG:

QRS complex: Less than 0.12 second, provided no bundle branch conduction disturbance is present

P waves: Normal and upright. If the electrical impulse is not generated by the SA node or blocked from entering the atria, atrial depolarization does not occur and the P wave is dropped.

Rate: Normal to slow, depending on the frequency and duration of sinus arrest

Rhythm: Irregular when sinus arrest is present

P-R interval: P-R intervals (when the P wave is present) of the underlying rhythm are normal (0.12 to 0.20 second) in the absence of atrioventricular block. Junctional escape beats may occur with no P waves.

CLINICAL SIGNIFICANCE

Frequent or prolonged episodes of sinus arrest may reduce cardiac output. The overall heart rate slows, and the atria do not contract; consequently, ventricular filling is reduced. If an escape pacemaker does not take over, ventricular asystole may result. This would cause lightheadedness followed by syncope. With this dysrhythmia, the danger exists that sinus node activity will stop completely. Another danger is that an escape pacemaker may not take over pacing. These developments would result in asystole.

MANAGEMENT

If the patient is asymptomatic, close observation is all that is required. In patients with bradycardia that produces symptoms, management may include the administration of ***atropine*** or transcutaneous cardiac pacing (see Figure 22-43).

DYSRHYTHMIAS ORIGINATING IN THE ATRIA

Atrial dysrhythmias may begin in the tissues of the atria or in the AV junction. Common causes of atrial dysrhythmias are ischemia, hypoxia, and atrial dilation caused by congestive heart failure, mitral valve abnormalities, or increased pulmonary artery pressures. Atrial dysrhythmias include wandering pacemaker, premature atrial complexes, paroxysmal supraventricular tachycardia, atrial flutter, and atrial fibrillation. ECG features common to all atrial dysrhythmias (provided no ventricular conduction disturbance is present) include the following:

- Normal QRS complexes
- P waves (if present) that differ in appearance from sinus P waves
- Abnormal, shortened, or prolonged P-R intervals

Wandering Pacemaker

DESCRIPTION

Wandering pacemaker (or wandering atrial pacemaker) occurs when the pacemaker shifts from the sinus node to another pacemaker site in the atria or the AV junction (Figure 22-47). The shift in the site usually is transient, back and forth along the sinoatrial node, atria, and atrioventricular junction.

ETIOLOGY

Wandering pacemaker is a type of sinus dysrhythmia. It may be normal in the very young, in older adults, and in well-conditioned athletes. The dysrhythmia generally is caused by the inhibitory vagal effect on the SA node and AV junction (often related to respiration). Vagal stimulation can cause pacemaker rates to slow. Other causes include associated underlying heart disease and the administration of digitalis.

NOTE

Another type of wandering atrial pacemaker is **multifocal atrial tachycardia (MAT)** (Figure 22-48). MAT resembles wandering pacemaker but is associated with rates often in the 120 to 150 beats/minute range. MAT is always considered pathological. This atrial tachycardia most often is found in patients with severe chronic obstructive pulmonary disease and may respond to management of the underlying disease. MAT often is mistaken for atrial fibrillation with rapid ventricular response (described later in this chapter).

RULES FOR INTERPRETATION (LEAD II MONITORING)

Wandering pacemaker has the following characteristics on the ECG:

QRS complex: Usually less than 0.12 second, provided no conduction block is present in the bundle branches

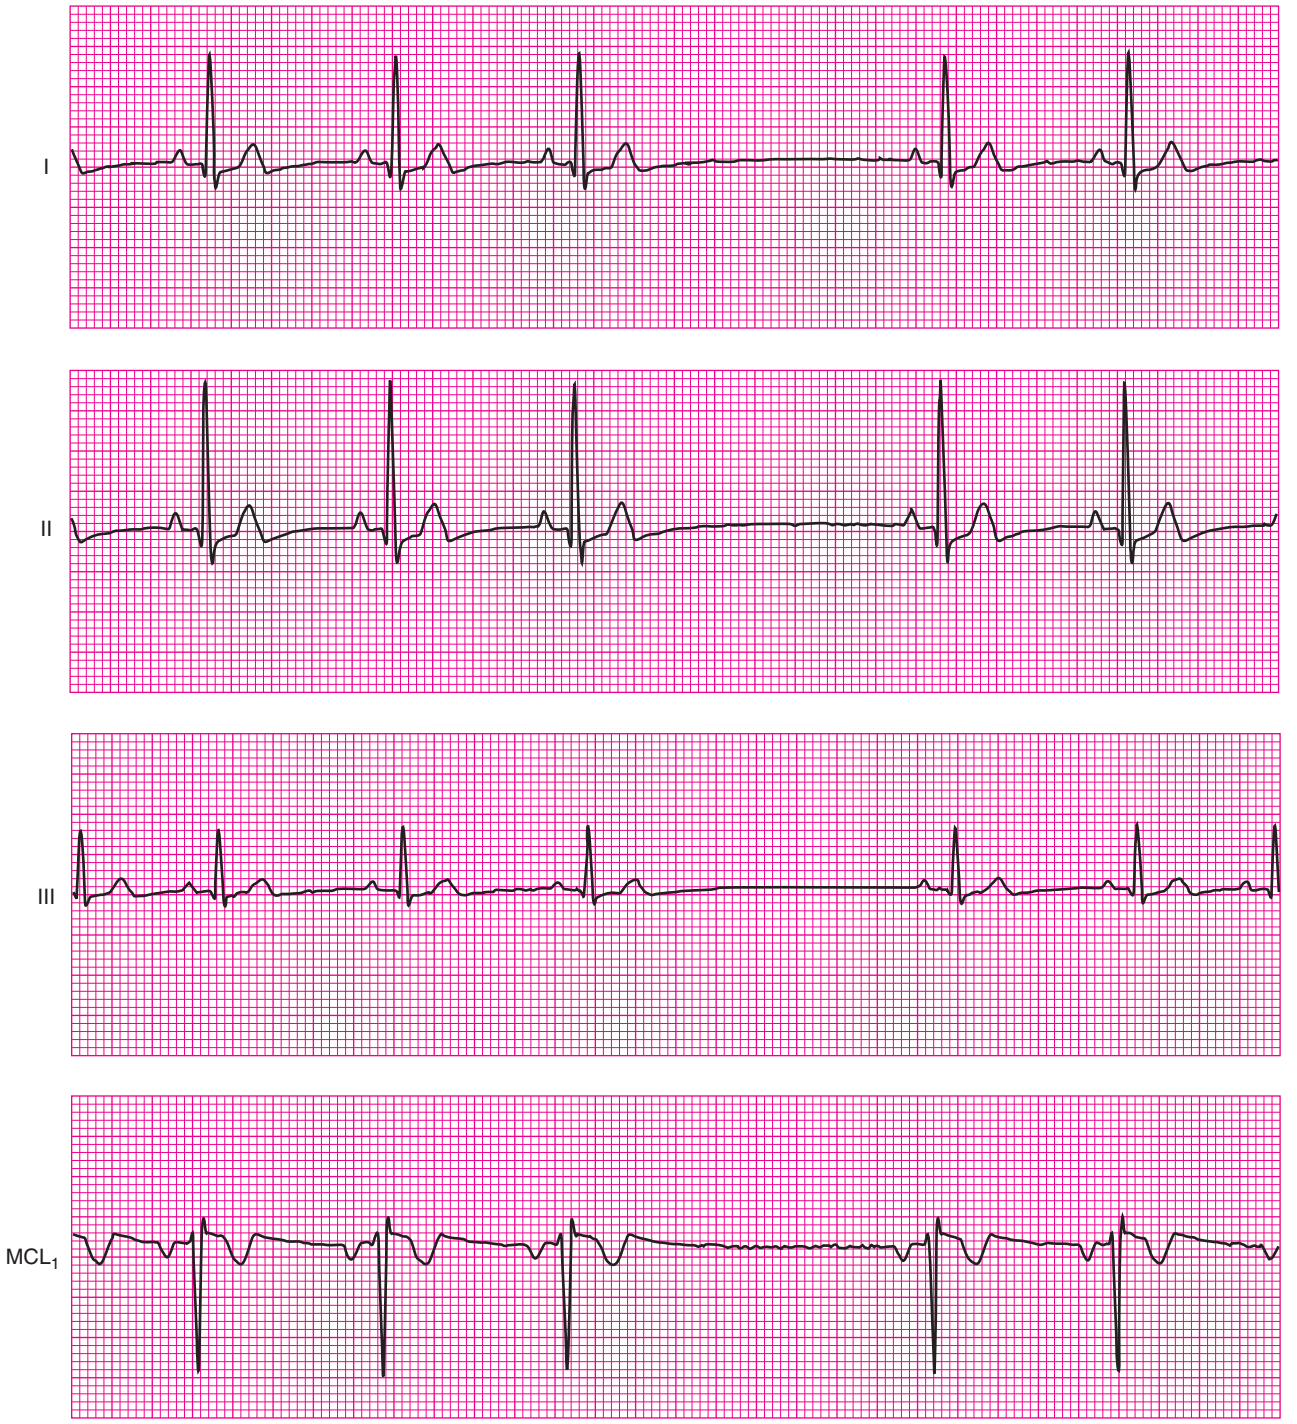

FIGURE 22-46 Sinus arrest.

P waves: Change in P-wave morphology from beat to beat. In lead II, the P waves may be upright, rounded, notched, inverted, biphasic, or buried in the QRS complex.

Rate: Usually 60 to 99 beats/minute. The rate may slow gradually when the pacemaker site shifts from the SA node to the atria or AV junction and may increase when the pacemaker site shifts back to the SA node.

Rhythm: Irregular P-R

P-R interval: Varies

CLINICAL SIGNIFICANCE

A wandering pacemaker usually does not produce serious signs and symptoms. Other atrial dysrhythmias (e.g., atrial fibrillation) occasionally are associated with this dysrhythmia.

MANAGEMENT

Sometimes a wandering pacemaker is a benign rhythm. In those instances, no management is required. Multifocal atrial tachycardia (MAT), however, may be precipitated by

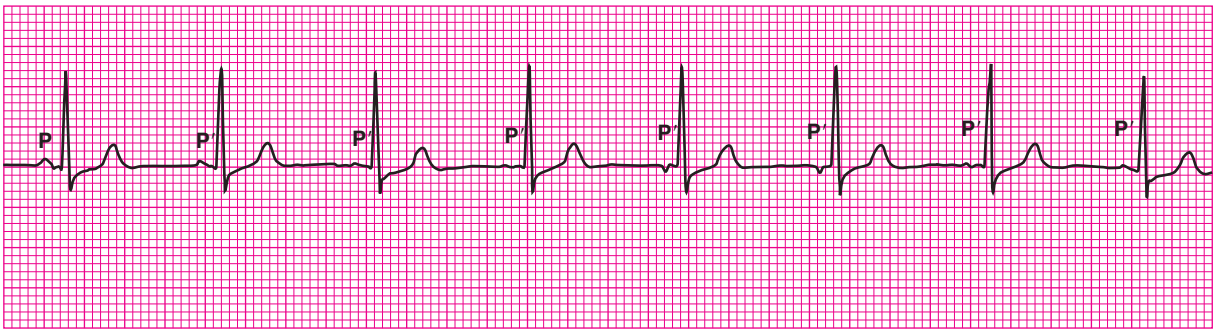

FIGURE 22-47 Wandering atrial pacemaker.

FIGURE 22-48. Multifocal atrial tachycardia. (Sole ML et al: *Introduction to critical care nursing,* ed 5, St Louis, 2009, Saunders.)

acute exacerbation of emphysema, congestive heart failure, or acute mitral valve regurgitation. Management is aimed at the underlying cause. Oxygen administration is usually the initial treatment of choice for MAT.

Premature Atrial Complex

DESCRIPTION

A **premature atrial complex (PAC)** is a single electrical impulse originating in the atria, outside the sinus node (Figure 22-49). The impulse creates a premature atrial complex (P wave). If conducted through the AV node, the impulse also causes a QRS complex before the next expected sinus beat. Because the PAC usually depolarizes the SA node prematurely, the timing of the SA node is reset. The next expected P wave of the underlying rhythm appears earlier than it would have if the SA node had not been disturbed. PACs may originate from a single ectopic pacemaker site or from multiple sites in the atria. PACs are thought to result from enhanced automaticity or a reentry mechanism (described later in this chapter).

CRITICAL THINKING

What do you feel when you palpate the pulse of a patient with premature atrial complexes?

ETIOLOGY

Premature atrial complexes may result from the following:

- Increase in catecholamines and sympathetic tone
- Use of caffeine, tobacco, or alcohol
- Use of sympathomimetic drugs ***(epinephrine, albuterol, norepinephrine)***
- Electrolyte imbalance
- Hypoxia
- Digitalis toxicity
- Cardiovascular disease
- In some cases, no apparent cause

RULES FOR INTERPRETATION (LEAD II MONITORING)

Premature atrial complexes have the following characteristics on the ECG:

QRS complex: Usually less than 0.12 second. The QRS complex may be greater than 0.12 second and appear bizarre if the PAC is conducted abnormally. The QRS complex may be absent as a result of a temporary complete AV block (nonconducted PAC) that occurs during the refractory period of the AV node or ventricles.

P waves: The P wave of a PAC differs in shape from a sinus P wave. It occurs earlier than the next expected sinus P wave and may be so early that it is

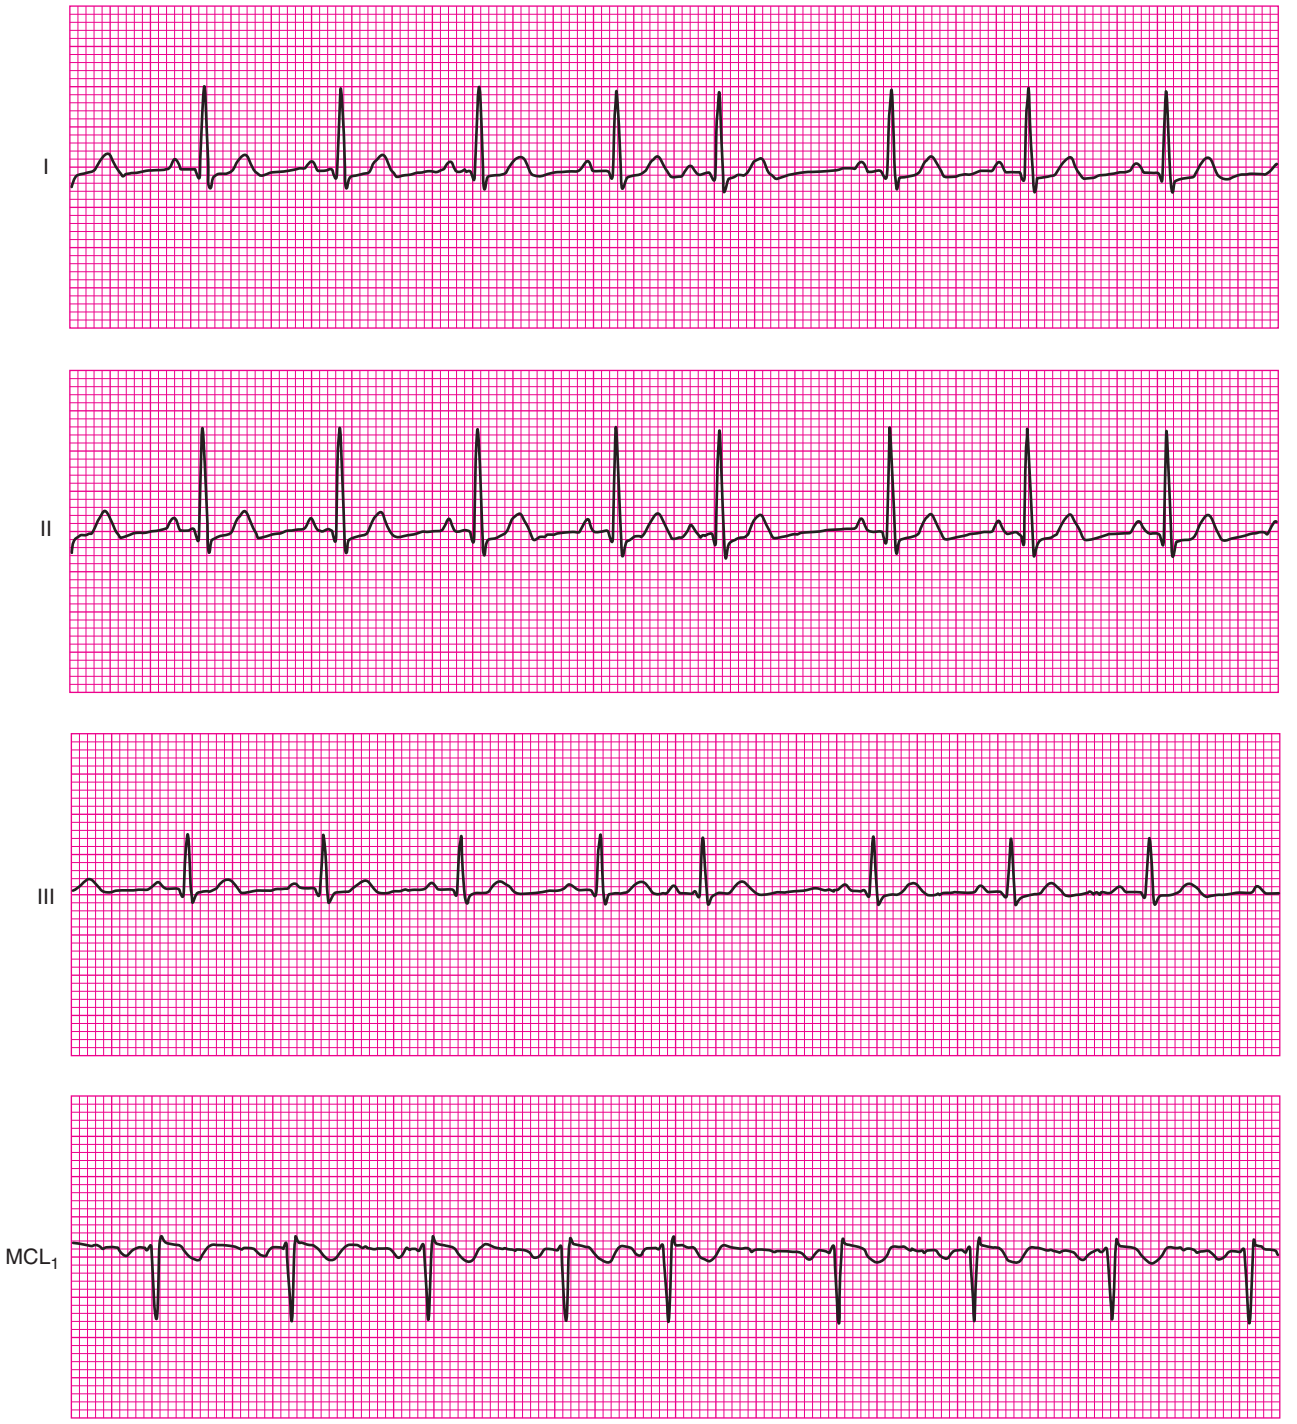

FIGURE 22-49 Premature atrial complex.

superimposed or hidden in the preceding T wave. The paramedic should evaluate the preceding T wave to see whether its shape is altered by the presence of a P wave.

Rate: Depends on the underlying rhythm

Rhythm: Usually the underlying rhythm is sinus and regular with irregular premature beats when the PACs occur.

P-R interval: Usually in the normal range but differs from those of the underlying rhythm. The P-R interval of a PAC varies from 0.20 second when the pacemaker site is near the SA node to 0.12 second when the pacemaker site is near the AV junction.

NOTE

A premature atrial complex (PAC) that looks different from other PACs *(PAC with aberrancy)* on the ECG may resemble a premature ventricular complex (a more serious complex). Distinguishing between these two types of dysrhythmias is important to determining the appropriate patient care.

CLINICAL SIGNIFICANCE

Isolated PACs in healthy patients are not significant. Frequent PACs that occur in patients with heart disease may lead to serious supraventricular dysrhythmias such as multifocal atrial tachycardia, atrial tachycardia, atrial flutter, atrial fibrillation, or paroxysmal supraventricular tachycardia.

MANAGEMENT

Prehospital care usually requires only observation. PACs that are frequent or that do not produce ventricular contraction *(nonconducted PACs)* may cause symptomatic bradycardia. In these rare cases, transcutaneous cardiac pacing or ***atropine*** may be indicated (see Figure 22-43).

Supraventricular Tachycardias

DESCRIPTION

Supraventricular tachycardia (SVT) is a complex group of dysrhythmias. SVT can be broadly defined as any tachycardia that directly or indirectly involves the atria or AV node (above the bundle of His). SVTs described in this section include AV nodal reentry tachycardia (AVNRT), AV reentry tachycardia (AVRT), and atrial tachycardia (AT). SVTs result from rapid atrial or junctional depolarization that overrides the rate of the SA node. (Atrial fibrillation and atrial flutter are also supraventricular tachycardias and are discussed later in this chapter.)

AV nodal reentry tachycardia (AVNRT) is the most common type of reentry SVT. AVNRT usually is caused by a PAC. When the dysrhythmia begins and ends abruptly, it is known as **paroxysmal supraventricular tachycardia** (PSVT) (Figure 22-50). Most SVTs are thought to result from a reentry mechanism that involves abnormal pathways in the AV node. In patients prone to reentry SVTs, the AV node is functionally divided into two pathways: a slow (alpha) pathway with a longer refractory period and a fast (beta) pathway with a shorter refractory period (Figure 22-51). These pathways permit impulses to be conducted from the atrium to the ventricle *(antegrade conduction),* or from the ventricle to the atrium *(retrograde conduction).* Reentry SVTs occur when a premature impulse becomes blocked in the fast pathway and then travels the slow pathway. During this process, the fast pathway recovers while the slow pathway is firing. This produces a reentry tachycardia in which the electrical impulses are caught in a cycle that continuously circulates around the AV node (Figure 22-52). The cycle and the tachycardia continue until the reentry pathway is interrupted. Most SVTs are characterized by repeated episodes *(paroxysms)* of atrial tachycardia. These episodes often have a sudden onset (lasting minutes to hours) and an abrupt termination.

AV reentry tachycardia (AVRT) is the second most common type of reentry SVT. As in AVNRT, a reentry circuit is involved in the AV node. In addition, patients who have AVRT are born with a conducting tissue *(accessory pathway)* in the heart muscle. This accessory pathway bridges the atrium and ventricles outside of the AV node (Figure 22-53). The two pathways of the reentry circuit can be composed of one accessory pathway and the AV node, or it can be made up of two accessory pathways without the participation of the AV node. The accessory pathways can conduct impulses either antegrade, retrograde, or in both directions. This abnormal conduction results in preexcitation of the ventricles. (Preexcitation syndromes are discussed later in this chapter.)

Atrial tachycardia (AT) is a rhythm disturbance that arises from an irritable site in the atria. The ectopic focus overrides the SA node, producing tachycardia. AT does not require the AV junction, accessory pathways, or ventricular tissue to sustain the fast rate. The dysrhythmia presents very similar to sinus tachycardia; however, the P waves differ some in shape. The morphology of the P wave in AT depends on the location in the atrium that is responsible for the fast rate. AT that begins and ends abruptly is known as **paroxysmal atrial tachycardia** (PAT).

ETIOLOGY

SVTs may occur at any age. These dysrhythmias are common in young adults and are more common in women than in men. SVTs are not commonly associated with underlying heart disease and are rare in patients with myocardial infarction. (However, SVTs can precipitate angina pectoris or myocardial infarction in patients with heart disease.) Precipitating factors include stress, overexertion, tobacco use, caffeine consumption, and illicit drug use (e.g., cocaine). SVT is common in patients with Wolff-Parkinson-White syndrome (described later in this chapter).

RULES FOR INTERPRETATION (LEAD II MONITORING)

SVT has the following characteristics on the ECG:

- *QRS complex*: Less than 0.12 second, provided no ventricular conduction disturbance is present
- *P waves*: The ectopic P waves differ from the normal sinus P waves. In lead II, the P waves may be normal and upright if the pacemaker site is near the sinoatrial node but inverted if they originate near the atrioventricular junction. The P waves frequently are buried in preceding T or U waves or QRS complexes and therefore cannot be identified.
- *Rate*: 150 to 250 beats/minute
- *Rhythm:* Regular except at onset and termination
- *P-R interval*: If P waves are discernible, the P-R interval often is shortened but may be normal or, rarely, prolonged.

CLINICAL SIGNIFICANCE

Supraventricular tachycardia may occur in patients with healthy hearts. Patients may tolerate it well for short periods. Often the dysrhythmia is accompanied by

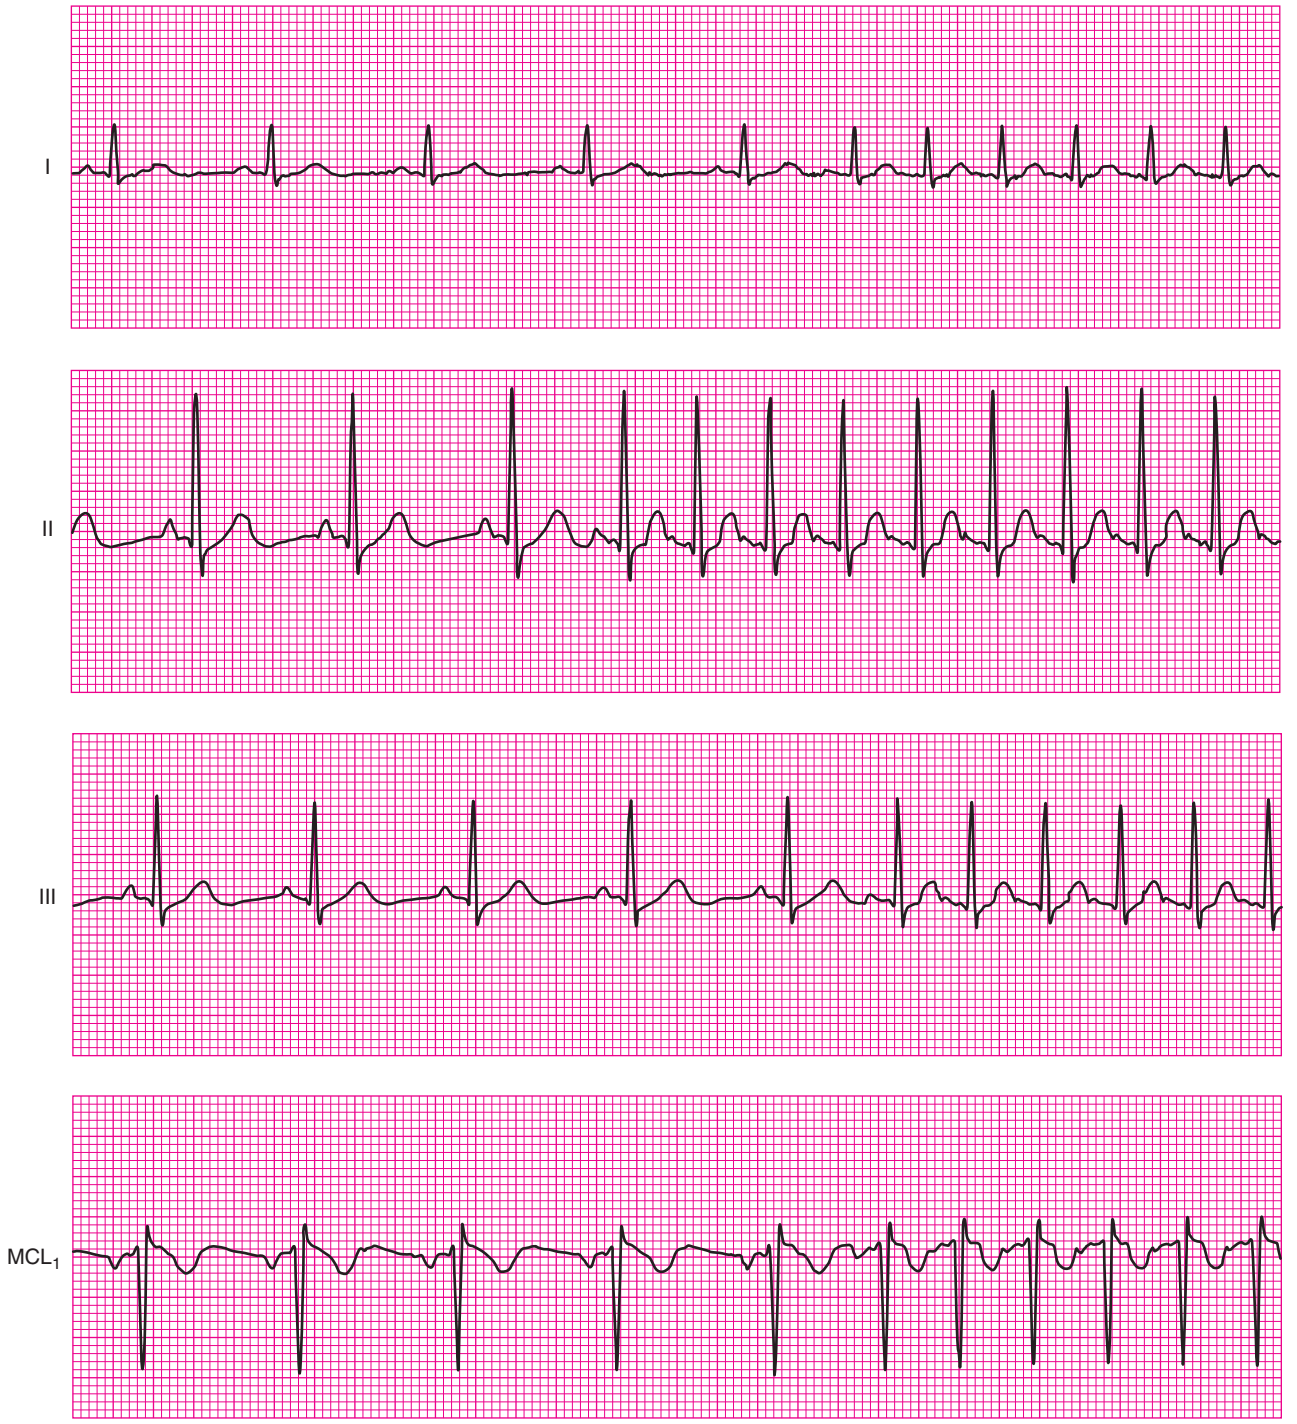

FIGURE 22-50 Paroxysmal supraventricular tachycardia.

palpitations, nervousness, and anxiety. (The patient often complains of a "racing heart.") A rapid ventricular rate may prevent the ventricles from filling fully. Therefore, SVT can compromise cardiac output in patients with existing heart disease. Decreased perfusion may cause confusion, vertigo, lightheadedness, and syncope and may precipitate angina pectoris, hypotension, or congestive heart failure. In addition, SVT increases the oxygen requirement of the heart. This may increase myocardial ischemia and the frequency and severity of the patient's chest pain.

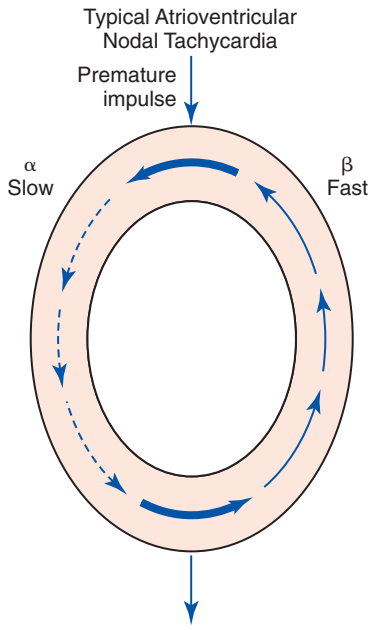

FIGURE 22-51 Atrioventricular nodal reentrant tachycardia (AVNRT) pathway.

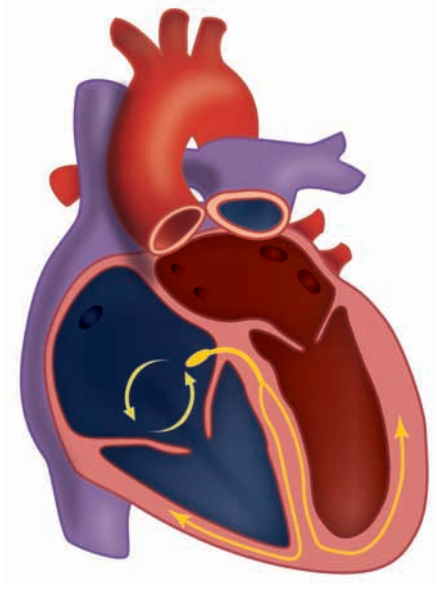

FIGURE 22-52 Atrioventricular nodal reentrant tachycardia (AVNRT).

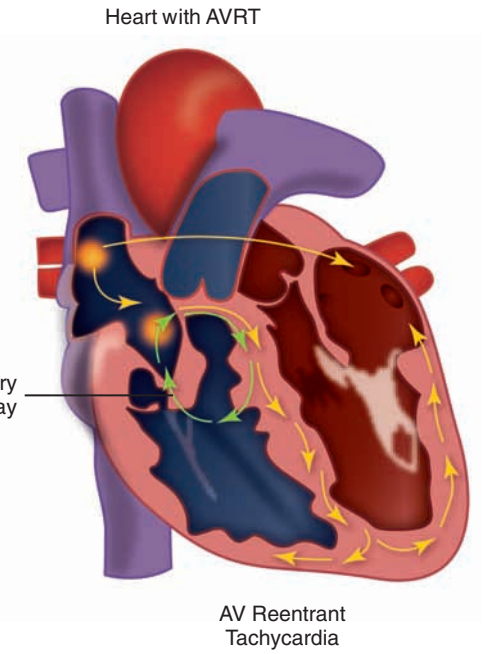

FIGURE 22-53 Atrioventricular nodal tachycardia (AVNT).

NOTE

The distinctions among the various supraventricular tachycardias and ventricular tachycardia (a lethal rhythm) may be difficult to make. However, they are crucial. Two critical points to remember are these. First, if the patient has serious signs and symptoms (particularly if the ventricular rate is greater than 150 beats/minute), the paramedic should prepare for immediate cardioversion. Second, if the tachycardia complex appears wide, the paramedic should manage the rhythm as ventricular tachycardia. These two clinical rules should help manage the most difficult tachydysrhythmias. Use of modified chest leads may help identify these rhythms.

MANAGEMENT

The paramedic should manage symptomatic supraventricular tachycardia promptly. This helps reverse the consequences of the reduced cardiac output and increased workload of the heart. If the patient is stable (conscious with normal blood pressure and without chest pain, congestive heart failure, or pulmonary edema), the paramedic should attempt the following techniques to terminate the supraventricular tachycardia (Figure 22-54).

Vagal Maneuvers. Vagal maneuvers can slow the heart and reduce the force of atrial contraction. These maneuvers stimulate the parasympathetic nerve fibers in the wall of the atria and in specialized tissues of the SA and AV nodes. They can interrupt and terminate some supraventricular tachycardias. Vagal maneuvers should be attempted only under medical direction. Furthermore, the patient must be stable (conscious, normotensive, and without chest pain, congestive heart failure, or pulmonary edema). Continuous ECG monitoring and an intravenous line must be in place before beginning these procedures. ***Atropine*** and airway equipment should be readily available. Vagal maneuvers include the **Valsalva maneuver,** the ice pack maneuver in children, and unilateral carotid sinus pressure.

Valsalva Maneuver. The paramedic should place the patient in a sitting or semi-sitting position with the head tilted down. The patient should be instructed to take in a deep breath and to bear down as if to have a bowel movement. (Children can be instructed to blow through a straw.) The forced expiration against a closed glottis stimulates the vagus nerve and may terminate the tachycardia. The procedure may be repeated if unsuccessful.

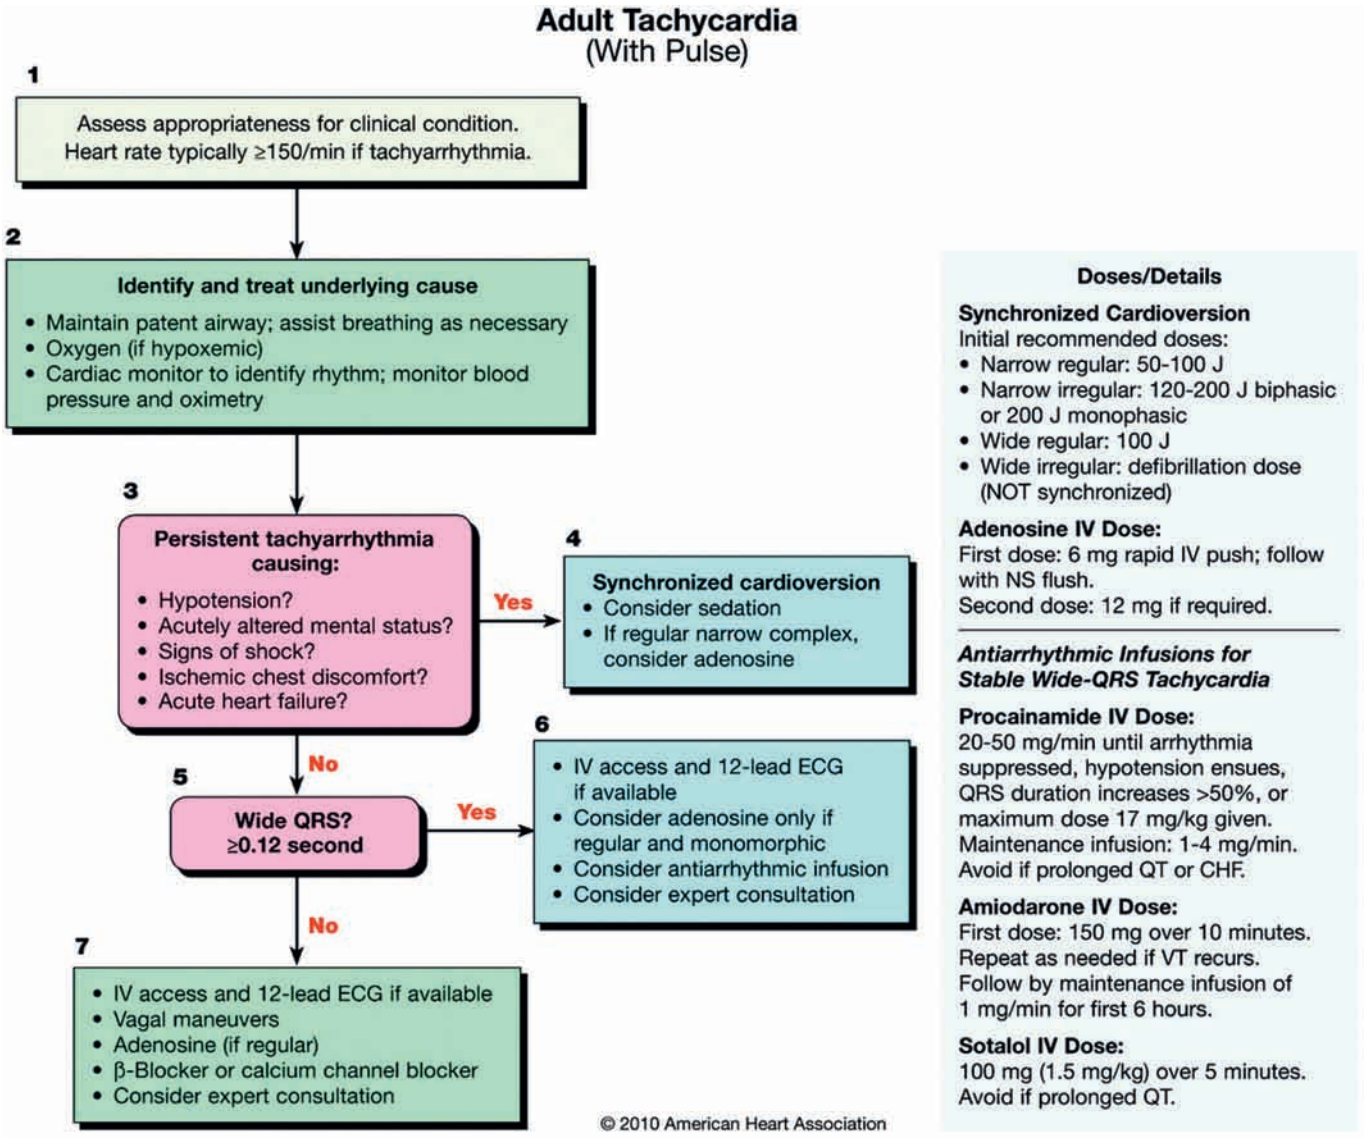

FIGURE 22-54 Tachycardia algorithm. (Reprinted with permission, American Heart Association Guidelines For CPR and ECC, *Circulation 122* [suppl 3]:S685-S919, American Heart Association, Inc, 2010.)

Ice Pack Maneuver. Placing an ice pack on the anterior neck of an infant or young child may stimulate the vagus nerve because of the *mammalian diving reflex* (see Chapter 45). (In the pediatric patient, this technique is performed with a washcloth soaked in ice water. The washcloth is placed across the patient's face, about to nostril level.) The paramedic should not attempt the ice pack maneuver if ischemic heart disease is present or suspected. The procedure may be repeated (per medical direction) if unsuccessful.

Unilateral Carotid Sinus Pressure. Carotid sinus pressure (carotid sinus massage) stimulates the carotid bodies located in the carotid arteries. The body interprets this localized pressure as an increase in blood pressure. This activates the autonomic nervous system and stimulates the vagus nerve. The heart rate slows in an attempt to lower blood pressure. The paramedic should auscultate the carotid arteries for the presence of a bruit (described in Chapter 20) before applying carotid sinus pressure. This vagal maneuver should not be used if bruits are present, if the patient is an older adult, or if the patient is known to have carotid artery disease or cerebral vascular disease. Possible complications from the procedure include cerebral emboli, stroke, syncope, sinus arrest, asystole, and an increased degree of atrioventricular block.[1] The procedure for applying unilateral carotid sinus pressure is as follows (Figure 22-55):

LOOK AGAIN
See Chapter 20: Secondary Assessment, pp. 542-543.

1. Position yourself behind the patient, who is lying supine with the neck extended and the head turned away from the side of the applied pressure.

FIGURE 22-55 Carotid sinus massage.

2. Gently palpate each carotid artery to confirm the presence of equal pulses. If pulses are unequal or if one is absent, do not apply carotid sinus pressure.
3. While the patient holds his or her breath for 4 to 5 seconds, auscultate for the presence of bruits.
4. To apply carotid sinus pressure, place the index and middle fingers over the artery on the neck just below the angle of the jaw. Compress the artery firmly against the vertebral column while massaging the area. (Inform the patient that he or she may experience some pain or discomfort.) Maintain pressure no longer than 5 to 10 seconds. Discontinue the massage immediately if bradycardia or signs of heart block develop or if the tachycardia breaks. *Apply pressure to only one carotid sinus at a time. Applying bilateral carotid sinus pressure may interfere with cerebral circulation.*
5. Observe the ECG monitor and run a strip during the procedure and obtain a tracing. Repeat the procedure in 2 to 3 minutes if it is ineffective.

CRITICAL THINKING
You perform carotid sinus massage on a patient with bruits or known carotid artery disease. What might occur?

Pharmacological Therapy. If vagal maneuvers fail or are contraindicated and the patient remains stable, administration of ***adenosine*** (the initial drug of choice), ***verapamil, diltiazem,*** beta blockers ***(metoprolol),*** or other antidysrhythmics may end symptomatic SVT.

NOTE
Supraventricular tachycardia (SVT) may be the result of an underlying rhythm (e.g., atrial fibrillation with a rapid ventricular response). The prudent course is to monitor the ECG continuously and run a strip while administering ***adenosine.*** This allows the underlying rhythm to be captured once the heart rate slows. Other medications may be needed to treat the underlying rhythm (e.g., ***diltiazem*** *or* ***verapamil***). It is not uncommon for the underlying rhythm to revert to SVT, requiring additional drug therapy.

NOTE
Administration of *diltiazem or* ***verapamil*** to a patient with ventricular tachycardia can be lethal. The paramedic must carefully evaluate the patient's ECG to distinguish between SVT with aberrant conduction and ventricular tachycardia. If the complexes are wide and ventricular tachycardia is suspected, the paramedic should manage the rhythm in the same way as ventricular tachycardia.

CRITICAL THINKING
What are some of the side effects of verapamil?

Drug treatment recommended by the American Heart Association for stable narrow-complex supraventricular tachycardias is based on rhythm interpretation and the stability of the patient .People with heart disease may experience a rapid heart rate, yet remain clinically stable. These patients often are chronically ill with heart disease and have adjusted to a reduced level of cardiac function. Based on the patient history and physical examination, the paramedic should be able to distinguish between acute and chronic or stable congestive heart failure. A ***sudden*** onset of signs and symptoms of congestive heart failure with impaired cardiac function (e.g., jugular vein distention, dyspnea, tachycardia, chest pain, or decreased level of consciousness) indicates that the patient is unstable.

Junctional tachycardia in adults is rare; it is not paroxysmal. Ectopic atrial tachycardia is also not paroxysmal. It often continues after drug treatment to block conduction through the AV node. Unlike reentry dysrhythmias, ectopic atrial tachycardia, multifocal atrial tachycardia, and sinus tachycardia are not responsive to electrical cardioversion.

For simplicity, in symptomatic narrow complex SVT, vagal maneuvers and ***adenosine*** should be used first to end the tachydysrhythmia. If ***adenosine*** is not effective and if the patient is hemodynamically stable and has no evidence of congestive heart failure, secondary drug treatment options include calcium channel blockers and beta blockers**.** These agents most likely will be used after diagnosis and evaluation by a physician.

Consecutive use of calcium channel blockers, beta blockers, and primary antidysrhythmics is discouraged. The general rule is to use only one antidysrhythmic agent; using several can result in more dysrhythmias and a drop in blood pressure. Furthermore, the paramedic should avoid negative inotropic drugs (***verapamil,*** beta blockers, flecainide, ***procainamide,*** propafenone, and sotalol) in hemodynamically unstable patients.

Several drug treatments are available for narrow-complex tachycardias (ventricular rate equal to or greater than 150 beats/minute). However, when serious signs and symptoms point to poor perfusion and clinical instability, synchronized electrical cardioversion is the treatment of choice to terminate the rhythm. (Cardioversion is presented later in this chapter.) Cardioversion should begin with a synchronized shock of 50 J or equivalent biphasic energy. (Atrial fibrillation should first be managed with a shock of 100 to 120 J biphasic.[1] If this fails, the energy may be increased in a stepwise manner per manufacturer's recommendation. Sedation should be considered before cardioversion if time permits.

NOTE
Cardioversion encompasses vagal, pharmacological, and electrical therapy. However, the term commonly is used to refer to electrical cardioversion.

CRITICAL THINKING
Why is the drug midazolam an ideal sedative to administer before cardioversion?

Atrial Flutter

DESCRIPTION

Atrial flutter is almost always a result of a rapid atrial reentry focus (Figure 22-56). Atrial flutter that is not slowed by preexisting atrioventricular block usually manifests a 2:1 atrioventricular conduction ratio and may look like SVT. (A 2:1 AV conduction ratio means that 50% of the atrial impulses are conducted through the ventricles.) However, 3:1, 4:1, and greater conduction ratios are not uncommon. These ratios produce a discrepancy between atrial and ventricular rates. The conduction ratios may be constant or variable. Atrial flutter may be seen with atrial fibrillation *(atrial fib-flutter)*. In rare cases, atrial flutter may conduct 1:1. This results in extremely fast ventricular rates with rapid hemodynamic deterioration.

ETIOLOGY

Atrial flutter usually is seen in middle-aged or older patients who have heart disease. At times, atrial flutter also occurs in patients with healthy hearts. The dysrhythmia commonly is associated with the following:

- Cardiomyopathy
- Cardiac hypertrophy
- Digitalis toxicity (rare)
- Hypoxia
- Congestive heart failure
- Pericarditis
- Myocarditis

RULES FOR INTERPRETATION (LEAD II MONITORING)

Atrial flutter has the following characteristics on the ECG:

QRS complex: Less than 0.12 second, unless ventricular conduction disturbance (aberrancy) is present

P waves: Normal P waves are absent. The flutter waves (f waves) usually resemble a sawtooth or picket fence pattern. The flutter waves represent atrial depolarization in an abnormal direction that is followed by atrial repolarization.

NOTE
Flutter waves may be difficult to identify with a 2:1 ratio of atrial to ventricular complexes. The paramedic should suspect 2:1 flutter when the rhythm is regular and the ventricular rate is 150 beats/minute.

Rate: The atrial rate is 250 to 300 beats/minute; the ventricular rate is regular but often less than the atrial rate.

FIGURE 22-56 Atrial flutter.

Rhythm: The atrial rhythm is regular; the ventricular rate is usually regular. However, the ventricular rate may be irregular if the AV conduction ratio varies.

P-R interval: Usually constant but may vary

CLINICAL SIGNIFICANCE

With a normal ventricular rate, atrial flutter usually is well tolerated by the patient. A rapid ventricular rate produces the same signs and symptoms of decreased cardiac output that are seen in patients with SVT. In addition, in some flutter rhythms (particularly a 2:1 atrial flutter), the atria do not contract regularly and empty before each ventricular contraction. The loss of the "atrial kick" results in incomplete filling of the ventricles. This may further reduce cardiac output.

MANAGEMENT

See Management of Atrial Fibrillation and Atrial Flutter.

NOTE
The pulse rate of a patient with this dysrhythmia (and other tachycardias) might not reflect the true heart rate. This is because not all heart contractions produce enough output of blood to create a palpable pulse.

Atrial Fibrillation

DESCRIPTION

Atrial fibrillation results from multiple areas of reentry within the atria (Figure 22-57). It also can result from ectopic atrial pacemakers. (The activity of the SA node is suppressed completely by atrial fibrillation.) Atrial fibrillation produces chaotic impulses too numerous for all to be conducted by the AV node through the ventricles. AV conduction is random. This results in an irregular but usually rapid ventricular response. Medications such as digoxin, beta blockers, or calcium channel blockers often are prescribed to slow the ventricular rate.

ETIOLOGY

Sudden onset (paroxysmal) atrial fibrillation may occur in young adults after heavy alcohol ingestion ("holiday heart" syndrome) or acute stress. In these cases, the fibrillation usually is self-limited and resolves without treatment. Chronic atrial fibrillation may be intermittent. It often is associated with rheumatic heart disease, congestive heart failure, and coronary heart disease. Chronic atrial fibrillation usually requires drug therapy with digitalis (or a calcium channel blocker or beta blocker). This slows the ventricular rate to 80 to 100 beats/minute. Atrial fibrillation may be a stable rhythm that does not require management. Less commonly, it may occur in cardiomyopathy, acute myocarditis and pericarditis, and chest trauma. It rarely is caused by digitalis toxicity. However, a slow, regular ventricular response with atrial fibrillation could be the result of digitalis toxicity.

RULES FOR INTERPRETATION (LEAD II MONITORING)

Atrial fibrillation has the following characteristics on the ECG:

QRS complex: Less than 0.12 second, provided no ventricular conduction disturbance is present

P waves: P waves and organized atrial contractions are absent. Fibrillation waves (f waves) may be fine (less than 1 mm) or coarse (greater than 1 mm). Fine f waves may be so small that they appear as a wavy or flat (isoelectric) line or are absent. The f waves are irregularly shaped, rounded (or pointed), and dissimilar.

Rate: The atrial rate is 350 to 700 beats/minute (cannot be counted); the ventricular rate varies greatly, depending on conduction through the AV node (average 150 to 180 beats/minute if uncontrolled).

Rhythm: Irregularly irregular

P-R interval: None

NOTE
Irregularly irregular rhythms are most likely to be atrial fibrillation.

CLINICAL SIGNIFICANCE

The atrial kick is lost in atrial fibrillation. This loss can reduce cardiac output by as much as 15%. This, coupled with a rapid ventricular response, may cause cardiovascular decompensation (angina pectoris, myocardial infarction, congestive heart failure, or cardiogenic shock).

MANAGEMENT OF ATRIAL FIBRILLATION AND ATRIAL FLUTTER

A risk of emboli formation exists when atrial fibrillation or atrial flutter has been present for longer than 48 hours. Formation of emboli in the heart increases the risk of "throwing a clot" or systemic embolization. This most often occurs when the atrial fibrillation is converted suddenly to a sinus rhythm. The algorithm cautions against converting atrial fibrillation or atrial flutter without first giving the patient drugs that prevent blood clotting. Electrical cardioversion and the use of antidysrhythmic agents that may convert the rhythm should be avoided unless the patient is unstable or hemodynamically compromised.[6]

Using drugs to control the heart rate is the recommended initial treatment for stable, rapid atrial fibrillation or atrial flutter regardless of how long the patient has had it. Specific drug treatment depends on the patient's condition and how stable the patient is. Using several different drugs can cause a dysrhythmia to develop (a **proarrhythmia**). The paramedic should use only one drug from the list of suggested drug treatments.

In patients with a rapid atrial fibrillation or flutter with a rapid ventricular response, the rate may be controlled with ***diltiazem*** or beta blockers. ***Amiodarone*** has a potential for rhythm conversion. Thus ***amiodarone*** should be reserved for use within the first 48 hours of dysrhythmia onset when other medications for rate control have failed. The use of calcium channel blocking agents and beta-blocking agents warrants caution in the presence of congestive heart failure because of their negative inotropic properties. Beta-blocking agents also should be used with caution in patients with asthma and chronic obstructive pulmonary disease. Another drug that may be effective for converting the rhythm is digoxin. Digoxin should be used only if the patient developed atrial fibrillation within 48 hours or less.

If the patient reports a history of Wolff-Parkinson-White syndrome or if the paramedic forms that impression in the field before the patient developed atrial fibrillation, alternative treatment is indicated.

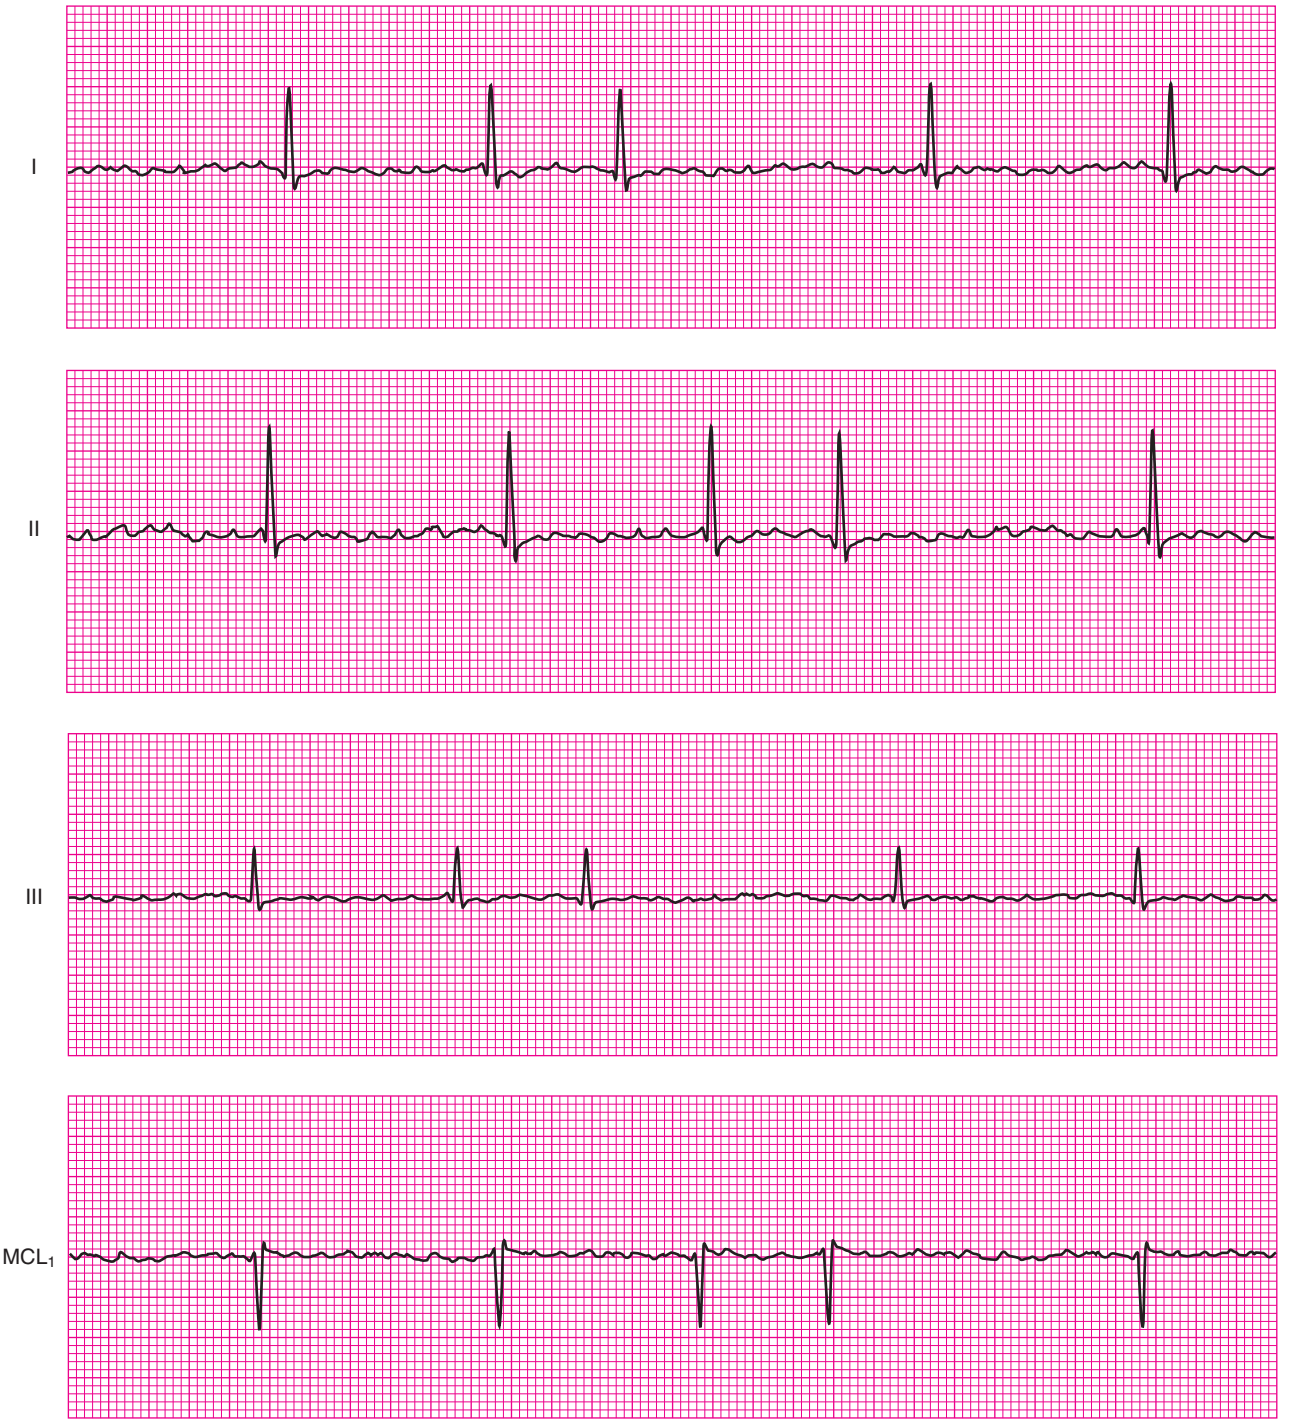

FIGURE 22-57 Atrial fibrillation.

If the patient has WPW syndrome, paramedics should not give ***adenosine, diltiazem, verapamil, digoxin*** or, in most cases, beta blockers. These drugs may cause a dangerous increase in the heart rate. If the patient has had the dysrhythmia for longer than 48 hours, the paramedic should avoid elective cardioversion except when the patient is unstable unless anticoagulation drugs have been given. However, when serious signs or symptoms occur, such as chest pain, shortness of breath, pulmonary congestion, a decreased level of consciousness, or hypotension, the paramedic should cardiovert the patient immediately. The initial attempt at cardioversion for atrial flutter should consist of a synchronized shock of 50 to 100 J.[1] If needed, the energy may be increased in a stepwise manner according to manufacturer's recommendations. Because atrial fibrillation is a more difficult rhythm to convert and lower joule settings have been known to cause asystole, recommendations are initially to use a synchronized shock of 100 to 120 J biphasic (200 J monophasic), followed by stepwise increases as recommended by the manufacturer if necessary (Box 22-7).[1]

BOX 22-7 Atrial Fibrillation/Flutter

With or without congestive heart failure:

Rate control	Diltiazem
Rhythm conversion	Nonemergency chemical or direct current cardioversion should be avoided, if possible; when indicated, it should be performed only by an experienced health care provider after careful evaluation and initiation of thromboembolic precautions.

DID YOU KNOW?

Catheter Ablation Therapy

Catheter ablation is an in-hospital procedure performed in an electrophysiology (EP) laboratory. During the procedure (which lasts several hours), three to five catheters are inserted into the heart through an artery or vein (or both) in the groin, neck, or arm. A transducer is inserted through one of the catheters so that intracardiac ultrasonography can be performed during the procedure. The ablation catheter is moved from spot to spot (mapping) to identify the origin of a dysrhythmia. A pacemaker-like device then is used to send electrical impulses to the heart to induce tachycardia. Once the area of the heart responsible for the dysrhythmia has been identified, an electrical impulse is delivered to the area through the catheter. The goal is to "disconnect" the pathway of the abnormal rhythm. Catheter ablation can be used to treat the following conditions:

- AV node reentrant tachycardia
- Accessory pathway disturbances
- Atrial fibrillation and atrial flutter
- Ventricular tachycardia

CRITICAL THINKING

What signs or symptoms would make you think these patients are unstable?

DYSRHYTHMIAS SUSTAINED OR ORIGINATING IN THE ATRIOVENTRICULAR JUNCTION

When the SA node and the atria cannot generate the electrical impulses needed to begin depolarization because of factors such as hypoxia, ischemia, myocardial infarction, and drug toxicity, the AV node or the area surrounding the AV node may assume the role of the secondary pacemaker. Rhythms that start in the AV node or AV junctional area are *junctional rhythms*. This type of rhythm usually is a benign dysrhythmia. Yet the paramedic must assess the rhythm to determine the patient's tolerance of the rhythm disturbance. Dysrhythmias that originate in the AV junction include premature junctional complexes, junctional escape complexes or junctional escape rhythms, and accelerated junctional rhythm.

In junctional rhythms, electrical impulses travel in a normal pathway from the AV junction through the bundle of His and bundle branches to the Purkinje fibers. The pathway ends in the ventricular muscle. Conduction through the ventricles proceeds normally. The QRS complex, therefore, usually is within normal limits (0.04 to 0.10 second). However, the impulse that depolarizes the atria travels in a backward or retrograde motion. The retrograde depolarization of the atria results in one of three P wave characteristics: (1) inverted P waves in lead II with a short P-R interval; (2) absent P waves; or (3) P waves after the QRS complex.

Premature Junctional Complex

DESCRIPTION

A **premature junctional complex** (PJC) results from a single electrical impulse from the AV junction (Figure 22-58). The impulse occurs before the next expected sinus impulse.

ETIOLOGY

Isolated PJCs may occur in a healthy person without apparent cause. Yet they more often are a result of heart disease or drug toxicity. Usually PJCs result from enhanced automaticity or a reentry mechanism. Premature junctional complexes have several causes:

- Digitalis toxicity
- Other cardiac medications (quinidine, ***procainamide***)
- Increased vagal tone on the SA node
- Sympathomimetic drugs (e.g., cocaine, methamphetamines)
- Hypoxia
- Congestive heart failure
- Damage to the AV junction

CRITICAL THINKING

Would the P wave be visible if it occurred during the QRS wave?

RULES FOR INTERPRETATION (LEAD II MONITORING)

Premature junctional complexes have the following characteristics on the ECG:

QRS complex: Usually less than 0.12 second, provided no ventricular conduction disturbance is present

P waves: May be associated with premature junctional complexes. P waves may occur before, during, or after the QRS complex or may be absent. If present, P waves are abnormal, differing in size, shape, and direction from normal P waves.

Rate: The heart rate is that of the underlying rhythm.

Rhythm: Usually regular, except when premature junctional complexes are present

P-R interval: Usually less than 0.12 second if the P wave precedes the QRS complex

CLINICAL SIGNIFICANCE

Occasional premature junctional complexes usually are not significant.

MANAGEMENT

No management is required.

Junctional Escape Complexes or Rhythms

DESCRIPTION

A **junctional escape beat** or rhythm (series of beats) occurs when the rate of the SA node falls below that of the AV junction (Figure 22-59). The dysrhythmia also may occur when the electrical impulses from the SA node or atria fail to reach the AV junction because of sinoatrial or

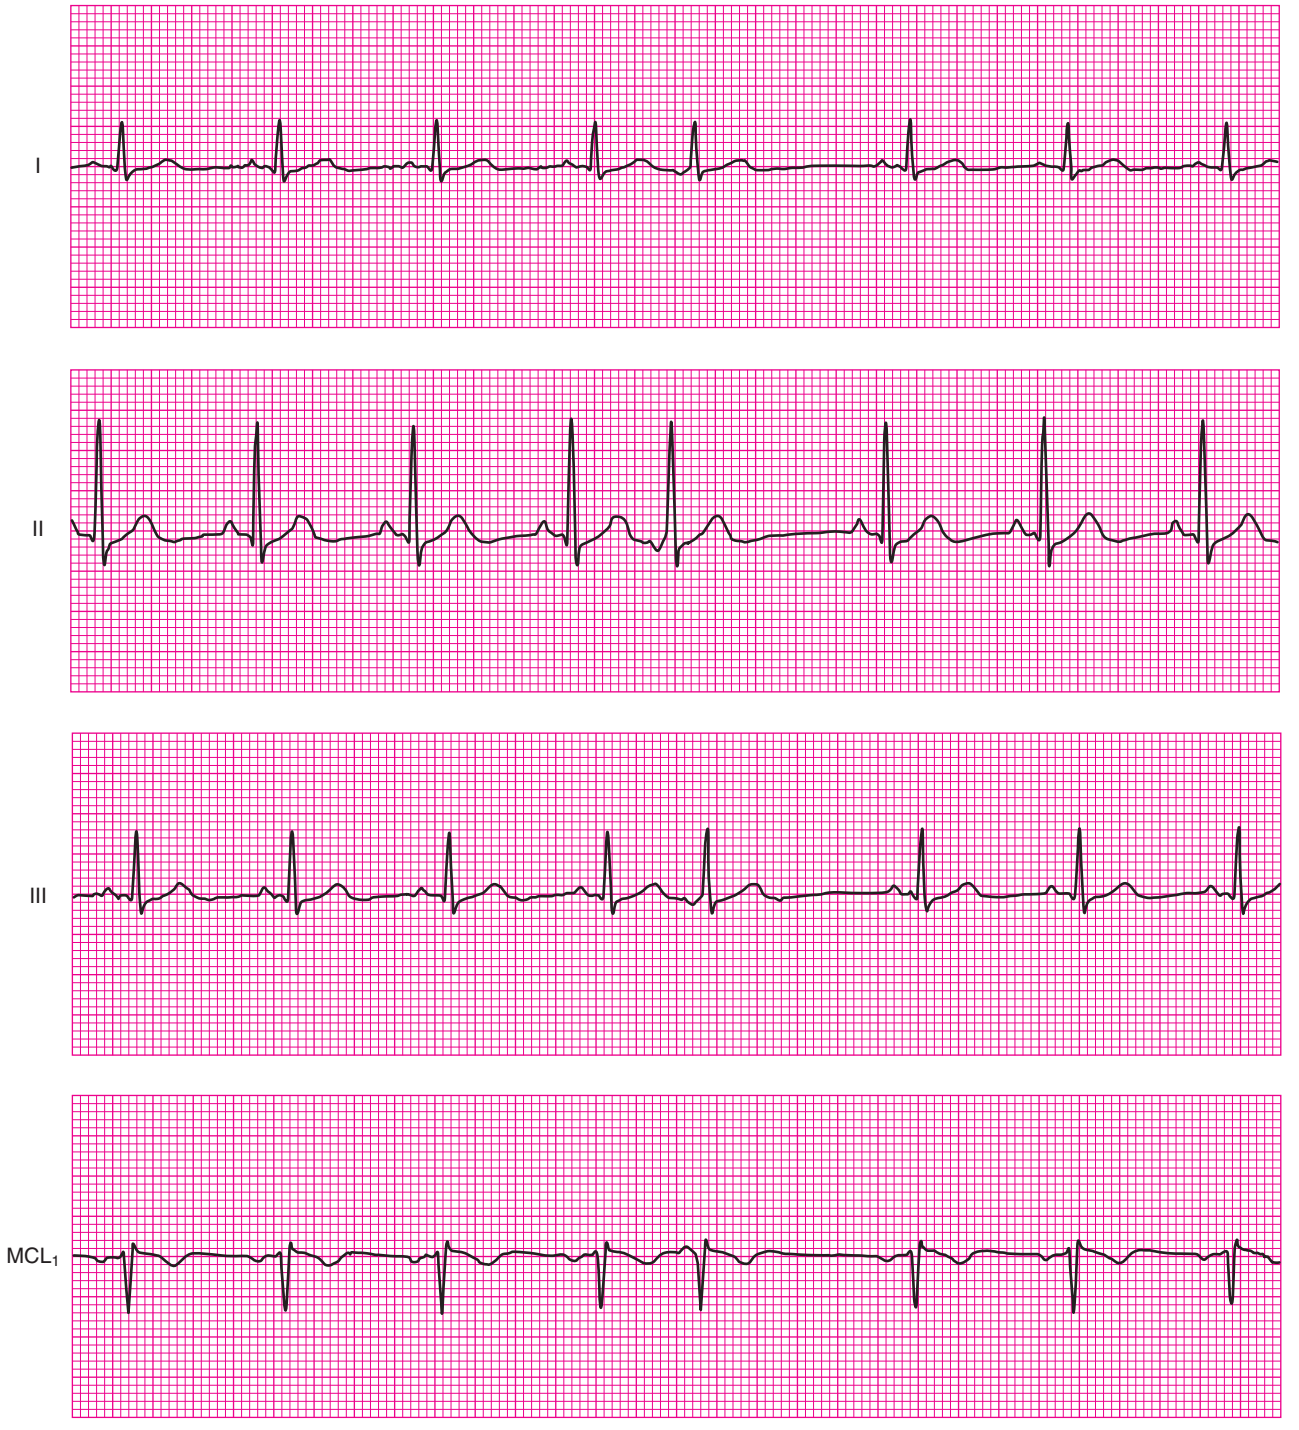

FIGURE 22-58 Premature junctional complexes.

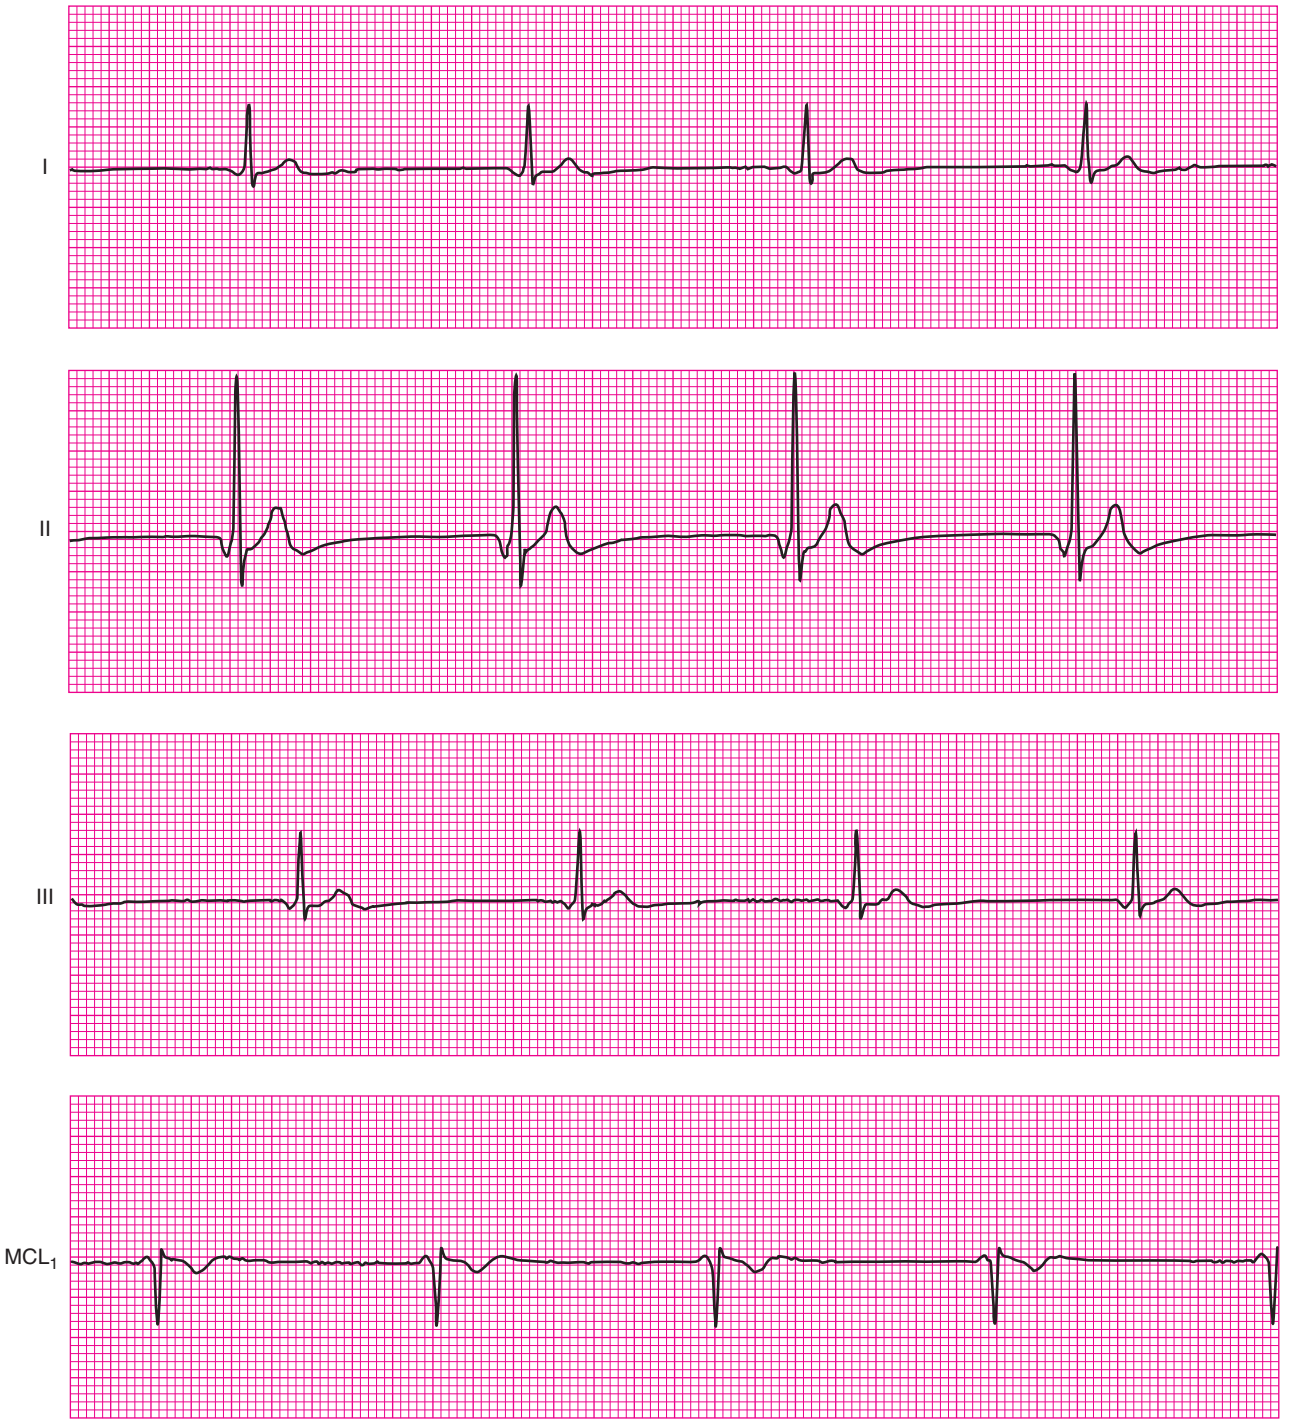

FIGURE 22-59 Junctional escape complex or rhythm.

atrioventricular block. The escape complex or rhythm provided by the AV junction serves as a safety mechanism. This mechanism prevents cardiac standstill. The AV junction begins firing at an inherent rate of 40 to 60 beats/minute within about 1 to 1.5 seconds of not receiving an impulse from the SA node.

ETIOLOGY

A junctional escape complex (isolated impulse) or a junctional escape rhythm (series of impulses) is a normal response. It may result from increased vagal tone on the sinoatrial node, a pathological slowing of the sinoatrial discharge, or complete atrioventricular block.

RULES FOR INTERPRETATION (LEAD II MONITORING)

Junctional escape complexes or rhythms have the following characteristics on the ECG:

- *QRS complex*: Usually less than 0.12 second, provided no preexisting bundle branch block is present
- *P waves*: May be present (with or without relationship to QRS complex) or absent. If P waves are present, they may occur before, after, or during the QRS complex. Depending on the pacemaker site, P waves may differ from normal P waves in size, shape, and direction and may be upright or inverted.
- *Rate*: Usually 40 to 60 beats/minute but may be less
- *Rhythm*: The ventricular rhythm usually is regular in junctional escape rhythm; it may be irregular if an isolated junctional escape complex is present.
- *P-R interval*: If P waves precede the QRS complex, the P-R interval commonly is shortened (less than 0.12 second) and constant.

CLINICAL SIGNIFICANCE

Junctional bradycardias can cause decreased cardiac output. Therefore, patients can have signs and symptoms similar to those of other bradycardias (e.g., the signs may include lightheadedness, hypotension, and syncope). As a rule, patients tolerate junctional rhythms of 50 beats/minute or greater.

MANAGEMENT

Patients who are stable do not need to be treated. If the patient is symptomatic or if ventricular irritability is present, drug therapy (beginning with ***atropine***) may be indicated. In severe cases and in patients unresponsive to ***atropine,*** external pacing may be necessary. If the sinoatrial node is diseased or damaged, the patient may need a permanent pacemaker (see Figure 22-43).

Accelerated Junctional Rhythm

DESCRIPTION

Accelerated junctional rhythm results from increased automaticity of the atrioventricular junction (Figure 22-60). This increase causes it to discharge faster than its intrinsic rate. (The intrinsic rate is 40 to 60 beats/minute.) This rate in turn overrides the main (sinoatrial node) pacemaker. The rate of this dysrhythmia (usually 60 to 99 beats/minute) does not truly constitute a tachycardia. Therefore, the dysrhythmia is called *accelerated junctional rhythm*. In this text, rapid junctional rhythms equal to or greater than 100 beats/minute (junctional tachycardia caused by a reentry mechanism) are discussed with other supraventricular tachycardias.

ETIOLOGY

An accelerated junctional rhythm commonly is a result of digitalis toxicity. Other causes of this rhythm include excessive catecholamine administration, damage to the atrioventricular junction, inferior wall myocardial infarction (described later in this chapter), and rheumatic fever.

RULES FOR INTERPRETATION (LEAD II MONITORING)

Accelerated junctional rhythm has the following characteristics on the ECG:

- *QRS complex*: Usually less than 0.12 second, provided no preexisting bundle branch block is present
- *P waves*: May be present (with or without relationship to the QRS complex), absent (retrograde atrioventricular block), or buried in the QRS complex. If present, P waves usually are inverted and appear before or after the QRS complex.
- *Rate*: Usually 60 to 99 beats/minute
- *Rhythm*: Regular
- *P-R interval*: If the P wave occurs before the QRS complex, the P-R interval will be less than 0.12 second. If the P wave follows the QRS complex, it technically is an R-P interval and usually is less than 0.20 second.

CLINICAL SIGNIFICANCE

Accelerated junctional rhythm usually is well tolerated by the patient. However, heart disease and lack of oxygen to the heart muscle may cause more serious dysrhythmias.

MANAGEMENT

Accelerated junctional rhythm generally requires no immediate treatment.

CRITICAL THINKING

Because no drug therapy is indicated, do you need to start an intravenous line on these patients?

DYSRHYTHMIAS ORIGINATING IN THE VENTRICLES

Ventricular dysrhythmias usually are considered a threat to life. Ventricular rhythm disturbances generally result from failure of the atria, atrioventricular junction, or both to initiate an electrical impulse. Such disturbances also can result from enhanced automaticity or reentry pathways in the ventricles. Enhanced automaticity and reentry can lead to premature ventricular complexes, ventricular tachycardia, and even ventricular fibrillation. Ventricular dysrhythmias often are associated with myocardial ischemia or infarction.

The ventricle is the least efficient pacemaker of the heart. It usually generates only 20 to 40 impulses per minute. However, it may discharge at rates up to 99 impulses per minute (accelerated idioventricular rhythm) or even faster (ventricular tachycardia) because of increased automaticity. Dysrhythmias originating in the ventricles include ventricular escape complexes or rhythms, premature ventricular complexes, ventricular tachycardia, ventricular fibrillation, asystole, and artificial pacemaker rhythm.

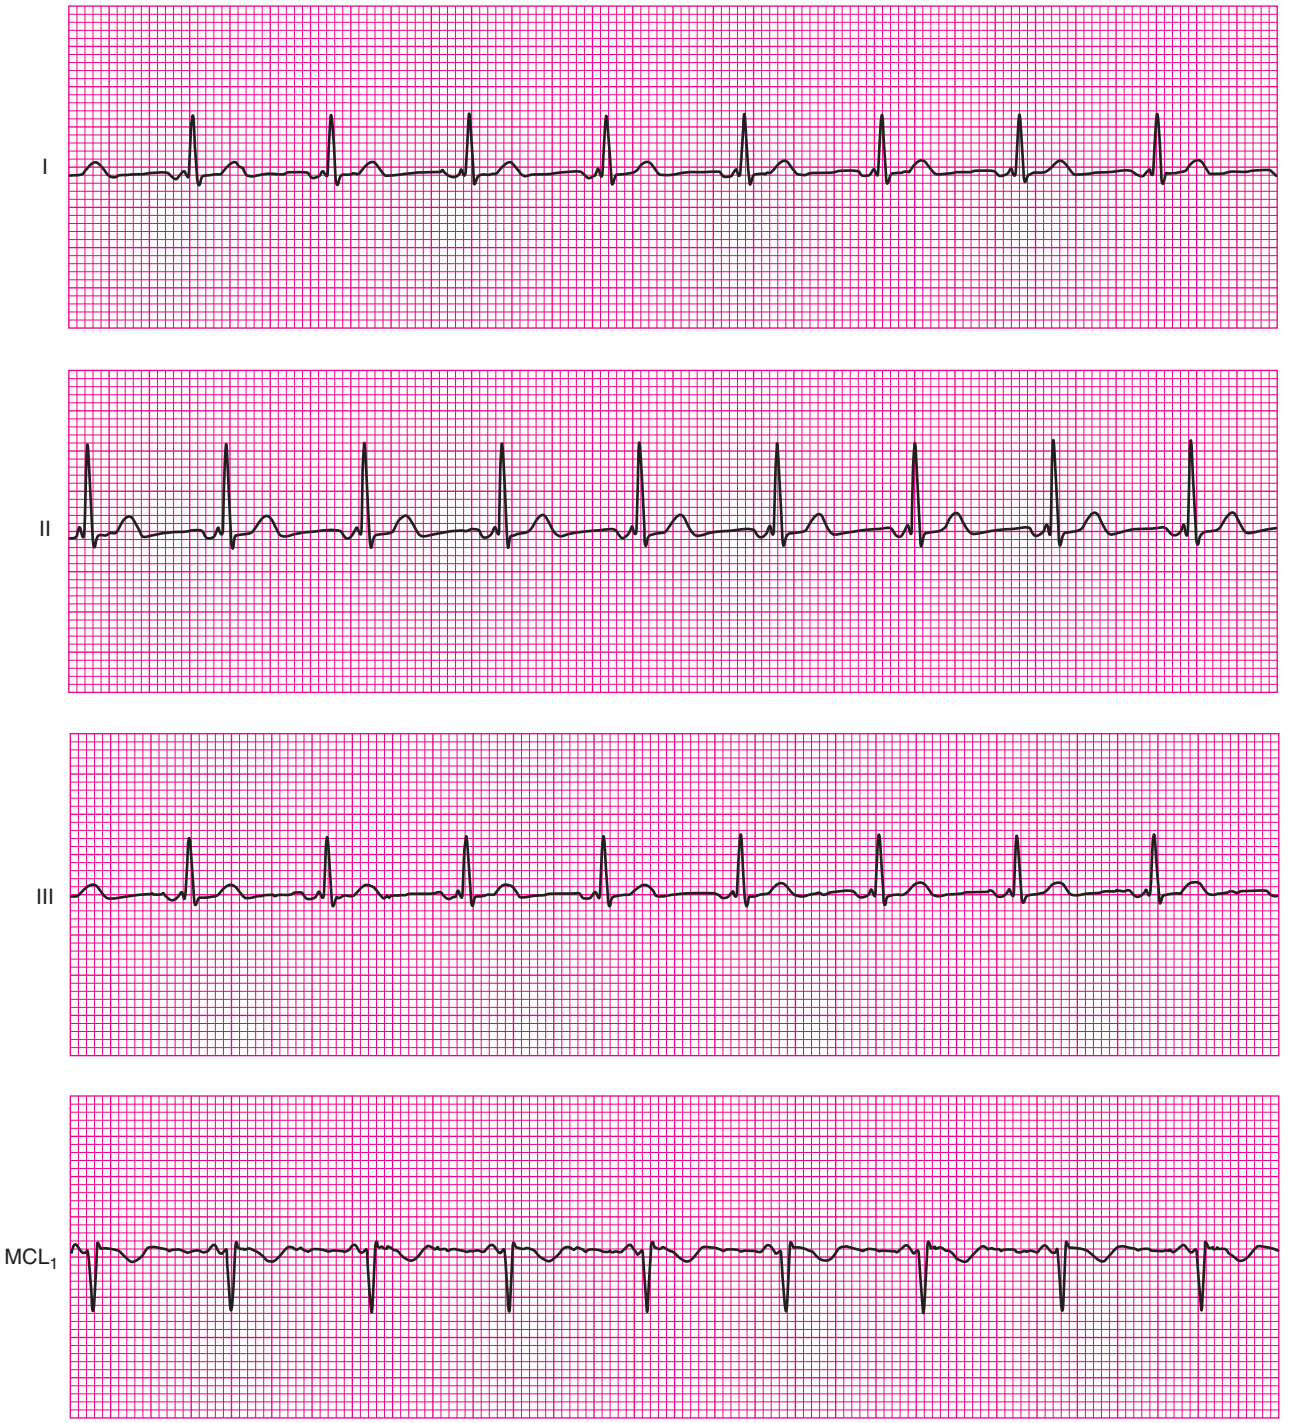

FIGURE 22-60 Accelerated junctional rhythm.

Because electrical impulses of ventricular origin start in the lower portion of the heart (the ventricular muscle, bundle branches, or Purkinje fibers), the electrical impulse must travel in a retrograde conduction pathway to depolarize the atria. The impulse may travel in an antegrade direction to depolarize the ventricles, depending on the site of initiation of the impulse. Regardless of the direction of depolarization, the normal, rapid conducting pathways are bypassed, producing three ECG features:

- QRS complexes are wide and bizarre in appearance. They are 0.12 second or greater in duration.
- P waves may be hidden in the QRS complex (this is because the atria are depolarized at about the same time as the ventricles), Alternatively, they may be superimposed on every second or third QRS complex when ventricular tachycardia with **atrioventricular dissociation** (P waves that have no set relation to the QRS complexes) is present.

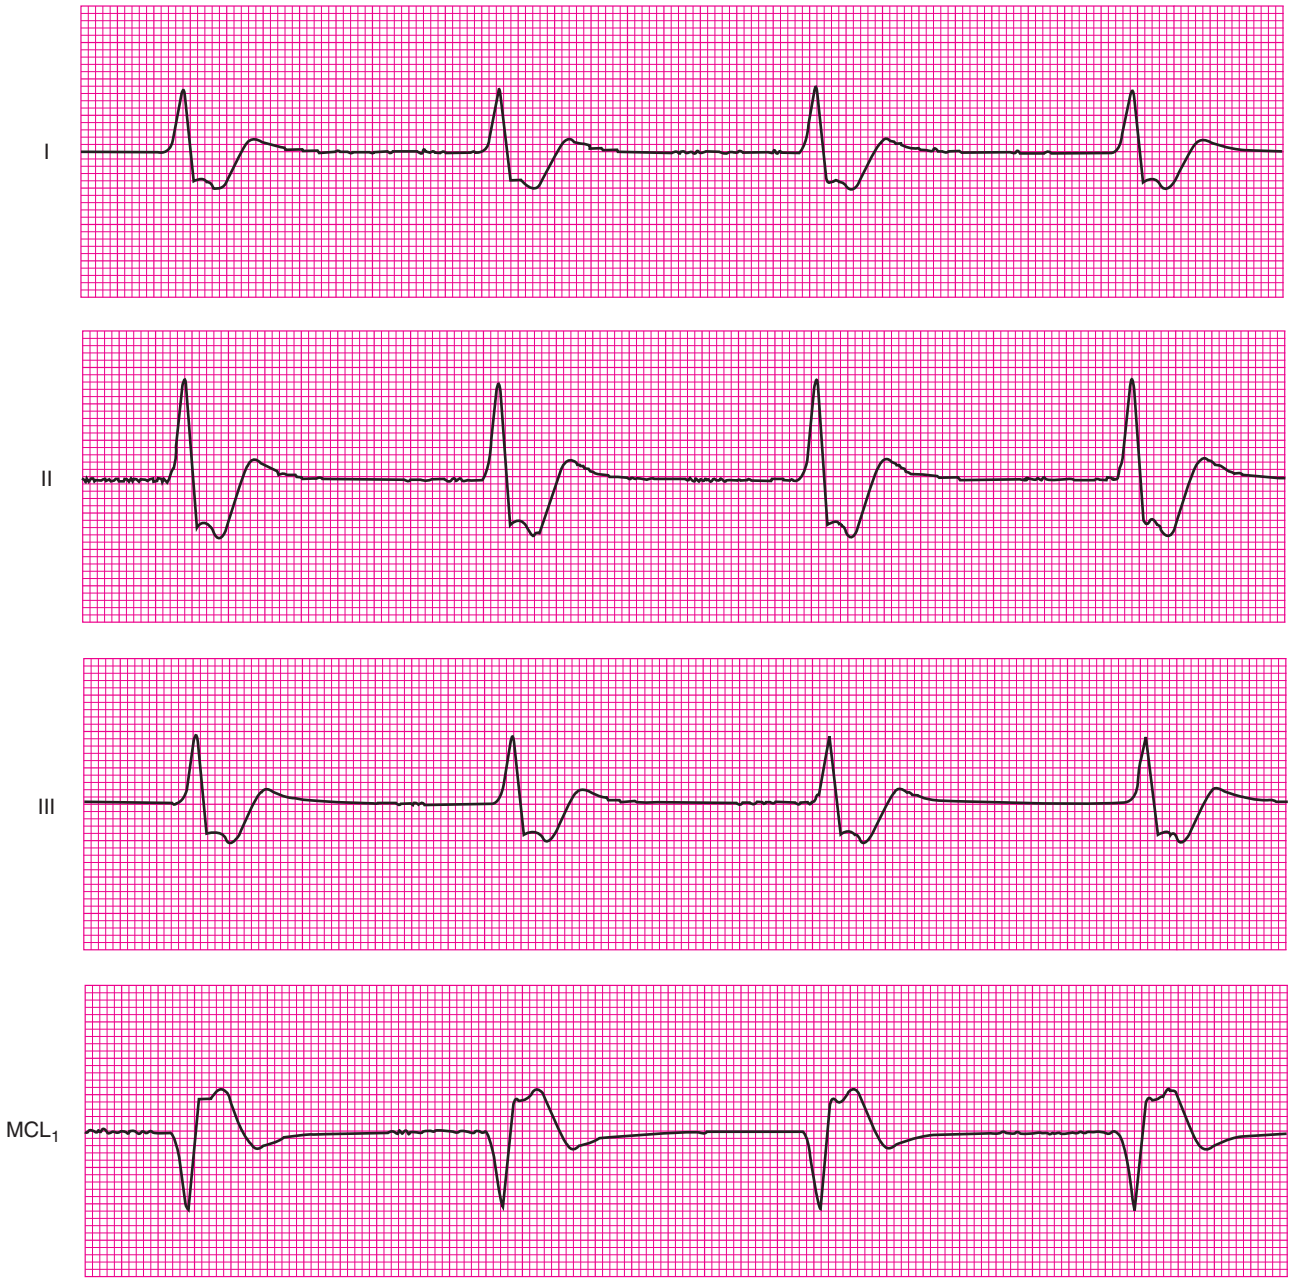

FIGURE 22-61 Ventricular escape rhythm.

- ST segments usually deviate from baseline. T waves frequently are sloped off in the opposite direction from the QRS complex.

Ventricular Escape Complexes or Rhythms

DESCRIPTION

A **ventricular escape complex** or rhythm is also known as *idioventricular rhythm* (Figures 22-61 and 22-62). The dysrhythmia results when impulses from higher pacemakers fail to fire or to reach the ventricles. It also results when the rate of discharge of higher pacemaker sites falls to less than that of the ventricles. Like the junctional escape complex or rhythm, this dysrhythmia serves as a compensatory mechanism to prevent cardiac standstill.

ETIOLOGY

Ventricular escape rhythms occur in two ways. First, the rate of impulse formation of the dominant pacemaker (usually the sinoatrial node) can fall below that of the ventricles. Second, the escape pacemaker in the atrioventricular junction can fail or fall below that of the pacemaker in the ventricles. This dysrhythmia often is seen as the first rhythm after defibrillation.

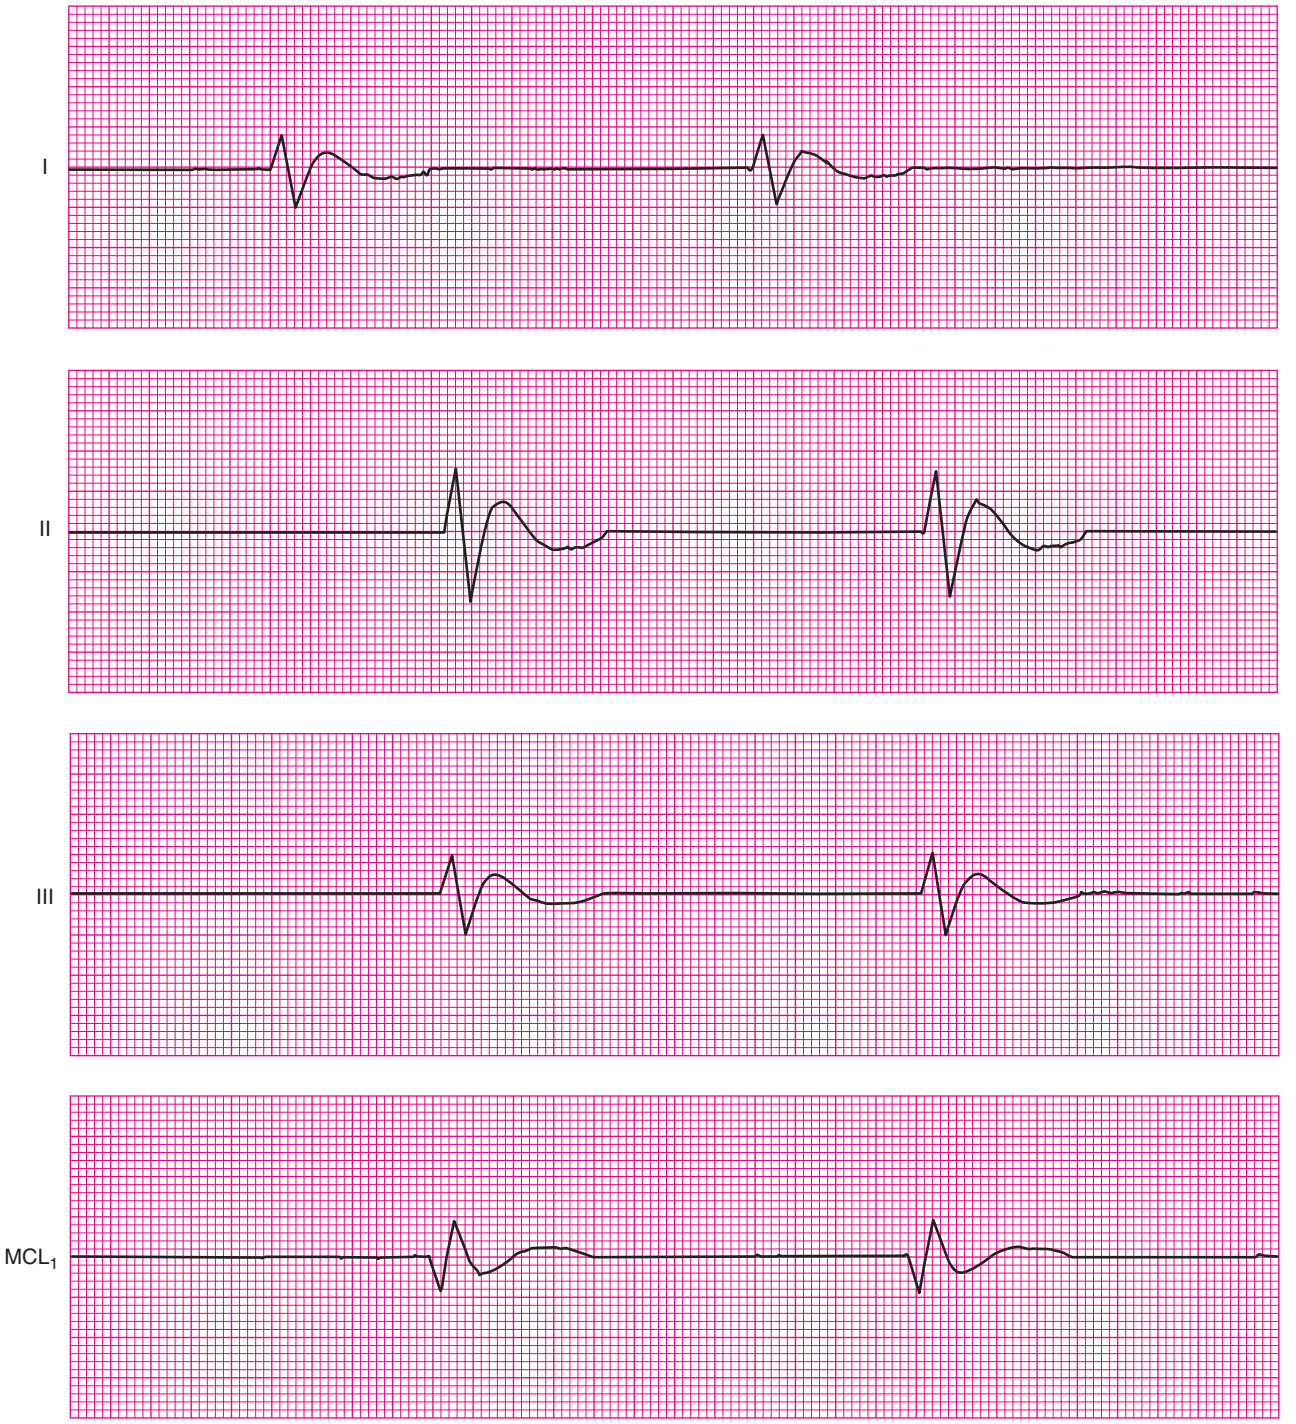

FIGURE 22-62 "Dying heart" (agonal) rhythm.

RULES FOR INTERPRETATION (LEAD II MONITORING)

Ventricular escape complexes or rhythms have the following characteristics on the ECG:

QRS complex: Generally exceeds 0.12 second and is bizarre in appearance. The shape of the QRS complex may vary in any given lead.

P waves: May be absent. If they are present and have no set relationship to the QRS complex, a third-degree atrioventricular block should be suspected.

Rate: Usually 20 to 40 beats/minute; may be lower

Rhythm: The ventricular rhythm usually is regular but may be irregular.

P-R interval: If P waves are present, the P-R interval is variable and irregular.

CLINICAL SIGNIFICANCE

A ventricular escape rhythm generally produces symptoms. This dysrhythmia is manifested by hypotension, decreased cardiac output, and decreased perfusion of the brain and

other vital organs, often resulting in syncope and shock. Patient assessment is essential, because the escape rhythm may be perfusing or nonperfusing (pulseless electrical activity).

MANAGEMENT

If the rhythm is perfusing, management must be directed at increasing the heart rate by administering oxygen, transcutaneous cardiac pacing, and/or ***dopamine.*** Managing the escape rhythm with ***lidocaine*** likely would be lethal and therefore is contraindicated. If the rhythm is nonperfusing, basic life support measures should be initiated and the treatment guidelines for pulseless arrest should be followed (Figure 22-63).

CRITICAL THINKING
Why might ***lidocaine*** be harmful in this situation?

Premature Ventricular Complex

DESCRIPTION

A **premature ventricular complex (PVC)** is a single ectopic impulse arising from an irritable focus in either ventricle (bundle branches, Purkinje fibers, or ventricular muscle) that occurs earlier than the next expected sinus beat (Figure 22-64). This dysrhythmia is common and can occur with any underlying cardiac rhythm. The dysrhythmia results from enhanced automaticity or a reentry mechanism.

When the ventricles initiate a premature ventricular complex, the atria may or may not respond and depolarize. If atrial depolarization does not occur, a P wave is seen on the ECG. If atrial depolarization does occur, the P wave occurs but often is hidden in the QRS complex. This happens because the timing and large electrical force of ventricular depolarization block out the electrical activity from the atrial depolarization. The altered sequence of ventricular depolarization results in a wide, bizarre QRS complex. Depolarization may be deflected in the opposite direction from the QRS complex in the underlying rhythm, or it may be deflected in the same direction (this depends on the location of the focus and the lead selected). The T wave that immediately follows the premature ventricular complex usually is deflected in the opposite direction from the QRS complex of the premature ventricular complex because of the altered sequence of repolarization.

CRITICAL THINKING
Why is the QRS deflection opposite the underlying rhythm?

A premature ventricular complex usually does not depolarize the sinoatrial node or interrupt its rhythm. (For instance, the P wave of the underlying rhythm that follows the premature ventricular complex occurs at its expected time but is obstructed by the premature ventricular complex and finds the ventricles refractory.) Therefore, the ectopic impulse usually is followed by a full **compensatory pause.** Compensatory pauses are confirmed by measuring the interval between the R wave before the premature ventricular complex and the R wave after it. If the pause is compensatory, the distance is at least two times the R-R interval of the underlying rhythm. At times, a premature ventricular complex falls between two sinus beats without interrupting the rhythm; this is called an *interpolated premature ventricular complex* (Figure 22-65).

Premature ventricular complexes may originate from a single ectopic pacemaker site (unifocal premature ventricular complexes) or from multiple sites in the ventricles (multifocal premature ventricular complexes) (Figure 22-66). **Unifocal premature ventricular complexes** look alike. **Multifocal premature ventricular complexes** have varying shapes and sizes.

Multifocal premature ventricular complexes are considered more dangerous than unifocal premature ventricular complexes. In general, this is because they result from increased myocardial irritability. A premature ventricular complex that occurs about the same time as ventricular activation by a normal impulse can cause ventricular depolarization at the same time. This **fusion beat** results in a QRS complex with the characteristics of a premature ventricular complex and the QRS complex of the underlying rhythm (Figure 22-67). Fusion beats confirm that the ectopic impulse is located in the ventricle rather than the atria.

Frequently, premature ventricular complexes occur in patterns of grouped beating. **Ventricular bigeminy** occurs when every other complex is a premature ventricular complex. **Ventricular trigeminy** occurs when every third complex is a premature ventricular complex (Figure 22-68). Quadrigeminy occurs when every fourth complex is a premature ventricular complex. Consecutive premature ventricular complexes that are not separated by a complex of the underlying rhythm also can occur on the ECG: *couplets* are two premature ventricular complexes in a row; *triplets* are three premature ventricular complexes in a row (a definition for ventricular tachycardia); *salvos* are three or more ventricular complexes in a row. These terms also may be used to describe patterns of premature atrial complexes and premature junctional complexes.

As do multifocal premature ventricular complexes, frequently occurring premature ventricular complexes usually indicate that the ventricles are highly irritable. These types of premature ventricular complexes can trigger life-threatening dysrhythmias, such as ventricular tachycardia and ventricular fibrillation. This is especially the case if they

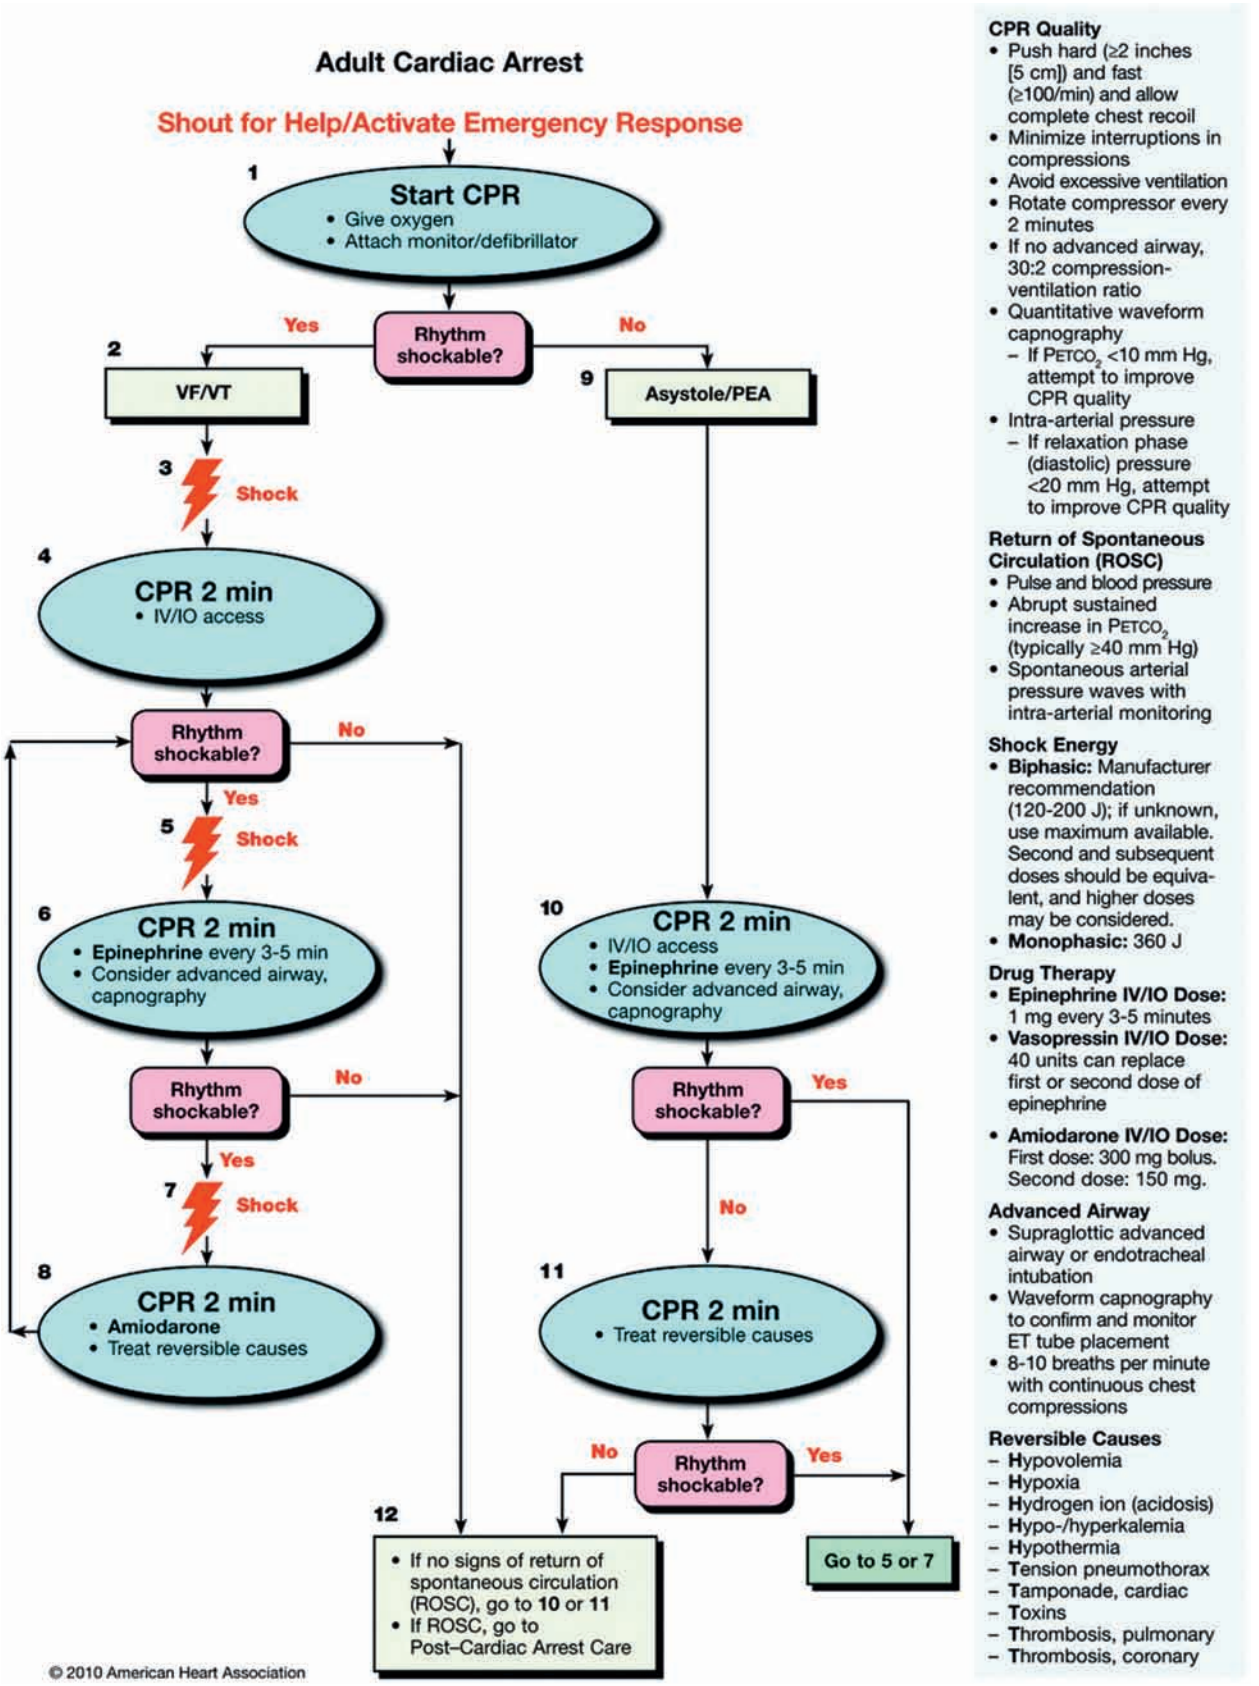

FIGURE 22-63 Advanced cardiac life support (ACLS) pulseless arrest algorithm. (Reprinted with permission, American Heart Association Guidelines For CPR and ECC, *Circulation 122* [suppl 3]:S685-S919, American Heart Association, Inc, 2010.)

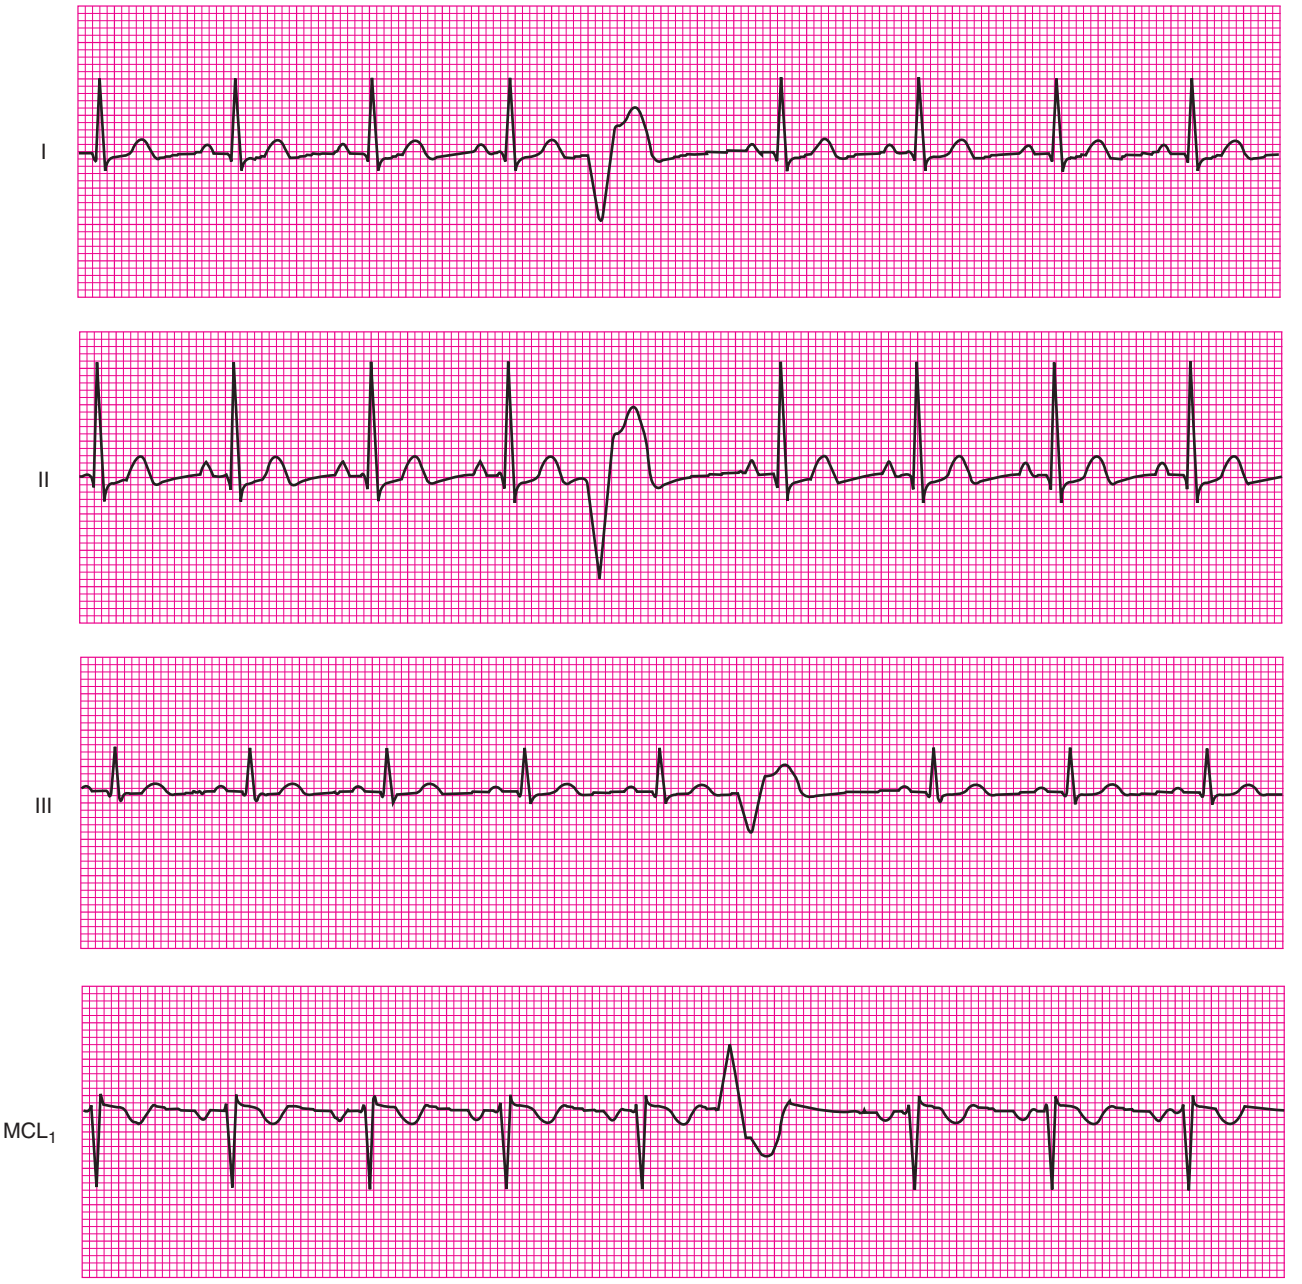

FIGURE 22-64 Premature ventricular complex.

occur during the T wave (relative refractory phase) of the cardiac cycle.

During this period, the heart muscle is at its greatest electrical instability. This is because in the relative refractory period, some of the ventricular muscle fibers may be partly repolarized; others may be completely repolarized; and still others may be completely refractory. Stimulation of the ventricles in the vulnerable period by an electrical impulse such as a premature ventricular complex, cardiac pacemaker, or cardioversion may cause ventricular fibrillation or ventricular tachycardia. The occurrence of a

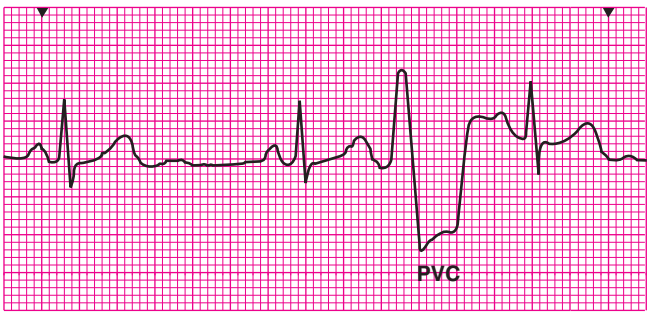

FIGURE 22-65 Interpolated premature ventricular complex.

FIGURE 22-66 **A,** Unifocal premature ventricular complexes. **B,** Multifocal premature ventricular complexes.

ventricular depolarization during the relative refractory period is known as the **R-on-T phenomenon** (Figure 22-69).

ETIOLOGY

Isolated premature ventricular complexes do occur in healthy people without apparent cause. They usually have no significance. Pathological premature ventricular complexes usually are a result of one or more of the following:

- Myocardial ischemia
- Hypoxia
- Acid-base and electrolyte imbalance
- Hypokalemia
- Congestive heart failure
- Increased catecholamine and sympathetic tone (as in emotional stress)
- Ingestion of stimulants (alcohol, caffeine, tobacco)
- Drug toxicity
- Sympathomimetic drugs (cocaine; stimulants such as phencyclidine, ***epinephrine,*** and methamphetamine)

RULES FOR INTERPRETATION (LEAD II MONITORING)

Premature ventricular complexes have the following characteristics on the ECG:

QRS complex: Equal to or greater than 0.12 second. Frequently distorted and bizarre P waves may be present or absent. If present, they usually are of the underlying rhythm and have no relationship to the premature ventricular complex.

Rate: Depends on the underlying rhythm and the number of premature ventricular complexes

Rhythm: Premature ventricular complexes interrupt the regularity of the underlying rhythm.

P-R interval: None

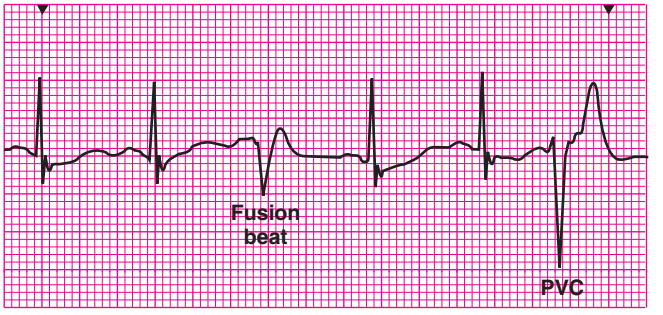

FIGURE 22-67 Fusion beat with premature ventricular complex.

CLINICAL SIGNIFICANCE

Premature ventricular complexes that occur in patients without heart disease usually do not produce serious signs and symptoms, although these patients may complain of

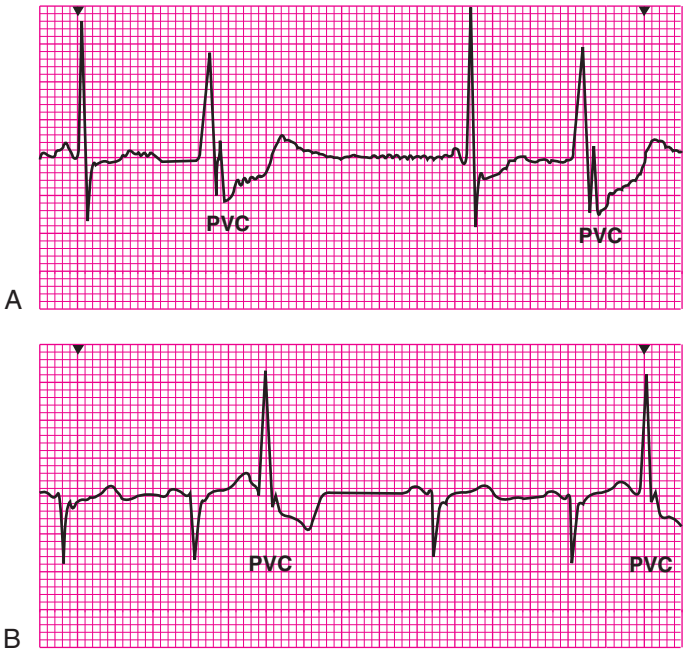

FIGURE 22-68 **A,** Bigeminy (unifocal premature ventricular complexes). **B,** Trigeminy (unifocal premature ventricular complexes).

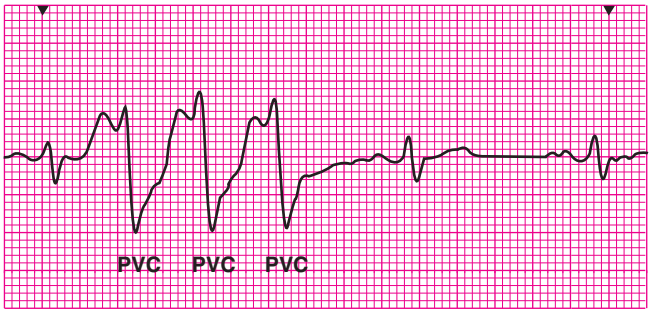

FIGURE 22-69 R-on-T phenomenon (unifocal premature ventricular complexes).

"skipped beats." Premature ventricular complexes that occur with heart disease (myocardial ischemia) may result from enhanced automaticity, a reentry mechanism, or both. These premature ventricular complexes may trigger lethal ventricular dysrhythmias. Premature ventricular complexes do not permit complete ventricular filling. Also, they may produce a diminished or nonpalpable pulse (nonperfusing premature ventricular complex). If the premature ventricular complexes occur often enough and early enough in the cardiac cycle, cardiac output drops.

Warning signs of serious ventricular dysrhythmias in patients with myocardial ischemia include frequent premature ventricular complexes, multifocal premature ventricular complexes, early premature ventricular complexes (R-on-T phenomenon), and patterns of grouped beating.

MANAGEMENT

Premature ventricular complexes that occur in patients without symptoms and without known heart disease seldom require treatment. In patients with myocardial ischemia, frequent premature ventricular complexes must be treated promptly with oxygen and antidysrhythmic drugs (e.g., beta blockers). At the hospital, the serum potassium level should be checked immediately. Hypokalemia, if present, should be treated promptly.

CRITICAL THINKING

A lidocaine drip is not regulated properly and infuses too rapidly. What signs and symptoms might the patient develop?

Ventricular Tachycardia

DESCRIPTION

Ventricular tachycardia (VT) is a dysrhythmia defined by three or more consecutive ventricular complexes that occur at a rate of more than 100 beats/minute (Figure 22-70). This dysrhythmia overrides the primary pacemaker. It starts suddenly and is triggered by a premature ventricular complex. During ventricular tachycardia, the atria and ventricles are not beating in step with each other. If ventricular tachycardia continues, the patient's condition may become unstable. Ventricular tachycardia can produce unconsciousness. Occasionally it can even lead to loss of a perfusing pulse. However, some patients in ventricular tachycardia may be able to walk and talk. The misconception that ventricular tachycardia cannot be associated with a reasonable blood pressure may result in inappropriate patient management. The origin of ventricular tachycardia is enhanced automaticity or reentry.

ETIOLOGY

Like premature ventricular complexes, ventricular tachycardia usually occurs in the presence of myocardial ischemia or significant cardiac disease. Other causes of ventricular tachycardia include the following:

- Acid-base and electrolyte imbalance
- Hypokalemia
- Congestive heart failure
- Increased catecholamine and sympathetic tone (as in emotional stress)
- Ingestion of stimulants (alcohol, caffeine, tobacco)
- Drug toxicity (digitalis, tricyclic antidepressants)
- Sympathomimetic drugs (cocaine, methamphetamines)
- Prolonged Q-T interval (may be caused by drugs or metabolic problems or may be congenital)

NOTE

Patients who have had a previous myocardial infarction with subsequent tachycardias and who are now experiencing a wide-complex tachycardia very likely are in ventricular tachycardia.

RULES FOR INTERPRETATION (LEAD II MONITORING)

Ventricular tachycardia has the following characteristics on the ECG:

QRS complex: Equal to or greater than 0.12 second and usually distorted and bizarre. The QRS complexes generally are identical, but if fusion beats are present, one or more QRS complexes may differ in size, shape, and direction.

P waves: May be absent. If present, P waves have no set relation to the QRS complex (atrioventricular dissociation). P waves occur at a slower rate than the ventricular focus and are superimposed on the QRS complexes.

Rate: Usually between 100 and 250 beats/minute

Rhythm: Usually regular (unless drug induced) but may be slightly irregular

P-R interval: If P waves are present, the P-R interval varies widely.

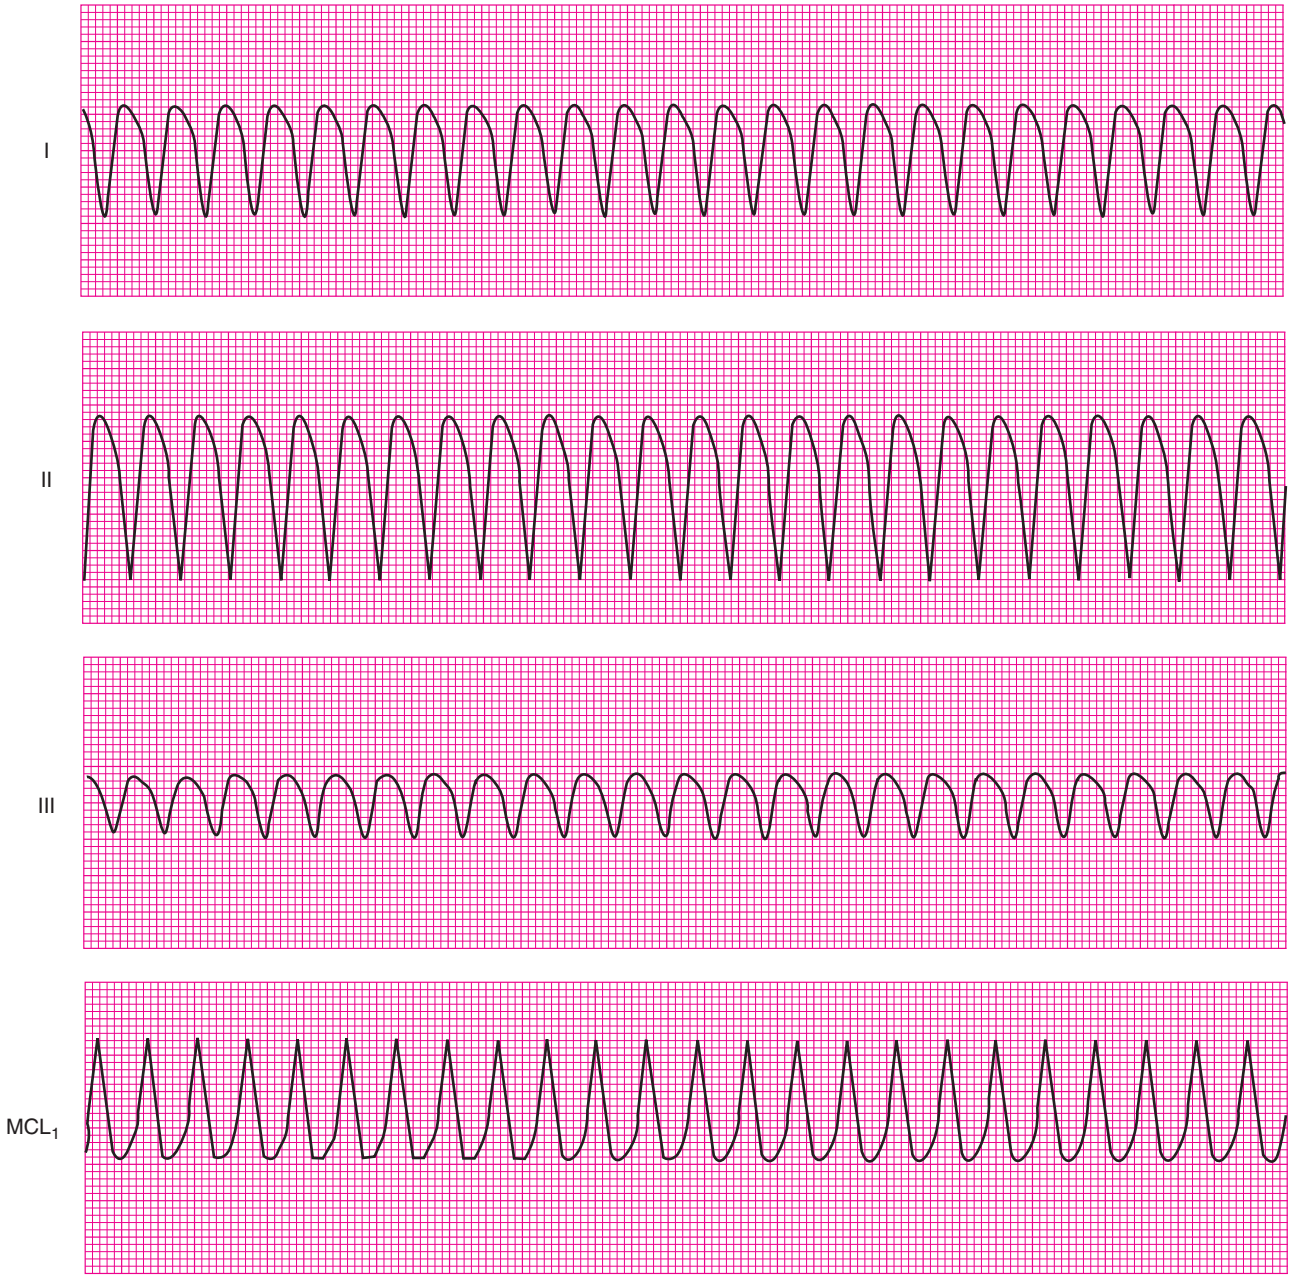

FIGURE 22-70 Ventricular tachycardia.

NOTE

Atrioventricular dissociation may precipitate **cannon A waves**. These are waves of pulse pressure that are visible in the jugular veins of a patient in ventricular tachycardia. Cannon A waves result when the right atrium pumps against a closed tricuspid valve; the waves of pressure consequently are directed into the jugular veins. Atrioventricular dissociation is diagnostic of ventricular tachycardia.

CLINICAL SIGNIFICANCE

Ventricular tachycardia usually indicates significant heart disease. The rapid rate and the loss of atrial kick cause a drop in cardiac output and decreased coronary artery and cerebral perfusion. The severity of symptoms varies with the rate of the ventricular tachycardia and how much heart disease is present. Ventricular tachycardia may be perfusing or nonperfusing; that is, it may produce a pulse or it may not. Ventricular tachycardia also may lead to ventricular fibrillation.

MANAGEMENT

The treatment of patients with ventricular tachycardia is based on their signs and symptoms and whether torsades de pointes is present. **Torsades de pointes** (Figure 22-71) is a type of polymorphic ventricular tachycardia. As with other supraventricular tachycardias, the paramedic should obtain a history and identify the rhythm (see Figure 22-54). If the patient is stable, a 12-lead ECG should be obtained.

Treatment of ventricular tachycardia depends on whether the QRS complex is *monomorphic* (having the same morphology or fixed shape) or *polymorphic* (having varying morphology). The paramedic should remember, however, that any wide-complex tachycardia that occurs with serious signs and symptoms (e.g., chest pain, dyspnea, decreased level of consciousness, or hypotension or other signs of shock) requires immediate cardioversion. In addition, patients who have ventricular tachycardia without a pulse should be treated as if the rhythm were ventricular fibrillation.

Treatment guidelines for **monomorphic ventricular tachycardia** are based on heart function (the cardiac ejection fraction). Signs and symptoms of failing heart function are pulmonary congestion and a decreased level of consciousness. Monomorphic ventricular tachycardia in a stable patient is managed with ***procainamide. Adenosine*** may be administered first if the nature of a regular wide-complex rhythm is uncertain.[1] Alternative drugs are ***amiodarone,*** and sotalol. Unstable patients with monomorphic ventricular tachycardia should receive immediate synchronized cardioversion. This should begin with an initial shock of 100 J. If no response to the first shock is seen, the dose should be increased (in stepwise fashion) according to manufacturer recommendations.[1] When unstable ventricular tachycardia is witnessed, a **precordial thump** may be performed if cardioversion is not immediately available.

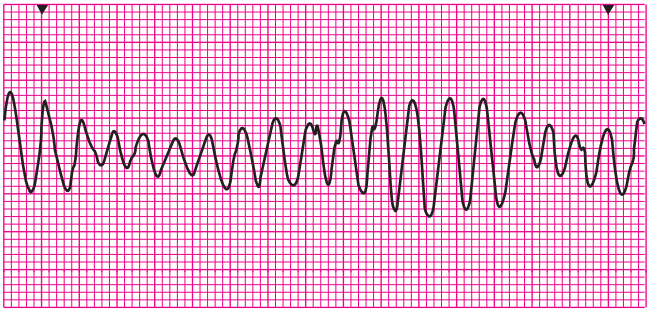

FIGURE 22-71 Torsades de pointes.

PRECORDIAL THUMP

Monitored adult patients whose rhythm is observed to be unstable ventricular tachycardia may be treated with a single precordial thump, provided that a defibrillator is readily available. (A precordial thump may cause ventricular tachycardia to deteriorate to asystole, ventricular fibrillation, or pulseless electrical activity.) A precordial thump may terminate a dysrhythmia by causing ventricular depolarization and the resumption of an organized rhythm. To deliver a precordial thump, the paramedic's arm and wrist should be parallel to the long axis of the sternum to avoid rib fractures and other injury. The thump is delivered to the midsternum with the heel of the fist from 10 to 12 inches. A conscious patient should be advised of the procedure.

DID YOU KNOW?

Cardiac Ejection Fraction

The **cardiac ejection fraction** is the percentage of ventricular blood volume released during a contraction. This measurement most often refers to the left ventricle (left ventricular ejection fraction [LVEF]). The LVEF is obtained through echocardiography, cardiac catheterization, or heart scans with magnetic resonance imaging, computed tomography, and nuclear medicine (nuclear stress test).

A normal LVEF ranges from 50% to 70%. The LVEF may be lower if the heart muscle has been damaged by a heart attack, heart muscle disease (cardiomyopathy), or other causes. An LVEF of 35% to 40% may confirm a diagnosis of heart failure. An LVEF below 35% increases the risk of life-threatening dysrhythmias that can cause sudden cardiac arrest and sudden cardiac death. An implantable cardioverter-defibrillator (ICD) often is recommended for these patients.

Polymorphic ventricular tachycardia can degenerate into ventricular fibrillation quickly and therefore requires immediate intervention. If the patient has polymorphic ventricular tachycardia and is unstable (as is often the case), the rhythm should be treated as ventricular fibrillation with high-energy unsynchronized shocks. (Synchronization is not usually possible with irregular wave forms, such as polymorphic ventricular tachycardia.) If the rhythm is torsades de pointes, it may be the result of a prolonged

Q-T interval. Medications that prolong the Q-T interval should be discontinued. Electrolyte imbalances should be corrected, and ***magnesium sulfate*** should be given intravenously.

NOTE

Drugs given to treat dysrhythmias also can cause dysrhythmias *(proarrhythmic)*. Sequential use of two or more antidysrhythmic drugs increases the incidence of bradycardias, hypotension, and torsades de pointes. Avoiding the use of more than one antidysrhythmic agent in treating narrow or wide QRS complex tachydysrhythmias is strongly recommended. In most cases, if an adequate dose of a single drug is unsuccessful in ending the dysrhythmia, synchronized cardioversion is the next treatment.

Ventricular Fibrillation

DESCRIPTION

Ventricular fibrillation (VF) is a chaotic ventricular rhythm that results in pulselessness (Figure 22-72). The cause of VF is multifocal reentry in the ventricles. The electrical impulses initiated by the multiple ectopic ventricular sites do not allow the heart to fully depolarize and repolarize. As a result, organized ventricular contraction does not occur. Ventricular fibrillation is the most common initial rhythm disturbance in sudden cardiac arrest.

ETIOLOGY

Ventricular fibrillation most commonly is associated with significant heart disease. The dysrhythmias also may be precipitated by premature ventricular complexes, R-on-T phenomenon (in rare cases), or a sustained ventricular tachycardia. Other causes include the following:

- Myocardial ischemia
- Acute myocardial infarction
- Third-degree atrioventricular block with a slow ventricular escape rhythm
- Cardiomyopathy
- Digitalis toxicity
- Hypoxia
- Acidosis
- Electrolyte imbalance (hypokalemia, hyperkalemia, submersion)
- Electrical injury
- Drug overdose or toxicity (cocaine, tricyclic antidepressants)

RULES FOR INTERPRETATION (ALL LEADS)

Ventricular fibrillation has the following characteristics on the ECG:

QRS complex: Absent
P waves: Absent
Rate: No coordinated ventricular contractions are present. The unsynchronized ventricular impulses occur at rates of 300 to 500 beats/minute.
Rhythm: Irregularly irregular
P-R interval: Absent

Because organized depolarizations of the atria and ventricles are absent, P waves, QRS complexes, ST segments, and T waves are absent. Ventricular fibrillatory waves are seen on the oscilloscope as bizarre, rounded, or pointed. They also appear considerably different in shape. They also vary at random from positive to negative. These waves represent twitching of small individual groups of muscle fibers. Fibrillatory waves less than 3 mm in amplitude are called **fine ventricular fibrillation.** Those greater than 3 mm are called **coarse ventricular fibrillation** (Figure 22-73). The fibrillatory waves may be so fine they appear as a flat line, resembling ventricular asystole.

NOTE

Coarse ventricular fibrillation usually indicates the recent onset of ventricular fibrillation. It can be readily converted by prompt defibrillation. The presence of fine ventricular fibrillation that approaches asystole often means that a considerable delay has occurred since collapse. Successful defibrillation is more difficult in these cases.[2]

CLINICAL SIGNIFICANCE

Ventricular fibrillation causes all life functions to cease because of a lack of circulating blood flow. The dysrhythmia initially may result in lightheadedness. Ventricular fibrillation usually is followed within seconds by loss of consciousness, apnea, and, if left untreated, death.

MANAGEMENT

For adult resuscitation, management of ventricular fibrillation and pulseless ventricular tachycardia is the most important sequence because most adult cardiac arrests result from these two rhythm disturbances. Also, the vast majority of successful resuscitations result from the appropriate management of these two dysrhythmias (see Figure 22-63).[1] Ventricular fibrillation and nonperfusing ventricular tachycardia are managed alike: basic life support (if a defibrillator is not immediately available), defibrillation, IV/IO access, and pharmacological therapy (***epinephrine*** [or ***vasopressin*** to replace the first or second dose] and ***amiodarone*** (***lidocaine*** if ***amiodarone*** is not available). Advanced airway with capnographic monitoring should be considered after initial CPR, defibrillation, and drug administration.[1] Other interventions may be performed to treat any identified underlying cause of arrest.

Fine VF

FIGURE 22-73 Coarse and fine ventricular fibrillation.

NOTE

With cardiac arrest, blood flow stops. Chest compressions create a small amount of blood flow to the vital organs, such as the brain and heart. The better the compressions, the more blood flow they produce. The American Heart Association recommends that chest compressions be "hard and fast" and at a rate of at least 100/minute (except in newborns). The association also recommends that chest compressions not be stopped to deliver ventilations after an advanced airway is in place when two or more rescuers are present. (When chest compressions are interrupted, blood flow stops and coronary perfusion pressure is reduced.[1])

This same train of thought applies to defibrillation: minimize interruptions in chest compressions. If an EMS provider does not witness the arrest in the out-of-hospital setting, the EMS crew may perform CPR while preparing for defibrillation. If the rhythm is shockable, one shock should be delivered, and then CPR should be resumed immediately, beginning with chest compressions. CPR should be continued for another five cycles (or about 2 minutes), before the rhythm is checked again. Theory holds that even when a shock eliminates ventricular fibrillation, several minutes are required for a normal rhythm to return and for the heart to create more blood flow. A brief period of chest compressions can deliver oxygen and sources of energy to the heart. This increases the likelihood that the heart will be able to pump blood effectively after the defibrillatory shock.[6] In addition, chest compressions should not be interrupted to charge a defibrillator or to "clear" the patient for shock delivery while the defibrillator is charging. (The patient should be cleared immediately before the shock is delivered, with no time wasted in between.)

Rhythm checks should be brief, and pulse checks should be performed only if an organized rhythm is observed (see Figure 22-63).

Ventricular Asystole

DESCRIPTION

Ventricular asystole (cardiac standstill) refers to the absence of all ventricular activity (Figure 22-74).

ETIOLOGY

Ventricular asystole may be the cause of cardiac arrest. It also may occur in complete heart block when there is no escape pacemaker. The dysrhythmia usually is associated with extensive heart disease. It often occurs after ventricular tachycardia, ventricular fibrillation, pulseless electrical activity, or an agonal escape rhythm in the dying heart.

RULES FOR INTERPRETATION (ALL LEADS)

Ventricular asystole has the following characteristics on the ECG:

QRS complexes: Absent
P waves: Absent or present
Rate: Absent
Rhythm: Absent
P-R interval: Absent

CLINICAL SIGNIFICANCE

Ventricular asystole produces no cardiac output and is an ominous dysrhythmia. Asystole often confirms death. The chance for resuscitation is small.

MANAGEMENT

The management of ventricular asystole is basic life support with effective CPR, and ***epinephrine*** (or ***vasopressin*** to replace the first or second dose) administration) Establish an advanced airway with an endotracheal tube or supraglottic airway with capnographic monitoring when possible (see Figure 22-63). If fine ventricular fibrillation is suspected, defibrillation is indicated. However, defibrillating asystole "just in case" is not recommended. Termination of resuscitation efforts in the prehospital setting, after meeting medical protocol (described later in this chapter), is indicated in this situation. Potential reversible causes of asystole should be considered before cessation of resuscitative efforts. These include hypoxia, hypovolemia, hyperkalemia, hypokalemia, hypothermia, tension pneumothorax, cardiac tamponade, STEMI, pulmonary edema, drug overdose, and acidosis.[1]

CRITICAL THINKING

What is the benefit to the community and to the patient's family if resuscitation is halted in the field after all appropriate guidelines have been followed?

Artificial Pacemaker Rhythms

DESCRIPTION

Artificial pacemakers generate a rhythm by regular electrical stimulation of the heart through an electrode implanted in the heart (Figure 22-75). The electrode is connected to a

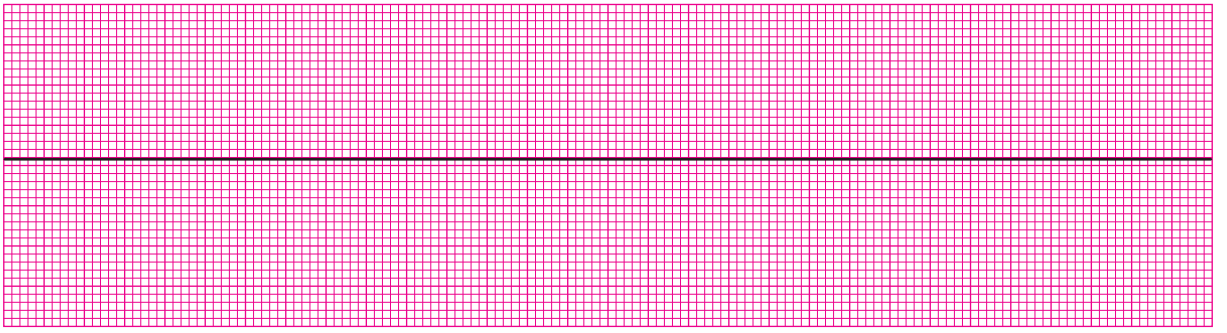

FIGURE 22-74 Ventricular asystole.

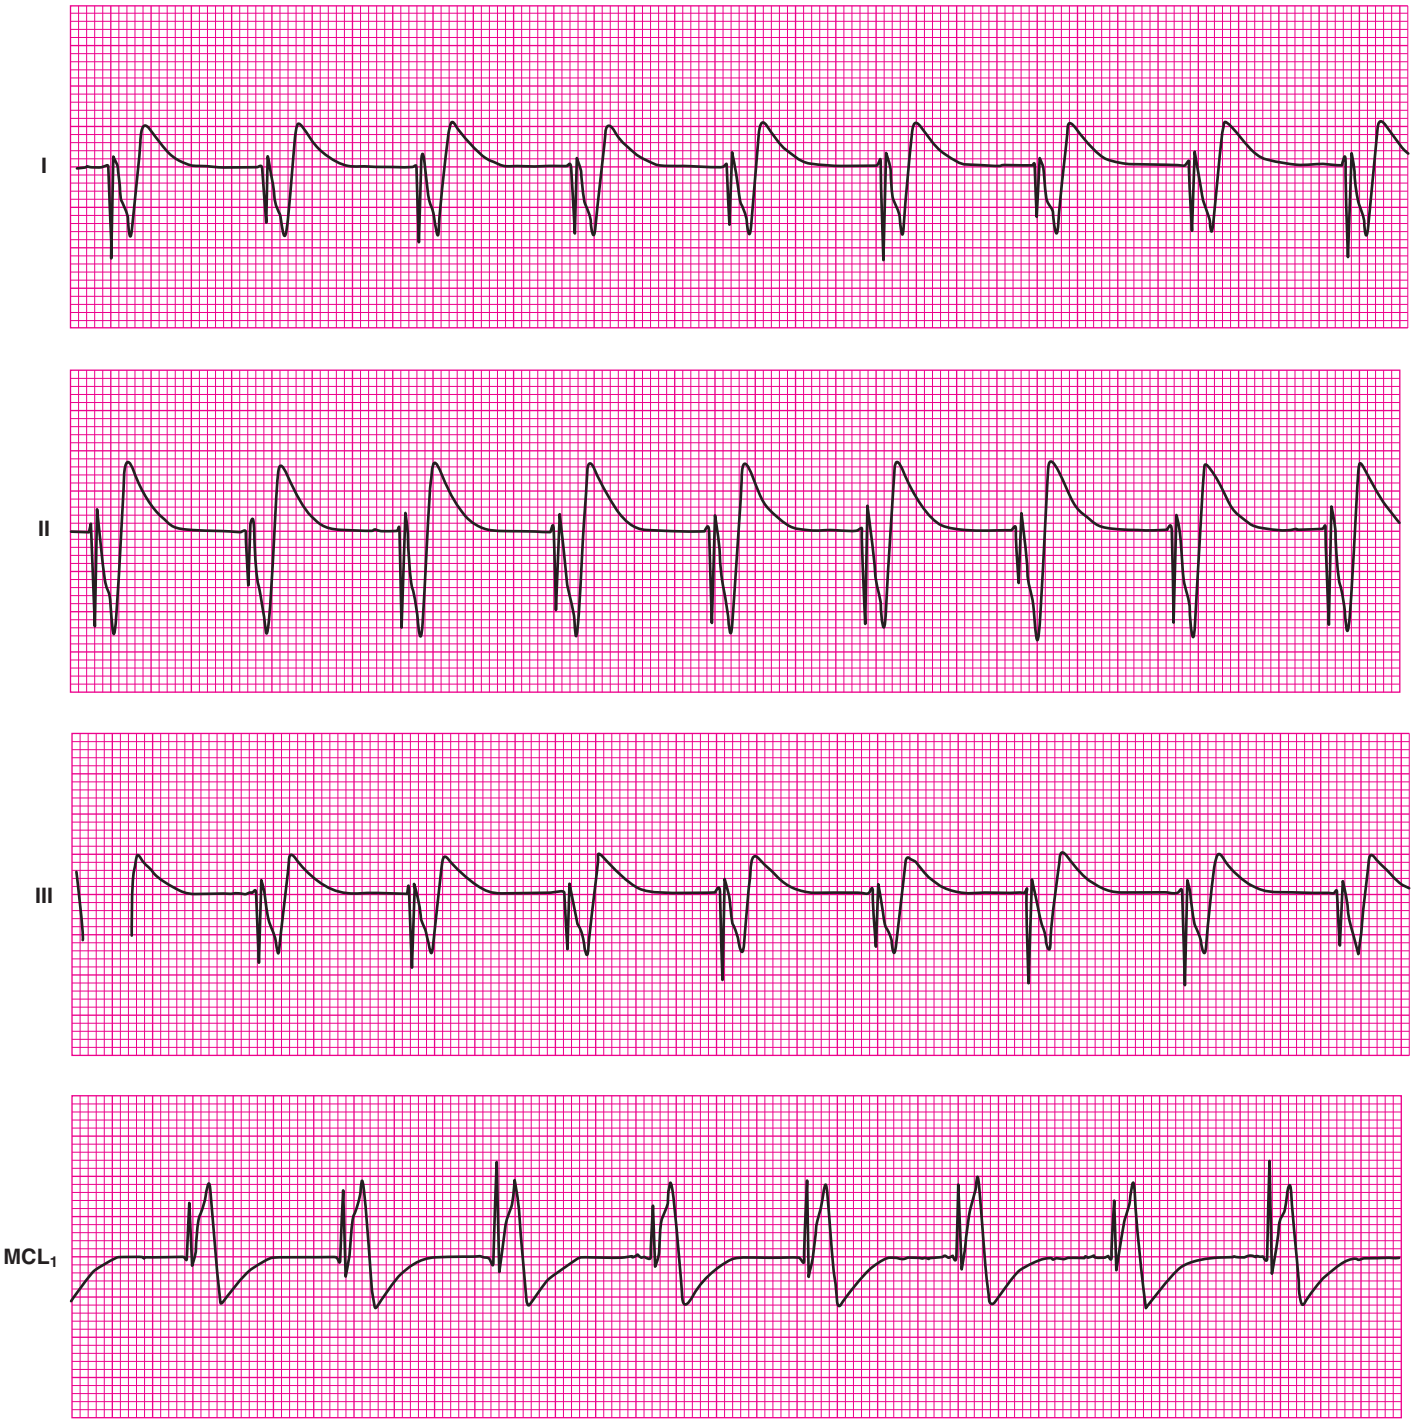

FIGURE 22-75 Artificial pacemaker rhythms.

power source (a battery cell implanted subcutaneously, typically in the right or left side of the chest). The tip of the pacemaker wire is at the apex of the right ventricle (ventricular pacemaker), in the right atrium (atrial pacemaker), or in both locations (dual-chamber pacemaker). These devices are placed in patients with complete heart block. They also are used by patients who have episodes of severe symptomatic bradycardia.

Some pacemakers fire continuously at a preset rate regardless of the patient's own electrical activity. These are known as *fixed-rate* or *asynchronous pacemakers*. They are rarely used today. Other pacemakers fire only if the patient's own rate drops below the preset rate of the pacemaker (they thereby act as an escape rhythm). These are known as *demand pacemakers*. Atrial and ventricular demand pacemakers pace the atria and ventricles when the intrinsic rate of the paced chamber drops dangerously low. *Atrial synchronous ventricular pacemakers* are synchronized with the patient's atrial rhythm. This type of pacemaker paces the ventricle after the patient's atria contract. This pacemaker is useful in patients with normal sinus node activity but various degrees of atrioventricular block. *Atrioventricular sequential pacemakers* pace the atria first and then the ventricles when normal impulses are absent or slowed in either or both chambers. If regular atrial activity is too slow, for example, the two chambers are paced sequentially to maintain the atrial kick. If the atrial rate is adequate, the atrial pacer does not fire. The ventricular pacemaker still fires if the ventricular rate is below a preset rate. This pacemaker is ideal for sick sinus syndrome and sinus arrest.

Rate-responsive pacemakers are a newer class of pacemakers. They can adjust their pacing rates to a patient's needs. They do this by sensing when cardiac output should be increased. Several methods of sensing metabolic activity are used. However, the most popular rate-responsive pacers detect patient movement to determine the best firing rate. These devices can increase both cardiac output and tolerance of physical activity. At times they may increase the patient's pacing rate inappropriately, such as if they sense muscle movement that is not caused by increased patient activity. Because the pacemaker spikes are difficult to visualize in all leads, fast pacemaker rates can easily be misinterpreted as ventricular tachycardia. Perform a 12-lead ECG if time permits.

RULES FOR INTERPRETATION (LEAD II MONITORING)

Artificial pacemaker rhythms have the following characteristics on the ECG:

QRS complex: If pacemaker induced, QRS complexes are 0.12 second or greater. Their appearance usually is bizarre, resembling a premature ventricular complex. The pacemaker is said to have electrical capture if each pacemaker spike elicits a QRS complex. If only the atria are paced, the QRS complexes usually are normal, provided no bundle branch block is present. With demand pacemakers, some of the patient's own QRS complexes may be present. These normal QRS complexes occur without pacemaker spikes.

P waves: May be present or absent, normal or abnormal. The relationship of the P waves to the pacemaker (QRS) complex varies by type of artificial pacemaker. Pacemaker spikes precede QRS complexes induced by ventricular pacemakers, whereas dual-chambered pacemakers also produce an atrial spike followed by a P wave. The pacemaker spike is a narrow deflection on the oscilloscope and represents the electrical discharge of the pacemaker. Pacemaker spikes indicate only that a pacemaker is discharging. They provide no information about ventricular contraction or perfusion.

CRITICAL THINKING

If a pacemaker fails, what rhythms might you see on the monitor?

Rate: Varies according to the preset rate of the pacemaker. Typically the rate is 60 to 80 beats/minute.

Rhythm: Regular if pacing is constant; irregular if pacing occurs only on demand

P-R interval: The presence and duration of P-R intervals depend on the underlying rhythm and vary by the type of artificial pacemaker.

CLINICAL SIGNIFICANCE

Pacemaker spikes indicate that the patient's heart rate is regulated by an artificial pacemaker. Pacemaker spikes followed by QRS complexes indicate electrical capture. If spikes do not elicit a QRS complex, the pacemaker is not capturing the ventricle electrically. Therefore, no ventricular contraction occurs. A large percentage of pacemaker failures occur within the first month after implantation (Box 22-8).

MANAGEMENT

Pacemaker failure is a true emergency. It requires immediate recognition and rapid transport for definitive care (this may include battery replacement or temporary pacemaker insertion). Paramedics should not delay transport to attempt to stabilize these patients. Five principles apply to the treatment of patients with pacemakers:

1. When examining an unconscious patient, be alert for battery packs implanted under the skin. Also be alert for any medical alert information.
2. Manage all dysrhythmias following the appropriate algorithm.
3. Manage ventricular irritability with appropriate drug therapy without fear of suppressing ventricular response to a pacemaker rhythm, as long as pacemaker failure is not a factor.
4. For patients with artificial pacemakers, defibrillate in the usual manner. However, do not deliver the charge directly over the implanted battery pack.

BOX 22-8 Four Possible Causes of Pacemaker Malfunction

1. *Battery failure:* Currently most implanted pacemakers use a lithium-iodine cell power source. This source provides stable voltage output for about 80% to 90% of the life of the battery. (The battery life is 5 to 10 years or longer.) Battery failure usually slows the pacemaker rate. It also usually reduces the spike amplitude. If the battery fails, the patient may have bradycardia or asystole.
2. *Runaway pacemaker:* This is a pacemaker that develops rapid discharge rates, which may reach 300 beats/minute. The problem occurs as the batteries reduce their voltage output. This type of failure rarely is seen in pacemakers used today, because the newer power sources provide a gradual increase in rate as the batteries run low.
3. *Failure of the sensing device in demand pacemakers:* Demand pacemakers may fail to shut off when patients have an adequate rate of their own. When this occurs, a competition develops between the natural and artificial pacemakers of the heart. The pacemaker may discharge during the vulnerable period of the cardiac cycle. This may result in dysrhythmias.
4. *Failure to capture:* Failure of the pacemaker to capture may have a variety of causes. These may include battery failure, loose or broken catheter electrode wires, inoperable electrodes, and a shift in the location of the catheter tip. In such cases, pacemaker spikes usually are present. However, they are not followed by P waves or QRS complexes.

5. Transcutaneous cardiac pacing, if indicated, may be used in the usual manner.

Besides pacemakers, implantable cardioverter-defibrillators also are common. The battery packs of these devices are located in the subcutaneous tissues of the abdominal wall. Emergency cardiac care can be given as usual. These devices present no danger to rescuers. However, paramedics should wear gloves to help avoid unpleasant sensations when the device discharges. (Implantable cardioverter-defibrillators are described further later in this chapter.)

DYSRHYTHMIAS THAT ARE DISORDERS OF CONDUCTION

Delay or blockage of the electrical impulse conduction in the heart is called a *heart block*. Heart blocks can occur anywhere in the atria between the sinoatrial node and the atrioventricular node or in the ventricles between the atrioventricular node and the Purkinje fibers. These conduction defects can be caused by diseased tissue in the conduction system or by a physiological block, such as occurs in atrial fibrillation or atrial flutter. Causes of heart blocks include atrioventricular junctional ischemia, atrioventricular junctional necrosis, degenerative disease of the conduction system, electrolyte imbalances (e.g., hyperkalemia), and drug toxicity, especially with digitalis.

Classifications

Conduction blocks may be classified based on several characteristics: the site of the block (e.g., left bundle branch block), the degree of block (e.g., second-degree atrioventricular block), or the category of atrioventricular conduction disturbance (e.g., type I). This text presents the dysrhythmias by degree and location. However, the term *degree* does not reflect directly the gradients of severity when applied to the classification of heart blocks. Any evaluation of heart block must consider the specific rates of the atria and ventricles, the patient's clinical presentation, and the findings of a complete history and physical examination before the clinical severity of AV conduction disturbances can be determined. The dysrhythmias discussed in this section include first-degree atrioventricular block; second-degree atrioventricular block type I (or *Wenckebach*); second-degree atrioventricular block type II; third-degree atrioventricular block (complete heart block); and ventricular conduction disturbances, including bundle branch blocks and hemiblocks.

Atrioventricular Blocks

The discussion of conduction disturbances of the heart begins with the atrioventricular blocks.

FIRST-DEGREE ATRIOVENTRICULAR BLOCK

Description. First-degree atrioventricular block is not a true block (Figure 22-76). Rather, the disturbance is a delay in conduction, usually at the level of the atrioventricular node. First-degree atrioventricular block is not considered a rhythm in itself, because it usually is superimposed on another rhythm. Therefore, the paramedic also must identify the underlying rhythm (e.g., sinus bradycardia with first-degree atrioventricular block).

Etiology. First-degree atrioventricular block may occur for no apparent reason. The dysrhythmia sometimes is associated with myocardial ischemia, acute myocardial infarction, increased vagal (parasympathetic) tone, or digitalis toxicity.

Rules for Interpretation (Lead II Monitoring). First-degree atrioventricular block has the following characteristics on the ECG:

QRS complex: Typically normal (less than 0.12 second), with an atrioventricular conduction ratio of 1:1 (a QRS complex follows each P wave)

P waves: Present; identical waves precede each QRS complex.

Rate: The rate is that of the underlying sinus or atrial rhythm.

Rhythm: The rhythm is that of the underlying rhythm.

P-R interval: A prolonged (greater than 0.20 second), constant P-R interval is the hallmark of first-degree atrioventricular block and often is the only alteration in the ECG.

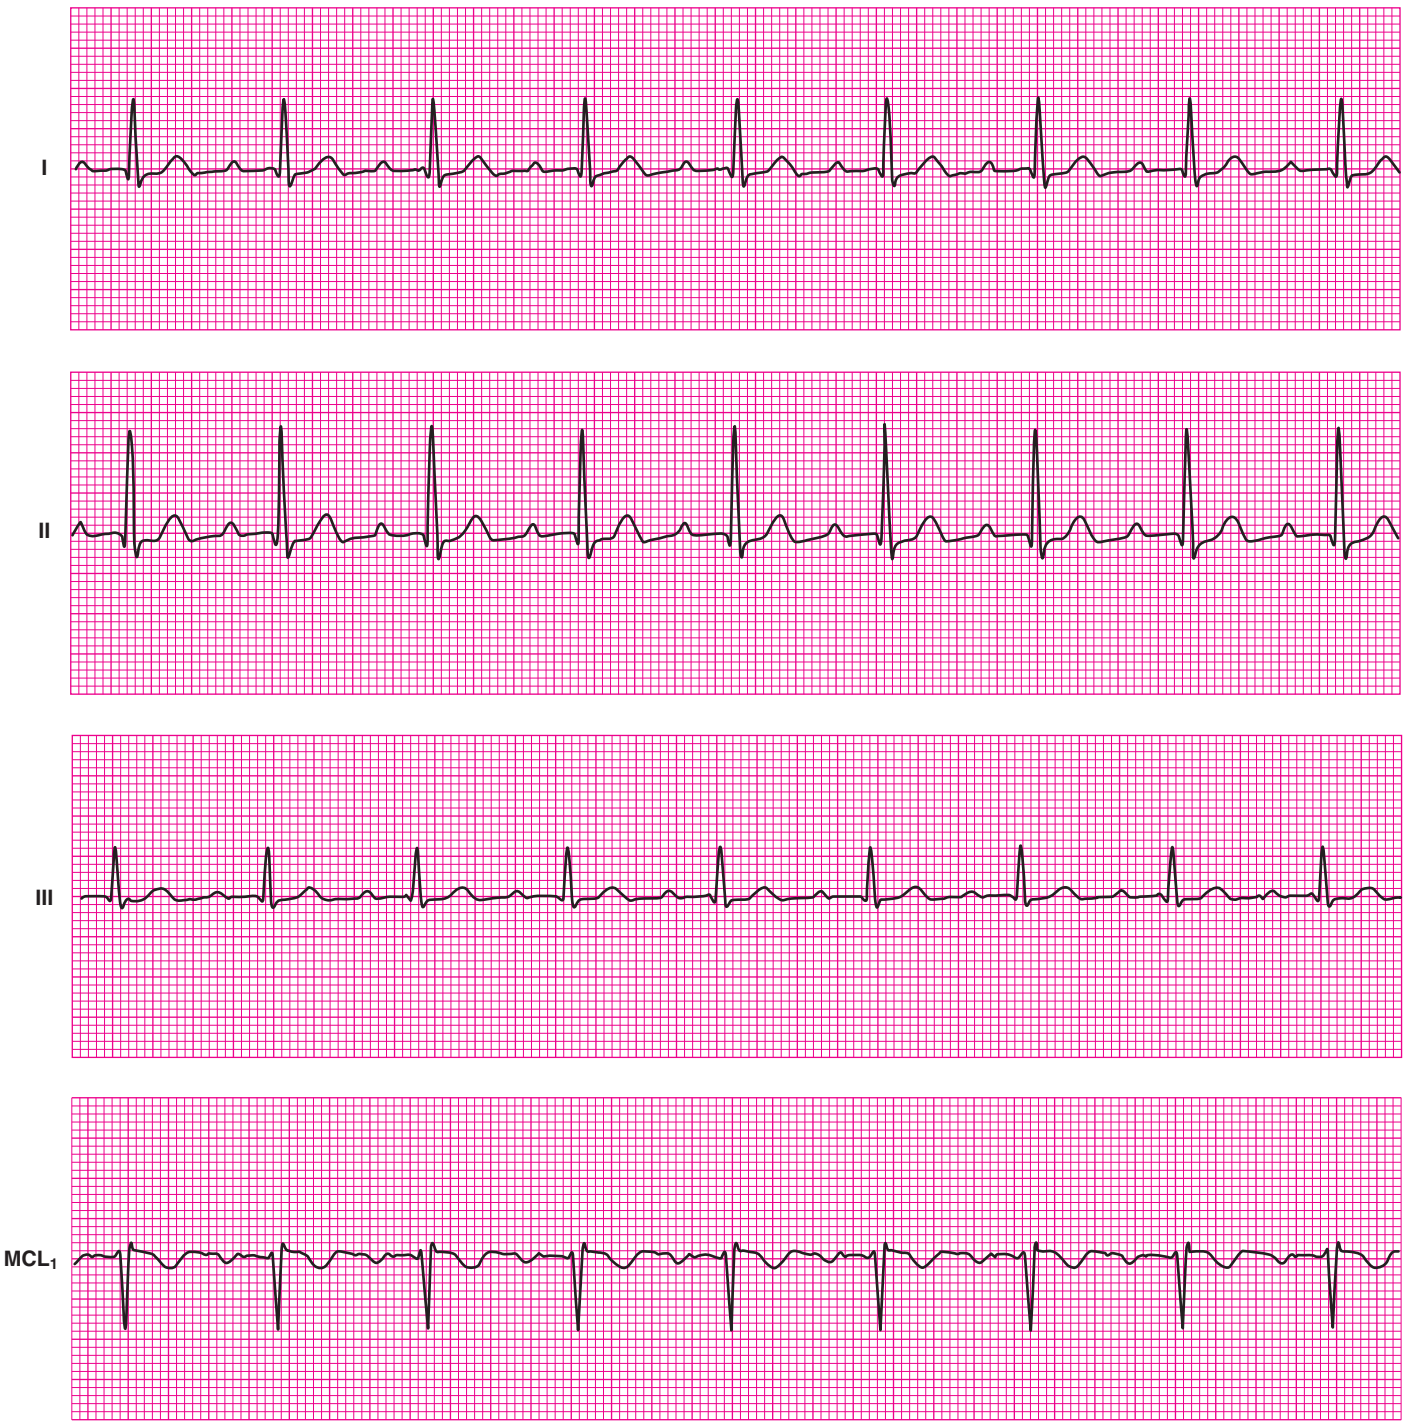

FIGURE 22-76 First-degree atrioventricular block.

Clinical Significance. As a general rule, first-degree atrioventricular block has little or no clinical significance, because all the impulses are conducted to the ventricles. In rare cases, however, a newly developed first-degree atrioventricular block progresses to a more serious atrioventricular block. The presence of first-degree AV block with a bundle branch block can signal the risk of complete heart block.[5]

Management. This dysrhythmia usually does not require treatment.

SECOND-DEGREE ATRIOVENTRICULAR BLOCK TYPE I (WENCKEBACH)

Description. Second-degree atrioventricular block type I is an intermittent block (Figure 22-77). It usually occurs at the level of the atrioventricular node. The conduction delay progressively increases from beat to beat until conduction to the ventricle is blocked. This dysrhythmia produces a characteristic cyclical pattern in which the P-R intervals get progressively longer until a P wave occurs that

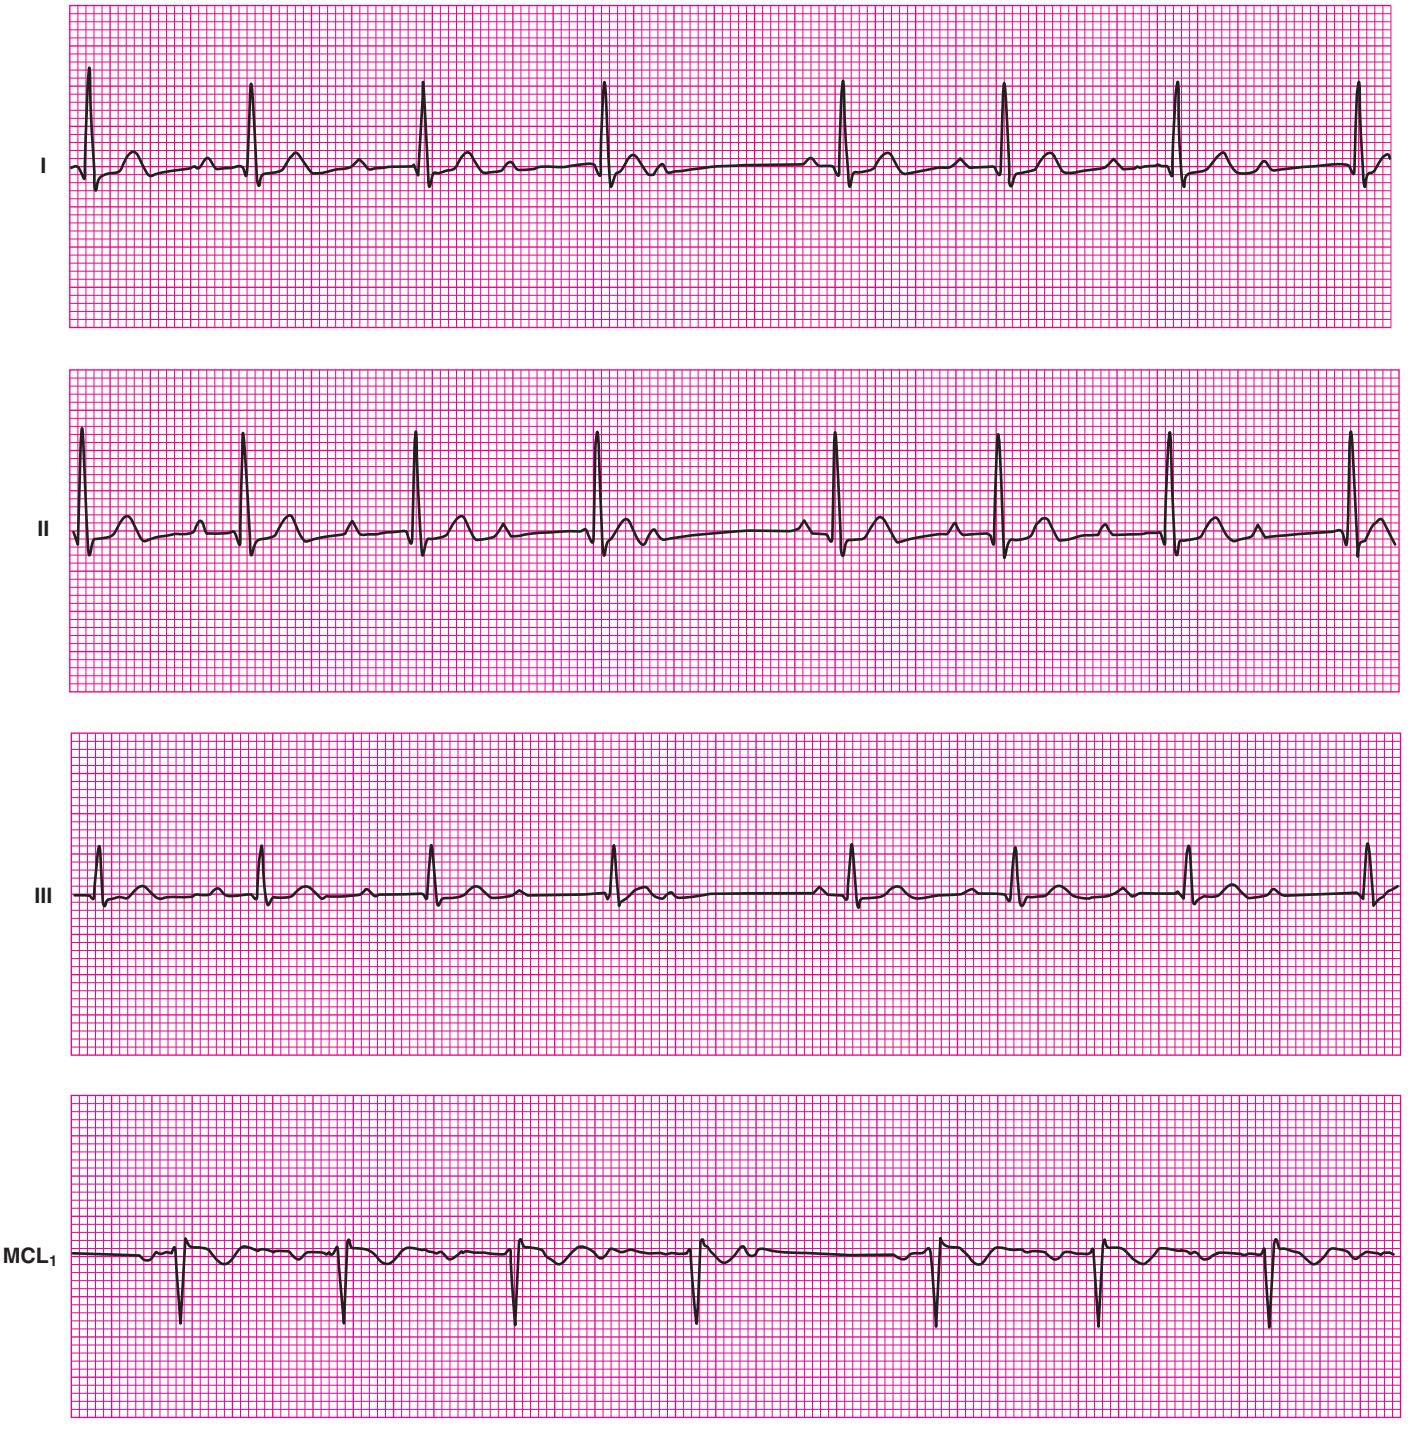

FIGURE 22-77 Second-degree atrioventricular block type I.

is not followed by a QRS complex. By the time the sinoatrial node fires again, atrioventricular conduction has had time to recover. The sequence then starts over.

Etiology. Second-degree atrioventricular block type I often occurs in acute myocardial infarction or acute myocarditis. Other causes include increased vagal tone, ischemia, drug toxicity (digitalis, propranolol, ***verapamil***), head injury, and electrolyte imbalance.

Rules for Interpretation (Lead II Monitoring). Second-degree atrioventricular block type I has the following characteristics on the ECG:

- *QRS complex*: Usually less than 0.12 second. Commonly, the atrioventricular conduction ratio (P waves to QRS complexes) is 5:4, 4:3, 3:2, or 2:1; the pattern may be constant or variable. A constant 2:1 block makes distinguishing between type I and type II blocks difficult. As a general rule, if the QRS complex is narrow, the block is probably a type I, 2:1 block. If the QRS complex is wide, the block is probably a type II, 2:1 block.[5]
- *P waves*: Upright, uniform, and preceding the QRS complex when the QRS complex occurs
- *Rate*: The atrial rate is that of the underlying sinus or atrial rhythm. The ventricular rate may be normal or slow but always is slightly less than the atrial rate.
- *Rhythm*: The atrial rhythm is regular; the ventricular rhythm is irregular (characteristic group beating).
- *P-R interval*: Progressively lengthens before the nonconducted P wave. The P-P interval is constant, but the R-R interval decreases until the dropped beat (producing grouping of QRS complexes).

Clinical Significance. Second-degree atrioventricular block type I usually is a transient and reversible phenomenon. However, it can progress to a more serious atrioventricular block. If dropped beats occur often, the patient may show signs and symptoms of decreased cardiac output.

Management. No management is required if the patient is asymptomatic. If the dropped beats compromise the heart rate and cardiac output, administration of ***atropine,*** transcutaneous cardiac pacing, or both may be indicated (see Figure 22-43).

SECOND-DEGREE ATRIOVENTRICULAR BLOCK TYPE II

Description. Second-degree atrioventricular block type II is an intermittent block (Figure 22-78). This dysrhythmia occurs when atrial impulses are not conducted to the ventricles. Unlike type I, this block is characterized by consecutive P waves that are conducted with a constant P-R interval before a dropped beat. This variation of atrioventricular block usually occurs in a regular sequence with the conduction ratios (P waves to QRS complexes), such as 2:1, 3:2, and 4:3 (Figure 22-79). Second-degree atrioventricular block type II usually occurs below the bundle of His.

When at least two consecutive P waves fail to be conducted to the ventricles, the atrioventricular block is referred to as a **high-grade atrioventricular block** (Figure 22-80). Clinically, serious high-grade atrioventricular blocks and those that are less serious are distinguished by the atrial and ventricular rates. A 2:1 block might be considered high grade (and certainly is clinically significant) when the patient's underlying atrial rate is 60 beats/minute. However, such a block is much less of concern if the patient's atrial rate is 120 beats/minute.

A type II 2:1 atrioventricular block sometimes may be difficult to distinguish from a type I 2:1 atrioventricular block. When assessing a patient who has two atrial complexes for each QRS complex, the paramedic should evaluate the normal cycle. If the normally conducted cycle has a prolonged P-R interval (greater than 0.20 second), a narrow QRS complex (less than 0.12 second, indicating the absence of bundle branch block), and an adequate escape rate, the patient probably has a type I 2:1 atrioventricular block. As stated previously, if the conducted QRS complex has a normal P-R interval, a wide QRS complex (greater than 0.12 second, which indicates the presence of a bundle branch block), and an adequate escape rate, a type II 2:1 atrioventricular block is most likely (Figure 22-81).

Etiology. Second-degree atrioventricular block type II usually is associated with an acute myocardial infarction that occurs in the septum. Unlike second-degree atrioventricular block type I, type II normally does not result solely from increased parasympathetic tone or drug toxicity.

Rules for Interpretation (Lead II Monitoring). Second-degree atrioventricular block type II has the following characteristics on the ECG:

- *QRS complex*: May be abnormal (equal to or greater than 0.12 second) because of bundle branch block
- *P waves*: Upright and uniform. Some P waves are not followed by QRS complexes.
- *Rate*: The atrial rate is unaffected and is that of the underlying sinus, atrial, or junctional rhythm. The ventricular rate is less than that of the atrial rate and often is bradycardic.
- *Rhythm*: Regular or irregular, depending on whether the conduction ratio is constant or variable
- *P-R interval*: Usually constant for conducted beats and may be greater than 0.20 second

Clinical Significance. Second-degree atrioventricular block type II is a serious dysrhythmia. It usually is considered malignant in the emergency setting (unlike type I atrioventricular blocks, which usually are considered benign). Slow ventricular rates may result in signs and symptoms of hypoperfusion. This dysrhythmia may progress to a more severe heart block or even to ventricular asystole.

Management. Regardless of the patient's initial condition, treatment involves insertion of a pacemaker. Prehospital care for symptomatic patients may consist of transcutaneous cardiac pacing and possibly the administration of beta-adrenergic drugs[1] (see Figure 22-43).

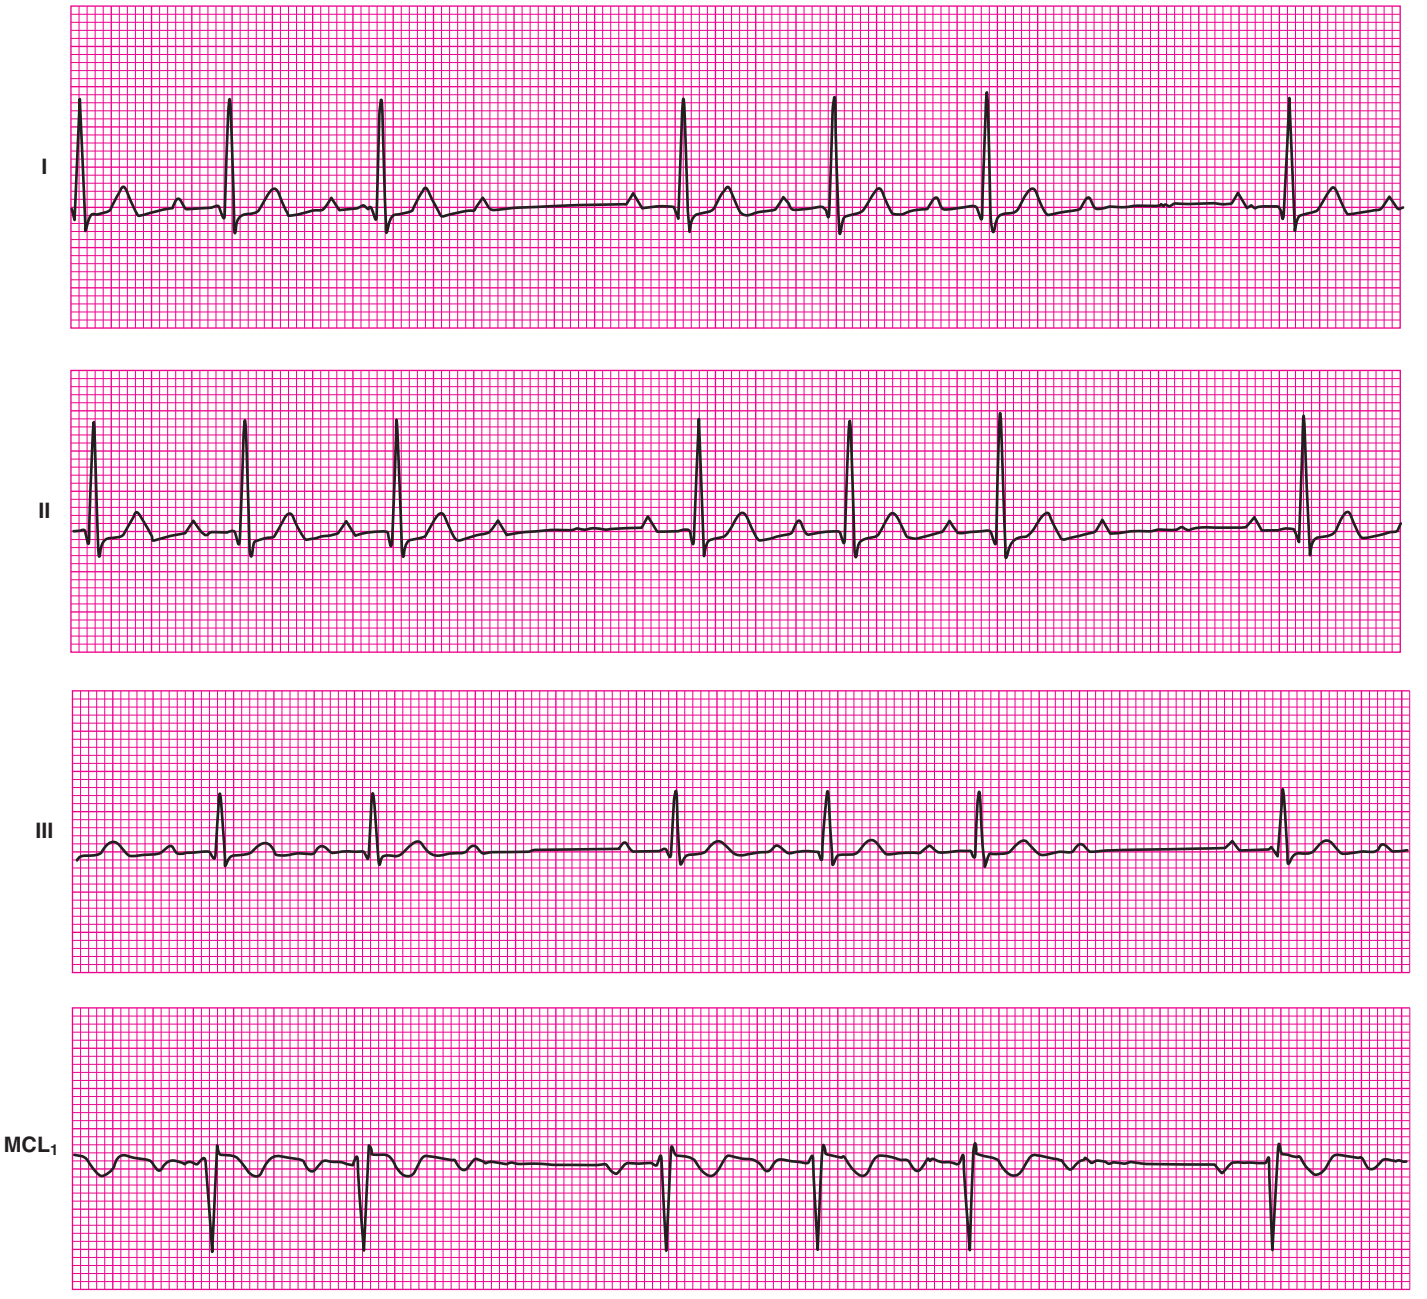

FIGURE 22-78 Second-degree atrioventricular block type II.

THIRD-DEGREE HEART BLOCK

Description. Third-degree atrioventricular block is also known as *complete heart block*. It results from complete electrical block at or below the atrioventricular node (infranodal) (Figure 22-82). The dysrhythmia is said to be present when the opportunity for conduction between the atria and the ventricles is present but conduction does not occur. In this condition the sinoatrial node serves as the pacemaker for the atria. An ectopic focus serves as a pacemaker in the ventricles. The result is P waves and QRS complexes that occur rhythmically, yet the rhythms are unrelated to each other (atrioventricular dissociation). The only electrical link between the atria and the ventricles is the atrioventricular node and bundle of His.

NOTE

Atropine should be used with caution in patients with complete heart block and wide-complex ventricular escape beats and also in patients with type II second-degree heart block.[1] (***Atropine*** may increase the degree of block or cause third-degree atrioventricular block.) Many patients with heart block cannot be managed effectively with only medication. Immediate transport to an emergency department is indicated.

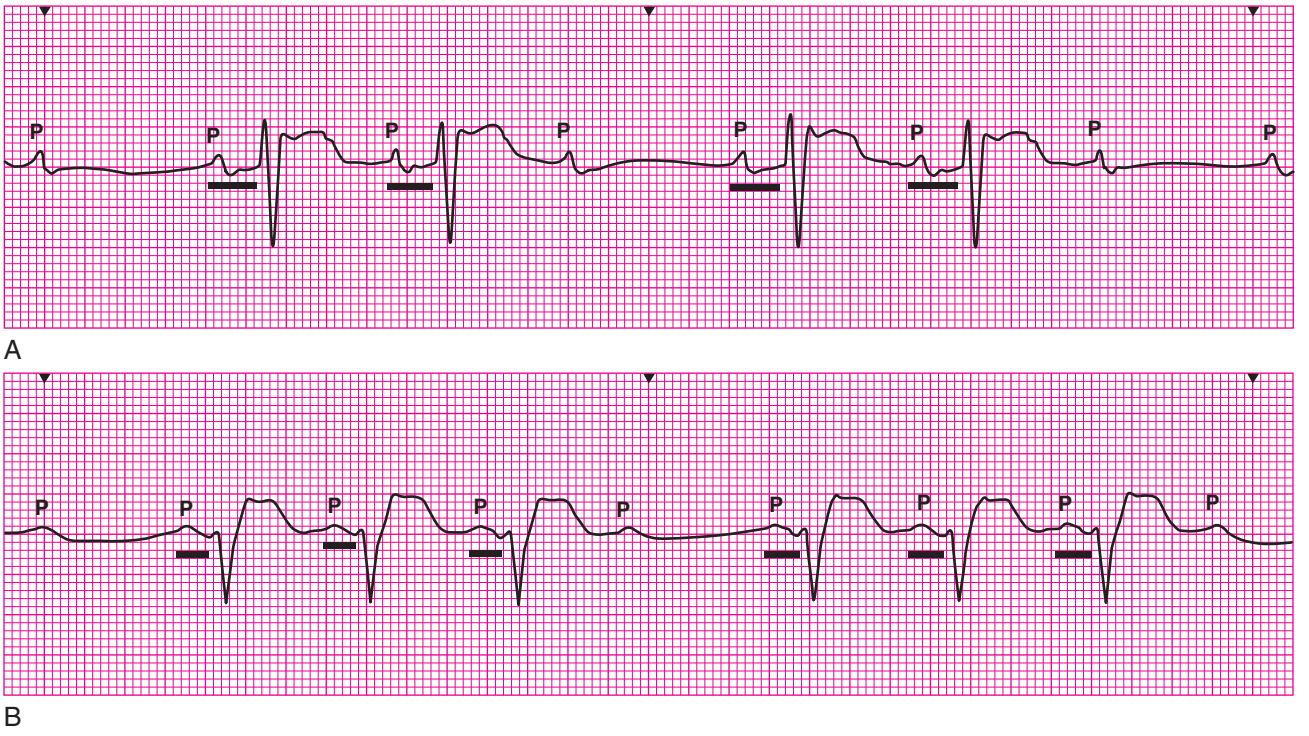

FIGURE 22-79 **A,** A 3:2 atrioventricular block. **B,** A 4:3 atrioventricular block.

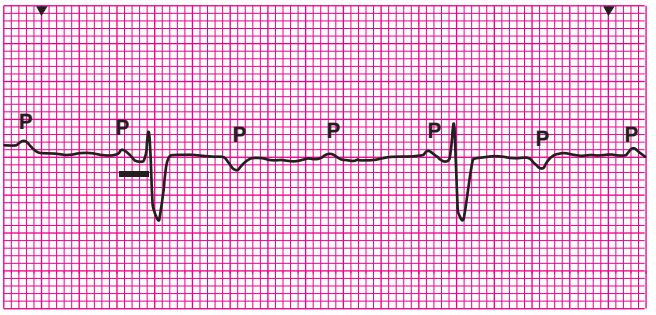

FIGURE 22-80 A 3:1 high-grade atrioventricular block.

Etiology. Common causes of third-degree atrioventricular block include increased vagal tone (which may produce a transient atrioventricular dissociation), septal necrosis, acute myocarditis, digitalis, beta-blocker, or calcium channel blocker toxicity, and electrolyte imbalance. The dysrhythmia also may occur in older adults as a result of chronic degenerative changes in the conduction system.

CRITICAL THINKING

When P waves and QRS complexes do not appear to be related to each other on the ECG, the paramedic should look at the shape of QRS-T waves. QRS-T waves altered by superimposed P waves suggest atrioventricular dissociation. Atrioventricular dissociation suggests third-degree atrioventricular block.

Rules for Interpretation (Lead II Monitoring). Third-degree heart block has the following characteristics on the ECG:

QRS complex: May be less than 0.12 second if the escape focus is below the atrioventricular node and above the bifurcation of the bundle branches or 0.12 second or greater if the escape focus is ventricular. A narrow QRS complex in third-degree heart block is less common than a wide QRS complex.

P waves: Present but with no relationship to the QRS complexes. In cases of atrial flutter or fibrillation, complete heart block is manifested by a slow, regular ventricular response.

Rate: The atrial rate is that of the underlying sinus or atrial rhythm. The ventricular rate typically is 40 to 60 beats/minute if the escape focus is junctional and less than 40 beats/minute if the escape focus is in the ventricles.

Rhythm: The atrial and ventricular rhythms usually are regular. The rhythms are independent of each other.

P-R interval: No relation exists between atrial and ventricular activity (Figure 22-83).

Clinical Significance. The patient may have signs and symptoms of severe bradycardia and decreased cardiac output. These are the result of the slow ventricular rate and asynchronous action of the atria and ventricles. Third-degree atrioventricular block associated with wide QRS complexes is an ominous sign. The dysrhythmia potentially is lethal. Patients with this rhythm often present as unstable.

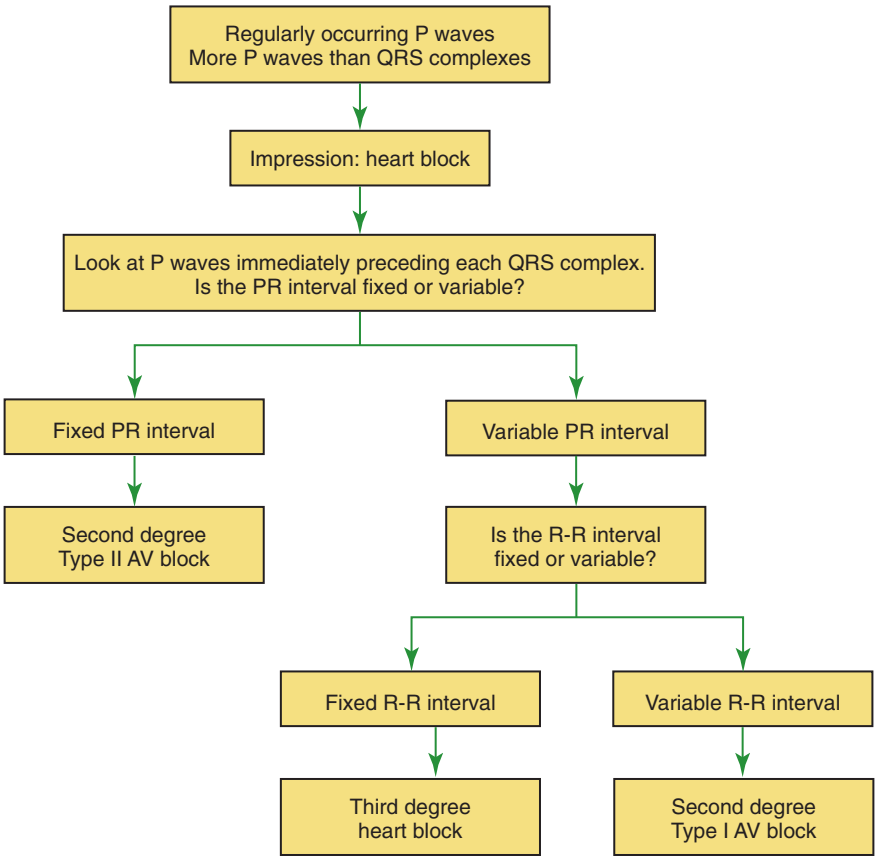

FIGURE 22-81 Identifying heart blocks.

NOTE

Complete atrioventricular block in the presence of atrial fibrillation often is caused by drug toxicity (usually ***digitalis***). Almost always some atrioventricular block occurs with atrial fibrillation or flutter. Yet complete atrioventricular block is recognized by a slow, regular ventricular response. (The response usually is slower than 60 beats/minute.) The QRS complex may be normal if the escape focus is from above the bifurcation of the bundle branches.

Management. Insertion of a pacemaker is the definitive treatment for symptomatic third-degree atrioventricular block and for asymptomatic third-degree heart block with bundle branch block. Initial prehospital care includes transcutaneous cardiac pacing or administration of a ***dopamine*** infusion to increase the ventricular rate, if needed, and administration of an ***epinephrine*** infusion.

Transcutaneous cardiac pacing is a class IIb intervention for symptomatic bradycardias that do not improve after atropine administration (see Figure 22-43). ***Atropine*** is unlikely to help patients with complete heart block and a wide QRS complex. The vagus nerve innervates the atria and AV node, and the focus controlling the heart in a third-degree block most often is in the ventricles.

CRITICAL THINKING

What should you tell the patient before starting transcutaneous cardiac pacing?

Ventricular Conduction Disturbances

Ventricular conduction disturbances (bundle branch blocks and hemiblocks) are delays or interruptions in the transmission of electrical impulses. These disturbances occur below the level of bifurcation of the bundle of His. Detection of these blocks is important. It helps to identify the patient at increased risk of severe bradycardia and third-degree heart block. This is especially true when the patient has other forms of atrioventricular block. Common causes of bundle branch block include the following:

- Acute heart failure
- Acute myocardial infarction
- Aortic stenosis
- Cardiomyopathy
- Hyperkalemia
- Infection (e.g., carditis)
- Ischemic heart disease
- Trauma

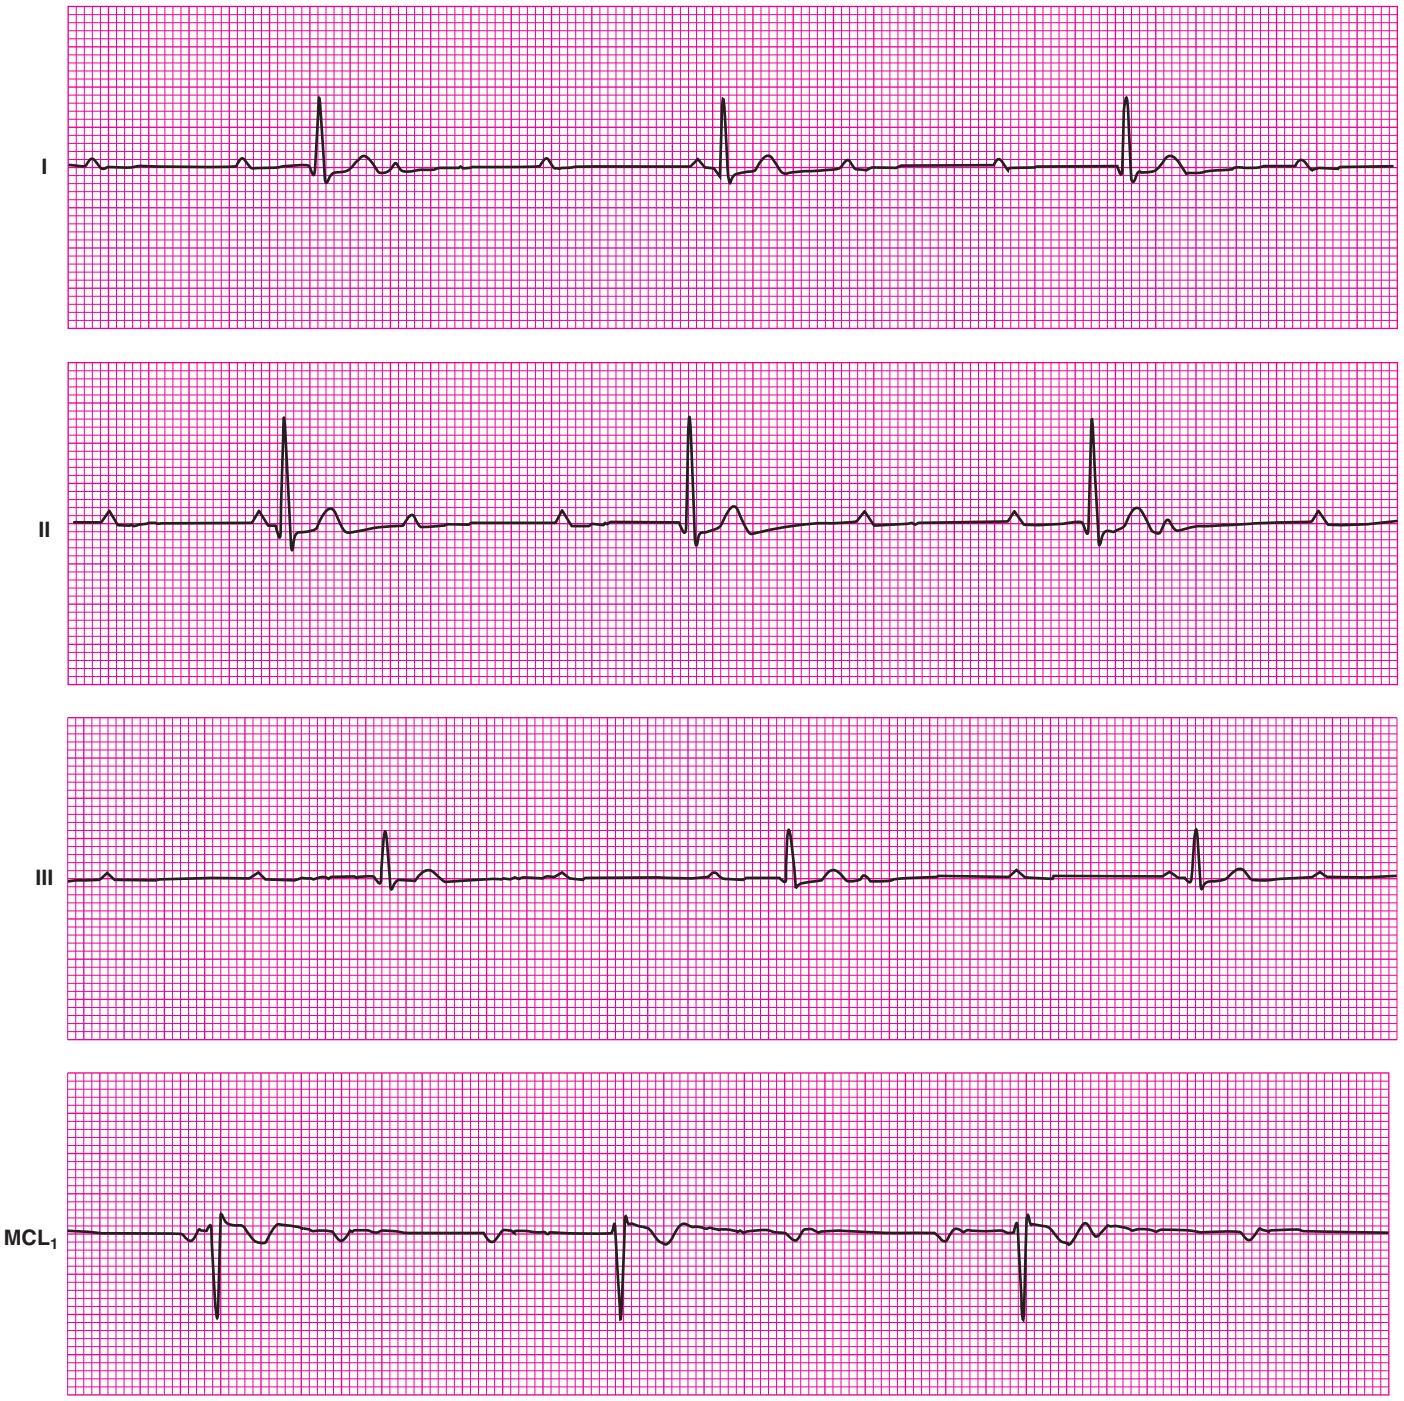

FIGURE 22-82 Third-degree atrioventricular block.

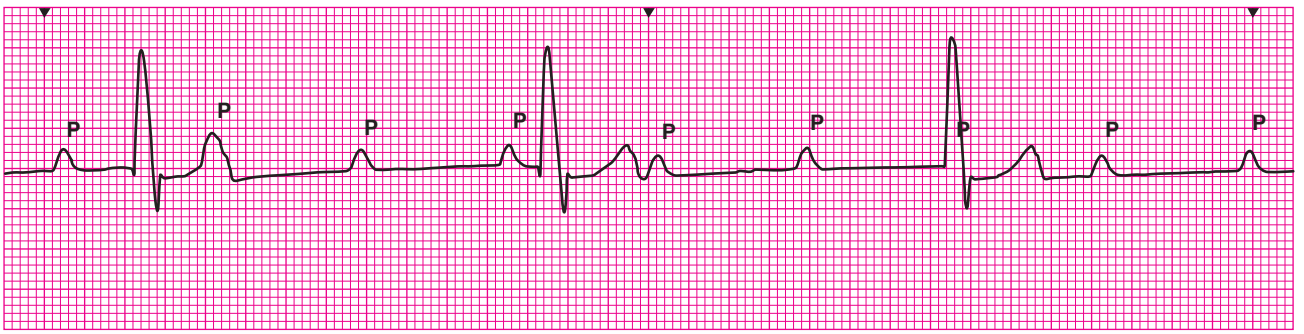

FIGURE 22-83 Third-degree block demonstrating P waves superimposed on the QRS complex.

BUNDLE BRANCH ANATOMY

To review, the bundle of His begins at the atrioventricular node and divides to form the left and right bundle branches (Figure 22-84). The right bundle branch continues toward the apex and spreads throughout the right ventricle. The left bundle branch subdivides into the anterior and posterior fascicles and spreads throughout the left ventricle. Conduction of electrical impulses through the Purkinje fibers stimulates the ventricles to contract.

With normal conduction, the first part of the ventricle to be stimulated is the left side of the septum. The electrical impulse then traverses the septum to stimulate the other side. Shortly thereafter, the left and right ventricles are stimulated at the same time. The left ventricle normally is much larger and thicker than the right ventricle; therefore, its electrical activity predominates over that of the right ventricle.

COMMON ELECTROCARDIOGRAM FINDINGS

When an electrical impulse is blocked from passing through the right or left bundle branch, aberration (abnormal conduction) occurs and one ventricle depolarizes and contracts before the other. Ventricular activation no longer occurs at the same time. As a result, the QRS complex widens (often with a slurred or notched appearance known as *rabbit ears*). The hallmark of bundle branch block is a QRS complex equal to or greater than 0.12 second. The two criteria for recognizing bundle branch block are:

- A QRS complex equal to or greater than 0.12 second
- QRS complexes produced by supraventricular activity

NOTE

Bundle branch block and *hemiblock* (fascicular block) are terms used to describe abnormal conduction or the interruption of impulses from above the bundle branches to the ventricles. The interruption may occur in either the anterior (superior) or the posterior (inferior) division. These patterns of abnormal or aberrant conduction must be recognized as different from beats of ventricular origin. Beats of ventricular origin can have similar QRS complex shapes.

Ventricular conduction disturbances are identified best by monitoring leads V_1 and V_6 with a 12-lead machine. These leads permit the easiest differentiation of the right and left bundle branch blocks. Lead V_1 looks at right and left bundle branches and should be monitored during transport of these patients.[7]

Normal Conduction. In normal ventricular stimulation, the electrical impulse reaches the septum first. It then travels from the left endocardium to the right endocardium of the septum (Figure 22-85). This impulse generates a small R wave in V_1. The rest of the impulses mainly are conducted away from the V_1 electrode. This yields a negative deflection. Therefore, during normal conduction, V_1 mainly is negative. The QRS complex also is usually 0.08 to 0.10 second wide (the same as any other narrow QRS complex).

Right Bundle Branch Block. In **right bundle branch block** (RBBB), the left bundle branch performs normally. Therefore, the left branch activates the left side of the heart before the right (Figure 22-86). When the left ventricle is

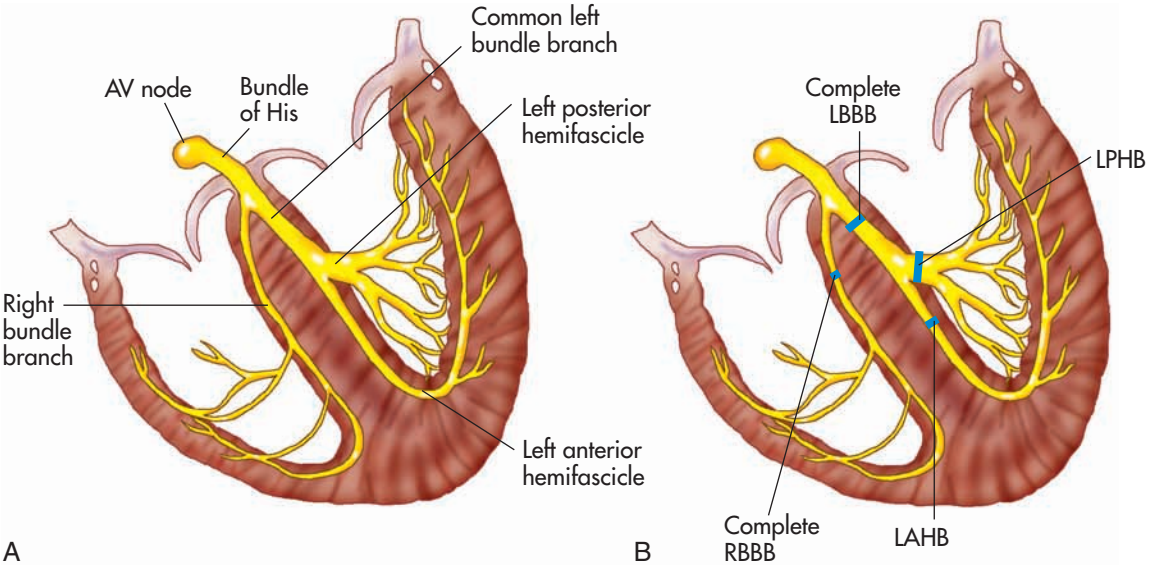

FIGURE 22-84 **A,** Simplified illustration of the major divisions of the ventricular conduction system. After passing through the atrioventricular node and the bundle of His, the electrical impulse is carried to the right and common left bundle branches. The latter structure divides into the left anterior and posterior hemifascicles. **B,** Possible sites of block and the conduction deficits that may be produced.

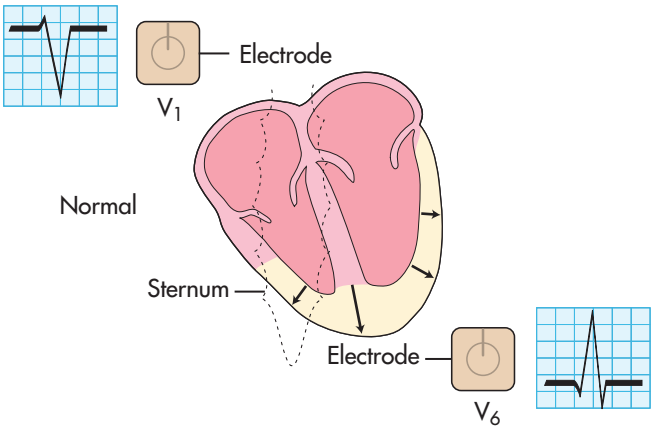

FIGURE 22-85 Normal ventricular conduction.

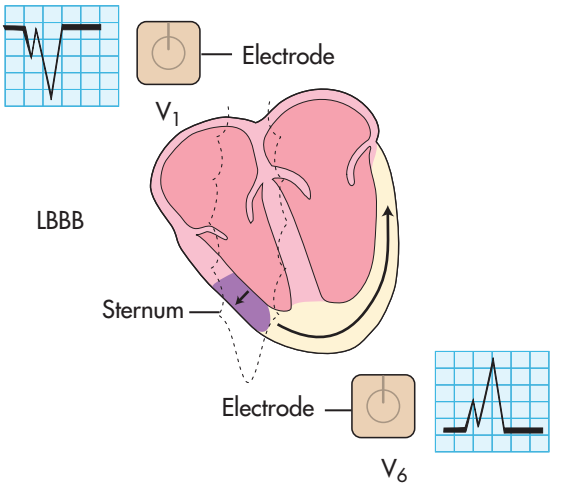

FIGURE 22-87 Left bundle branch block.

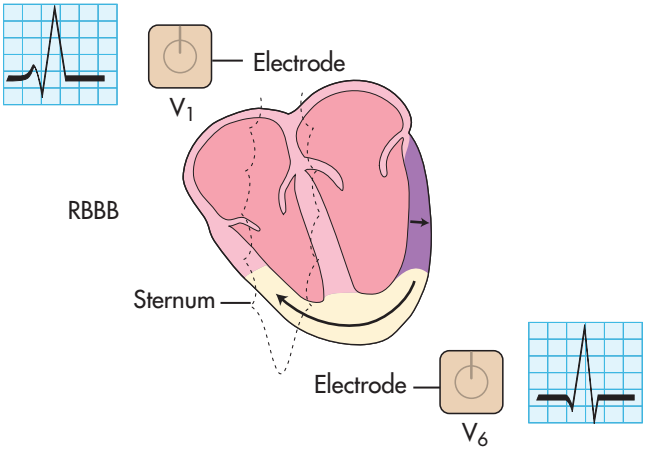

FIGURE 22-86 Right bundle branch block.

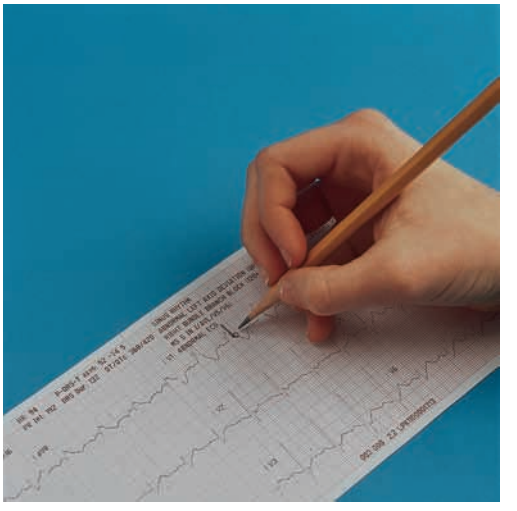

FIGURE 22-88 To distinguish left from right bundle branch blocks, find the J point of the QRS complex, draw a line backward into the QRS complex, and fill in the triangle created by this line and the last portion of the QRS complex. The direction the triangle points distinguishes the two types of blocks.

activated initially, the impulse travels away from the V_1 electrode. This yields a negative deflection (S wave). The electrical impulse then travels across the interventricular septum and activates the right ventricle. Because the impulse is coming back toward the V_1 electrode, a large positive deflection (R wave) occurs. This results in the RSR′ pattern seen in V_1 in patients with right bundle branch block. The QRS (or in this case, RSR) complex is at least 0.12 second. Whenever the two criteria for bundle branch block are met and V_1 displays an RSR′ pattern, right bundle branch block should be suspected.

NOTE

In right bundle branch block (RBBB), the left ventricle receives the electrical impulse first. In left bundle branch block (LBBB), the opposite occurs. Because one ventricle contracts slightly later than the other, two QRS complexes are produced that often appear joined.

Left Bundle Branch Block. In the more serious **left bundle branch block** (LBBB), the fibers that usually stimulate the interventricular septum are blocked. This blockage alters normal septal activation and sends it in the opposite direction (Figure 22-87). The septum is depolarized by the right bundle branch, and the right ventricle then is activated. Because the impulse is leading away from V_1, the lead shows a deep, wide S wave (QS pattern). As with right bundle branch block, the activation takes at least 0.12 second. Whenever the two criteria for bundle branch block are met and a QS pattern is seen in V_1, a left bundle branch block should be suspected. Patients with new or presumed new left bundle branch block have lost a lot of myocardium; left ventricular failure may develop and may lead to death.

BOX 22-9 Turn Signal Method of Determining Right or Left Bundle Branch Block

As a shortcut for identifying right or left bundle branch block, the paramedic should envision the turn signal mechanism in a vehicle. The turn signal is pushed "up" to turn *right* and pushed "down" to turn *left*.

When lead V_1 is monitored, the bundle branch block may be determined by the following procedure (Figure 22-88):

1. Find a QRS complex that is at least 0.12 second wide.
2. Count backward three small boxes from the beginning of the QRS complex and move straight up to see the J point.
3. Draw a line backward from the J point into the QRS complex.
4. Fill in the triangle created by this line and the last portion of the QRS complex.
5. If the triangle points up, it is a right bundle branch block.
6. If the triangle points down, it is a left bundle branch block.

The turn signal method (Box 22-9) is a means of differentiating right and left bundle branch block.

NOTE
A clear RSR′ or QS pattern in V_1 cannot always be identified. The turn signal method is another means of determining which bundle is blocked. Using this method to evaluate the ECG can help the paramedic identify which ventricle was depolarized last.

MANAGEMENT OF BUNDLE BRANCH BLOCKS AND HEMIBLOCKS

No specific treatment is necessary for persistent bundle branch blocks or hemiblocks. (New onset LBBB with chest pain may be acute coronary syndrome.) In these cases, the LBBB should be treated as ST-segment elevation myocardial infarction (STEMI). However, if other conditions (e.g., hypoxia, ischemia, electrolyte imbalance, or drug toxicity) are causing a block, these conditions should be treated. Some emergency medication administered to patients with cardiac disease (e.g., ***procainamide, digoxin,*** and ***verapamil*** or ***diltiazem***) can slow electrical impulse conduction through the atrioventricular node. To administer these medicines safely, the paramedic must make sure the patient is not at a high risk of developing complete heart block. Those at such risk include the following:

- Any patient with type II atrioventricular block
- Any patient with evidence of disease in both bundle branches
- Any patient with two or more blocks of any kind (e.g., prolonged P-R interval and anterior hemiblock, right bundle branch block and anterior hemiblock, type I atrioventricular block, and left bundle branch block)

Prehospital care for these patients should include management of any accompanying signs and symptoms, transport, constant ECG monitoring, and anticipation of the possible need for external pacing. Emergency pacing has been recommended for the following four indications[1]:

1. Hemodynamically compromising bradycardias
2. Bradycardias with malignant escape rhythms unresponsive to pharmacological therapy
3. Overdrive pacing of refractory supraventricular or ventricular tachycardia unresponsive to pharmacological therapy or cardioversion
4. Bradyasystolic cardiac arrest (in rare situations)

The American Heart Association also recommends pacing readiness in the setting of acute myocardial infarction for patients with symptomatic sinus node dysfunction; second-degree atrioventricular block type II; third-degree heart block; or newly acquired left, right, or alternating bundle branch block or bifascicular block.[1]

Pulseless Electrical Activity

The term **pulseless electrical activity** (also known as *electromechanical dissociation*) (Figure 22-89) is defined as the absence of a detectable pulse and the presence of some type of electrical activity other than ventricular tachycardia or ventricular fibrillation.[1] The outcome of pulseless electrical activity almost always is poor unless an underlying cause can be identified and corrected. The paramedic must maintain circulation for the patient with basic and advanced life support techniques while searching for a correctable cause.

CRITICAL THINKING
What rhythms might you see on the monitor when a patient is in pulseless electrical activity?

Correctable causes of pulseless electrical activity are cardiac tamponade, tension pneumothorax, pulmonary embolism, myocardial infarction, hypoxemia, acidosis, hypokalemia, hyperkalemia, hypothermia, and overdoses (e.g., narcotics, cyclic antidepressants, beta blockers, and digitalis). Other, less correctable causes include massive myocardial damage from infarction, prolonged ischemia during resuscitation, profound hypovolemia, and massive pulmonary embolism. Patients in profound shock of any type (including anaphylactic, septic, neurogenic, and hypovolemic shock) may have pulseless electrical activity.

The paramedic should manage tension pneumothorax with needle decompression. If the patient is hypoxic, the paramedic should manage the patient by improving oxygenation and ventilation. If acute hypovolemia is present (because of hemorrhage), the paramedic should begin fluid resuscitation with volume expanders. The paramedic

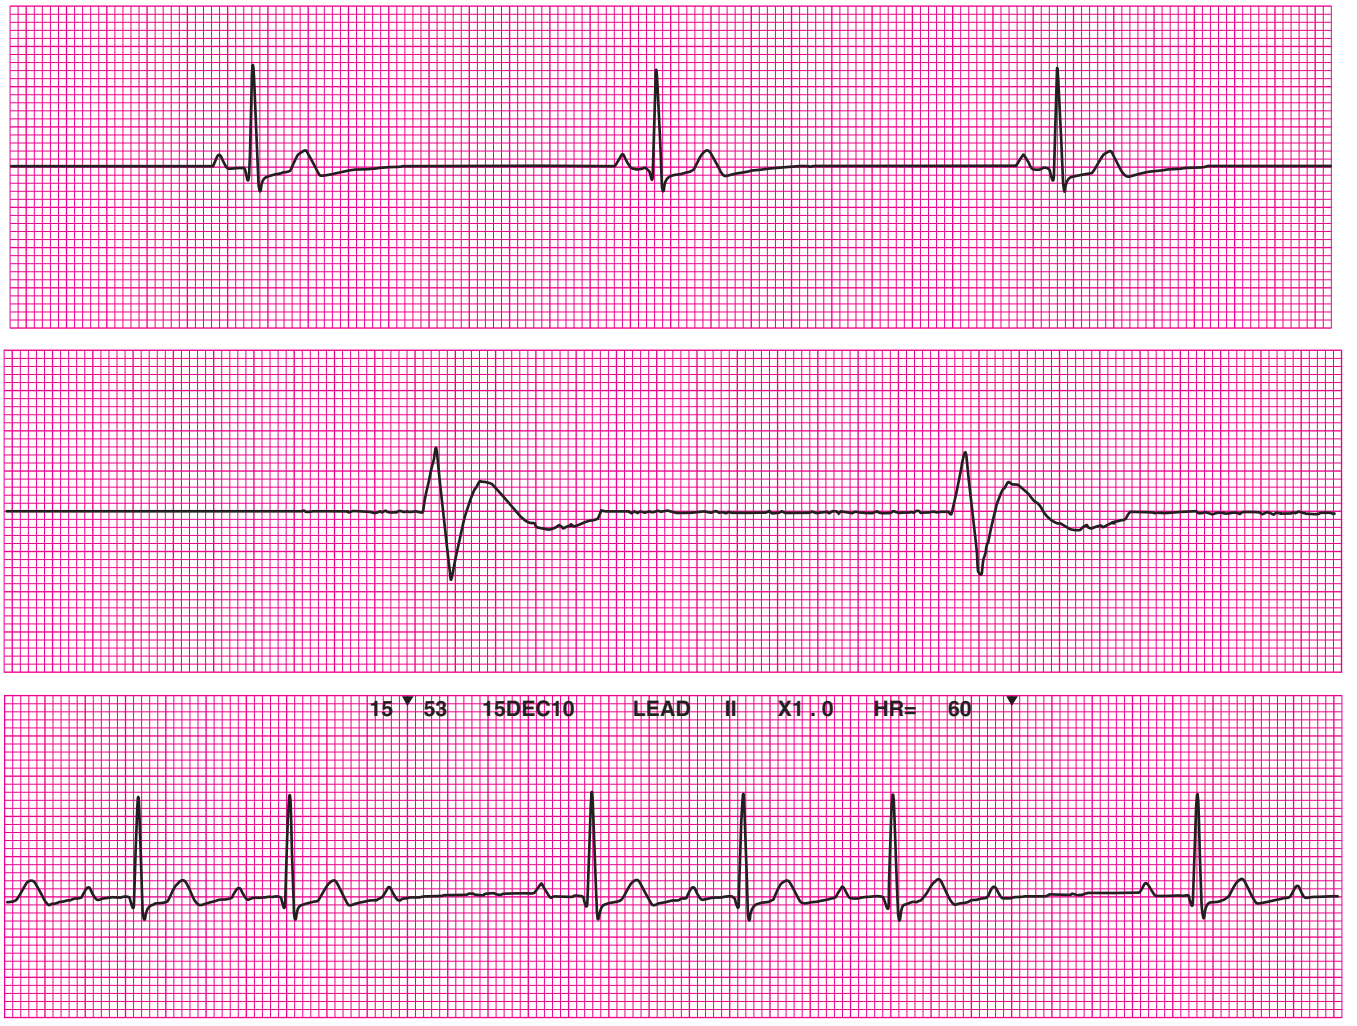

FIGURE 22-89 Various pulseless electrical activity rhythms as seen in lead II.

should manage acidosis by ensuring adequate cardiopulmonary resuscitation and hyperventilation. If preexisting acidosis (e.g., diabetic ketoacidosis), cyclic antidepressant overdose, or hyperkalemia is suspected (e.g., a patient on home dialysis), use of ***sodium bicarbonate*** may be indicated. ***Calcium*** is a specific therapy for hyperkalemia and calcium channel blocker toxicity. Both of these conditions can produce pulseless electrical activity. Besides calcium channel blockers, other drugs taken in toxic amounts can produce wide-complex pulseless electrical activity. These overdoses can be managed with specific therapy. The therapy may be effective in reestablishing a perfusing rhythm (see Figure 22-63).

CRITICAL THINKING

What patient care measures should you take in this case?

Preexcitation Syndromes

Preexcitation syndrome (anomalous or accelerated atrioventricular conduction) is associated with an abnormal conduction pathway between the atria and ventricles. This pathway bypasses the atrioventricular node or the bundle of His or both. This allows the electrical impulses to initiate depolarization of the ventricles earlier than usual. The most common preexcitation syndrome is **Wolff-Parkinson-White syndrome.**

WOLFF-PARKINSON-WHITE SYNDROME

Description. In some hearts an accessory muscle bundle (the **bundle of Kent** or *Kent fibers*) connects the lateral wall of the atrium and the ventricle, bypassing the atrioventricular node. This produces an early activation of the ventricle (Wolff-Parkinson-White syndrome).[7] WPW syndrome is thought to be of minor clinical significance unless a tachycardia is present. In that case, the syndrome can become life threatening.

NOTE

Another preexcitation syndrome grouped with WPW syndrome is *Lown-Ganong-Levine (LGL) syndrome*. As in WPW syndrome, the accessory pathway in LGL syndrome does not share the rate-slowing properties of the AV node and may conduct electrical activity at a significantly higher rate than the AV node. Proposed theories to explain LGL syndrome are the possible presence of intranodal fibers *(James fibers, Mahaim fibers)* that bypass all or part of the AV node and run from the atrium to the bundle of His.[8]

NOTE

The QRS complexes in LGL syndrome are normal, because ventricular contraction is initiated in the normal manner. The broad complexes seen in an asymptomatic individual with WPW syndrome are not a feature of LGL syndrome. The delta waves seen in WPW syndrome are not seen in LGL syndrome, because the accessory pathway does not connect to the ventricles; therefore, ventricular contraction does not start early.

Etiology. Wolff-Parkinson-White syndrome may occur in young, healthy individuals (mainly men) without apparent cause. It also may occur in multiple members of a family. It may be present in successive generations.

Rules for Interpretation (Lead II Monitoring). Wolff-Parkinson-White syndrome has the following characteristics on the ECG:

QRS complex: May be normal or wide (depending on whether conduction is retrograde or anterograde along the bundle of Kent). Conduction that occurs normally down the atrioventricular node and simultaneously in an anterograde fashion along the accessory pathway results in a meeting of the two waves of depolarization that forms a fusion (delta wave). A **delta wave** is evidenced by slurring or notching of the onset of the QRS complex and is a diagnostic finding in WPW syndrome. (Not all leads show the delta wave.) Paramedics should keep in mind that QRS widening may simulate right or left bundle branch block.

P waves: Normal

Rate: Normal unless associated with rapid supraventricular tachycardia

Rhythm: Regular

P-R interval: Usually less than 0.12 second, because the normal delay at the atrioventricular node does not occur

The three characteristic ECG findings in Wolff-Parkinson-White syndrome are a short P-R interval, a delta wave, and QRS widening (Figure 22-90).

Clinical Significance. Patients with WPW syndrome are highly susceptible to bouts of paroxysmal supraventricular tachycardias. The reason is that the accessory pathway provides a ready-made reentry circuit. This allows continued transmission of the impulse from the atria to the ventricles. Most tachydysrhythmias seen in Wolff-Parkinson-White syndrome occur with the wave of depolarization progressing from the atrioventricular node to the bundle of His to the accessory pathway. In the accessory pathway the impulse is conducted in a retrograde direction to the atria. Therefore, most tachydysrhythmias seen in WPW syndrome are narrow complexes. Patients with Wolff-Parkinson-White

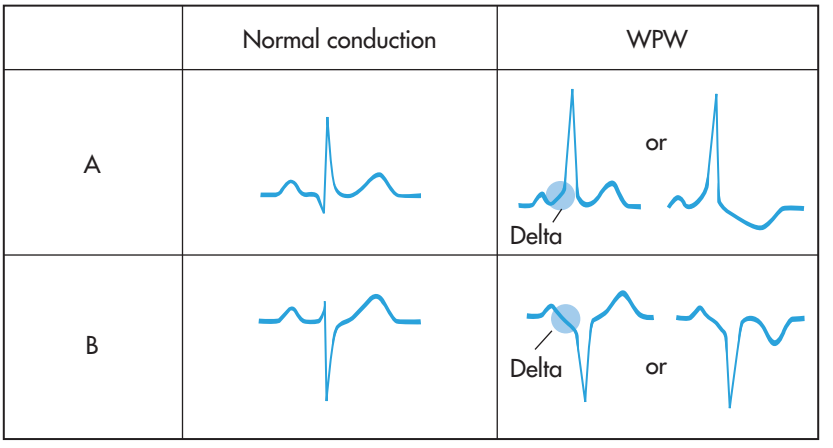

FIGURE 22-90 Characteristic findings in Wolff-Parkinson-White (WPW) syndrome (short P-R interval, QRS widening, and delta wave) compared with normal conduction. **A,** Usual appearance of WPW syndrome in leads where the QRS complex is predominantly upright. **B,** Appearance of WPW syndrome; the RS complex is predominantly negative.

syndrome may have attacks of paroxysmal tachydysrhythmias for many years. However, these attacks are not always benign. The atrioventricular node may be bypassed. Conduction rates also can greatly exceed those in patients whose atrioventricular node is part of the reentry circuit. This leads to rapid tachycardias. These can precipitate congestive heart failure and even death from ventricular fibrillation.

Management. Recognition of Wolff-Parkinson-White syndrome is crucial. Differentiation of the syndrome from ventricular tachycardia and uncomplicated supraventricular tachycardia also is a key factor. Many emergency drugs used to manage other reentry tachycardias are contraindicated in Wolff-Parkinson-White syndrome. AV nodal blocking agents (e.g., ***adenosine,*** calcium channel blockers, ***digoxin,*** and possibly beta blockers) should not be administered. These drugs can cause a paradoxical increase in the ventricular response to the rapid atrial impulses of atrial fibrillation. Management must be based on the patient's signs and symptoms. If the patient's heart rate is normal, no emergency care is required. If the patient has a rapid tachycardia, emergency treatment to restore normal rhythm is needed. The treatment is aimed at blocking conduction through the accessory pathways from the atria to the ventricle.

Prehospital care may include pharmacological therapy for specific dysrhythmias, vagal maneuvers, and cardioversion for severe clinical deterioration. ***Verapamil*** and ***diltiazem*** are contraindicated in wide QRS complex tachycardia because these drugs can speed conduction down the accessory pathway (greater than 280 beats/minute). This increase in conduction may lead to ventricular fibrillation and sudden death. Therefore, in patients with wide QRS complex tachycardia, the drug treatment depends on the patient's signs and symptoms and their severity.

To review, ***amiodarone*** is the drug of choice for presumed supraventricular tachycardia and supraventricular tachycardia with aberrant conduction. (***Procainamide*** is an alternative drug that may be used.) The paramedic should perform cardioversion without delay in patients with rapid ventricular rates (greater than 150 beats/minute) who are unstable.

SECTION SIX
The 12-Lead Electrocardiogram

12-LEAD MONITORING

As stated earlier, the 12-lead ECG has become standard in many EMS systems that provide advanced life support. 12-Lead acquisition and interpretation now is recognized as a key skill for paramedics.[9] The ability to interpret a 12-lead ECG can affect transport decisions and medication and treatment selections. In addition, this skill can help paramedics predict the likelihood that a patient will become unstable. 12-Lead ECG monitoring can be used to:

- Determine the presence and location of bundle branch blocks
- Determine the electrical axis and the presence of fascicular blocks
- Identify ST-segment and T-wave changes relative to myocardial ischemia, injury, and infarction
- Identify ventricular tachycardia in wide-complex tachycardia

Lead Review

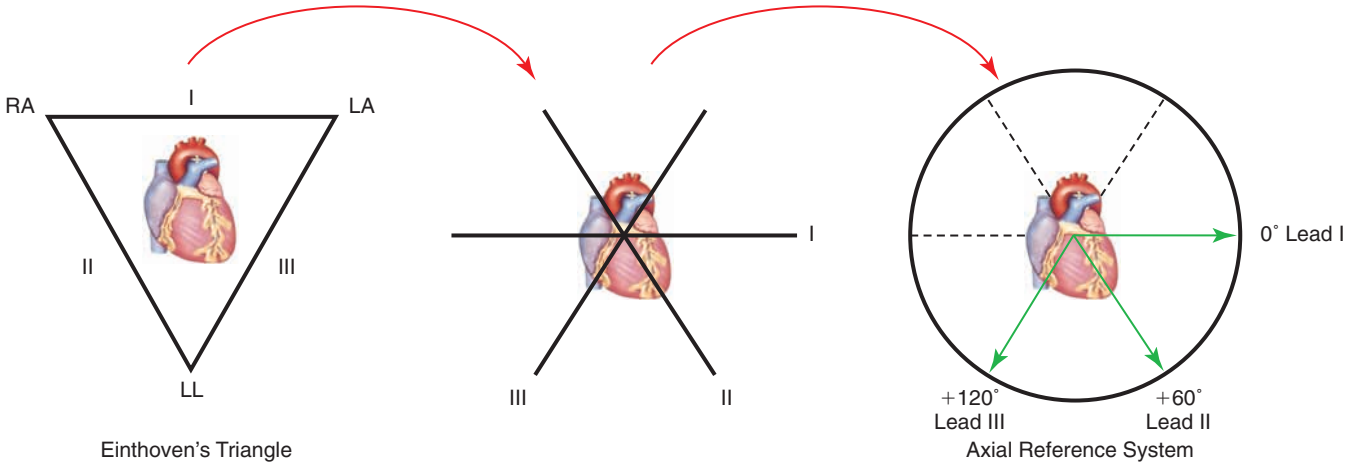
As explained earlier, ECG machines provide many views of the electrical activity of the heart by monitoring voltage changes between electrodes applied to the body. To review, the modern ECG uses 12 leads: three standard limb leads; three augmented limb leads, and six precordial (chest) leads. The standard limb leads are I, II, and III. The augmented limb leads are aV_R, aV_L, and aV_F. The precordial leads are V_1 through V_6.

NOTE

Leads should not be confused with *electrodes*. The 12-lead ECG uses only 10 electrodes. However, the machine interprets 12 leads, or "views," of the heart using computerized calculations.

The imaginary lines join the positive and negative electrodes of each lead, forming a straight line between the positive and negative poles. This straight line is known as the *axis* of the ECG lead. The axes of the standard limb leads represent the average direction of the electrical activity of the heart. If these axes are moved so that they cross a common midpoint without changing their orientation, they form a triaxial reference system (three intersecting lines of reference). Lead I is a lateral (leftward) lead. It assesses the electrical activity of the heart from a vantage point that is defined as 0 degrees on a circle. This circle is divided into an upper negative 180 degrees and a lower positive 180 degrees. Leads II and III are inferior leads. They assess the electrical activity of the heart from vantage points of +60 degrees and +120 degrees, respectively.

The augmented limb leads (Figure 22-91) record the difference in electrical potential between the positive electrode of an extremity lead and a vantage point. The vantage point of zero electrical potential is at the center of the electrical field of the heart. As a result, the axis of each lead is formed by the line from the electrode site (on the right arm, left arm, or left leg) to the center of the heart. The aV_R, aV_L, and aV_F leads intersect at angles different from the standard limb leads and produce three other intersecting lines of reference. When these six lines of reference are combined (one every 30 degrees), they form the hexaxial reference system (Figure 22-92). Lead aV_L acts as a lateral (leftward) lead. It records the electrical activity of the heart from a vantage point that looks down from the left arm. Lead aV_F



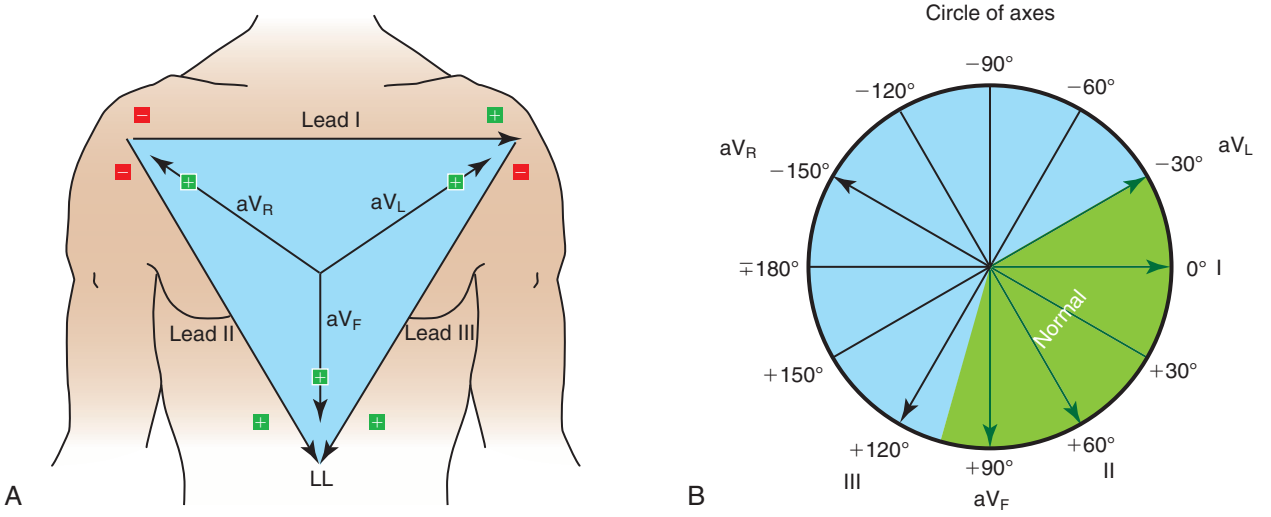


FIGURE 22-91 Augmented limb leads.

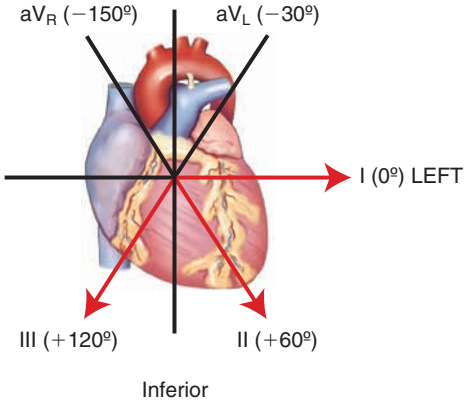

FIGURE 22-92 Hexaxial reference system.

acts as an inferior lead. It records the electrical activity of the heart from a vantage point that looks up from the left lower extremity. Lead aV_R is a distant recording electrode. It looks down at the heart from the right arm. Based on these lead descriptions, the lateral, or left-sided, limb leads are I and aV_L. The inferior leads are II, III, and aV_F.

NOTE
Each of the six limb leads (three standard limb leads and three augmented limb leads) records the same cardiac activity from a different angle.

The six precordial leads (Figure 22-93) are projected through the AV node toward the patient's back. In this view, the anterior chest wall is considered positive, and the patient's back is considered negative. This horizontal plane separates the body into top and bottom halves. The chest

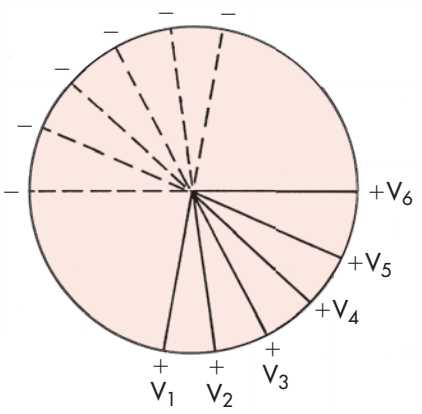

FIGURE 22-93 The precordial leads. The positive poles of the chest leads point anteriorly and the negative poles *(dashed lines)* point posteriorly. (Sole ML et al: *Introduction to critical care nursing,* ed 5, St Louis, 2009, Saunders.)

leads monitor electrical current in successive steps from the patient's right to left side. Leads V_1 and V_2 are right chest leads that view the septum of the heart (septal leads). Leads V_3 and V_4 view the anterior wall of the left ventricle (anterior leads). Leads V_5 and V_6 view the lateral wall of the left ventricle (lateral leads) (Figure 22-94).

Table 22-2 shows the area of the heart viewed by each of the 12 leads.

NOTE

Lead aV_R is the only limb lead on the right side of the body. It does not view a specific area of the heart. The aV_R lead may be useful in evaluating ST segment elevation in some coronary syndromes, in patients with acute pericarditis, in tricyclic antidepressant (TCA) poisoning, and in WPW syndrome.[10]

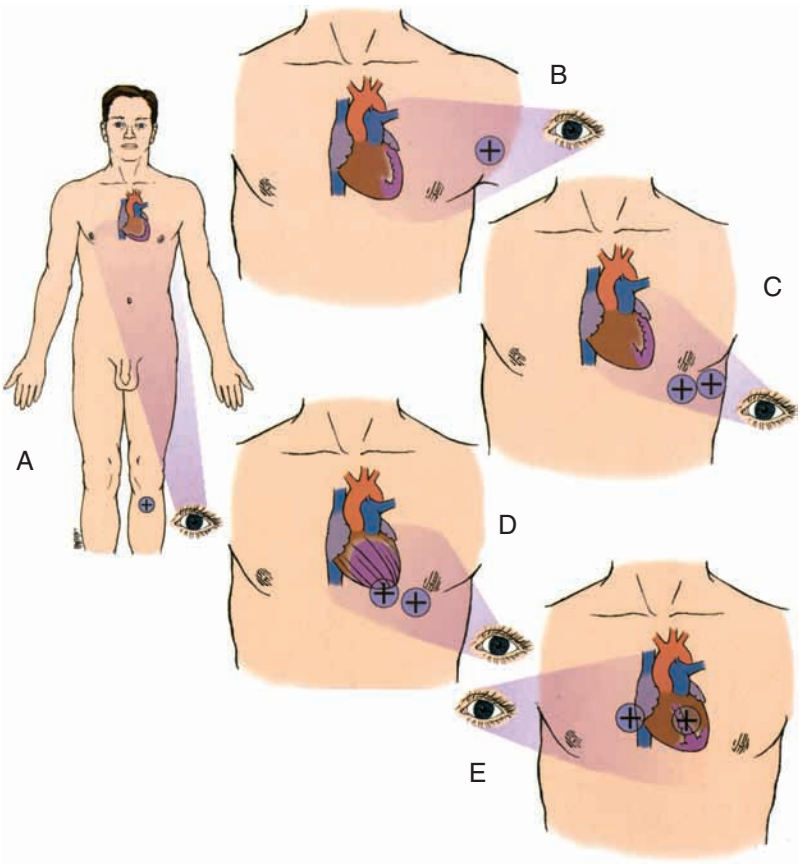

FIGURE 22-94 **A,** Leads II, III, and aV_F each has a positive electrode positioned on the left leg. From the perspective of the left leg, each of these leads "sees" the inferior wall of the left ventricle. **B,** From their vantage point on the left arm, leads I and aV_L "look" in at the lateral wall of the left ventricle. **C,** Leads V_5 and V_6 also view the lateral wall, because they are positioned on the axillary area of the left chest. **D,** Leads V_3 and V_4 are positioned in the area of the anterior chest. From this perspective, these leads "see" the anterior wall of the left ventricle. **E,** The septal wall is "seen" by leads V_1 and V_2, which are positioned next to the sternum. (Phalen T, Aehlert BJ: *The 12-lead ECG in acute coronary syndromes,* ed 3, St Louis, 2010, Mosby.)

TABLE 22-2 Lead Views of the Heart

Lead	Area of the Heart

V_2 through V_6	V_1

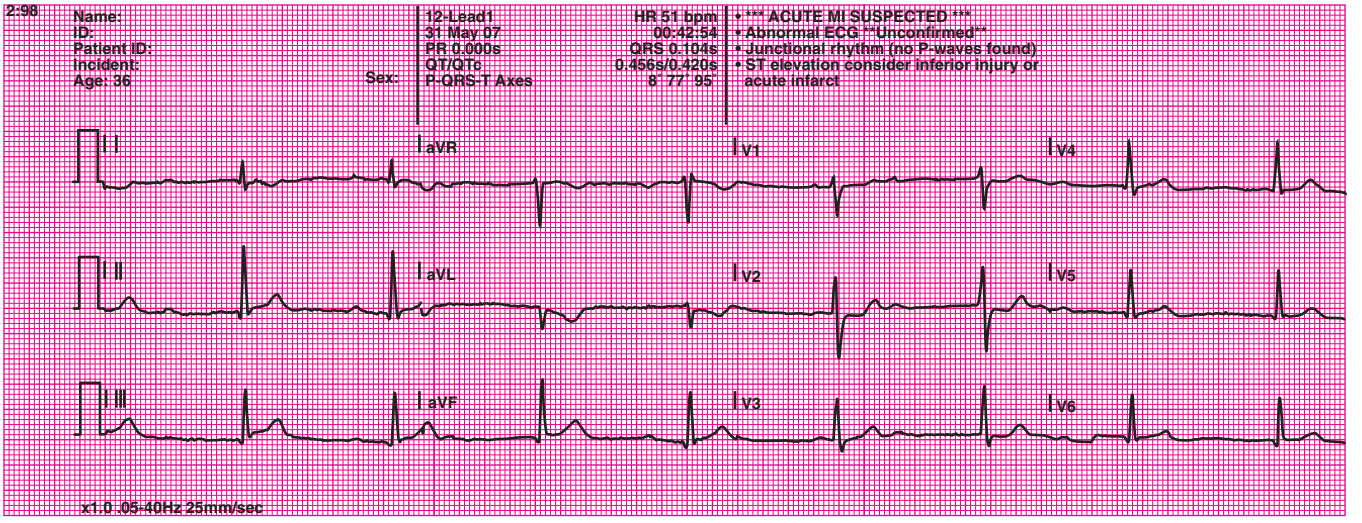

FIGURE 22-95 A 12-lead ECG strip. (Modified from Wesley K: *Huszar's basic dysrhythmias and acute coronary syndromes: interpretation and management,* ed 4, St Louis, 2010, Mosby.)

Normal 12-Lead ECG

The 12-lead ECG is recorded electronically on ECG paper in four separate columns. Column one records leads I, II, and III. Column two records aV_R, aV_L, and aV_F. Column three records V_1, V_2, and V_3. Column four records V_4, V_5, and V_6 (Figure 22-95). When viewing any ECG, it is important to remember that if the electrical current moves toward a positive electrode, the ECG complex will have a positive (upward) deflection from the baseline. Likewise, if the electrical current moves away from the positive electrode, the ECG complex will have a negative (downward) deflection from the baseline.

In a normal 12-lead ECG, limb leads I, II, III, aV_F, and aV_L have a positive R wave. This is because the positive wave of depolarization in the heart cells moves toward positive electrodes (aV_R is the only limb lead that has a negative complex). Chest leads are also always positive. However, leads V_1 through V_6 display the progressive nature of ventricular depolarization. As such, chest lead V_1 normally is negative (at or below baseline); V_2 is more positive; V_3 is progressively upright; and V_4 through V_6 are directly upright. This is called the *normal R wave progression* (Table 22-3).

12-LEAD ECG AND BUNDLE BRANCH BLOCKS

As stated earlier, heart blocks can occur in any of three areas: the SA node, the AV node, or the bundle branches. These blocks interrupt the normal passage of electrical stimulation in the heart. The sudden appearance of an AV block or bundle branch block may indicate impending myocardial infarction.

NOTE

The paramedic should always measure the P-R interval and the QRS complex of any ECG. A prolonged P-R interval indicates AV node block. A wide QRS complex indicates either ventricular tachycardia or a block in the bundle branches. Most commonly, preexisting bundle branch block is continuously present (fixed bundle branch block). The patient shows a wide QRS independent of the heart rate. However, as the heart rate increases, the QRS shape may change as a result of changes in the pattern of ventricular activation. This can lead to misdiagnosis of ventricular tachycardia in these patients.[11] Thorough evaluation of the patient, the ECG, and the electrical axis (described later) is important to correctly manage these patients.

To review, in left bundle branch block, the left ventricle depolarizes late. In right bundle branch block, the right ventricle depolarizes late. This delay results in a wide QRS complex greater than 0.12 second. With LBBB, the block often yields a QS pattern in V_1. With RBBB, the delay yields a negative S wave and a large positive R wave. This results in an RSR′ pattern. When bundle branch block is suspected, the paramedic should look at chest leads V_1 and V_2 (right chest) and leads V_5 and V_6 (left chest). If the QRS complex is wide with an RSR′ pattern in V_1 or V_2, RBBB may be present. If the wide QRS complex has a QS pattern in V_5 or V_6, LBBB may be present (Figure 22-96).

DETERMINATION OF THE AXIS

As stated previously, the electrical **axis** is the direction of electrical impulse flow in the heart that stimulates contraction. This general direction of ventricular depolarization is known as the *mean QRS vector*. Generally, the current travels down from the AV node and to the left side of the heart. Therefore, the mean QRS vector points downward and toward the patient's left side. The position of the QRS vector can be visualized in a circle that lies on top of the patient's chest. The circle is divided into degrees with the AV node at the center. The normal QRS vector is 0 to +90 degrees (Figure 22-97).

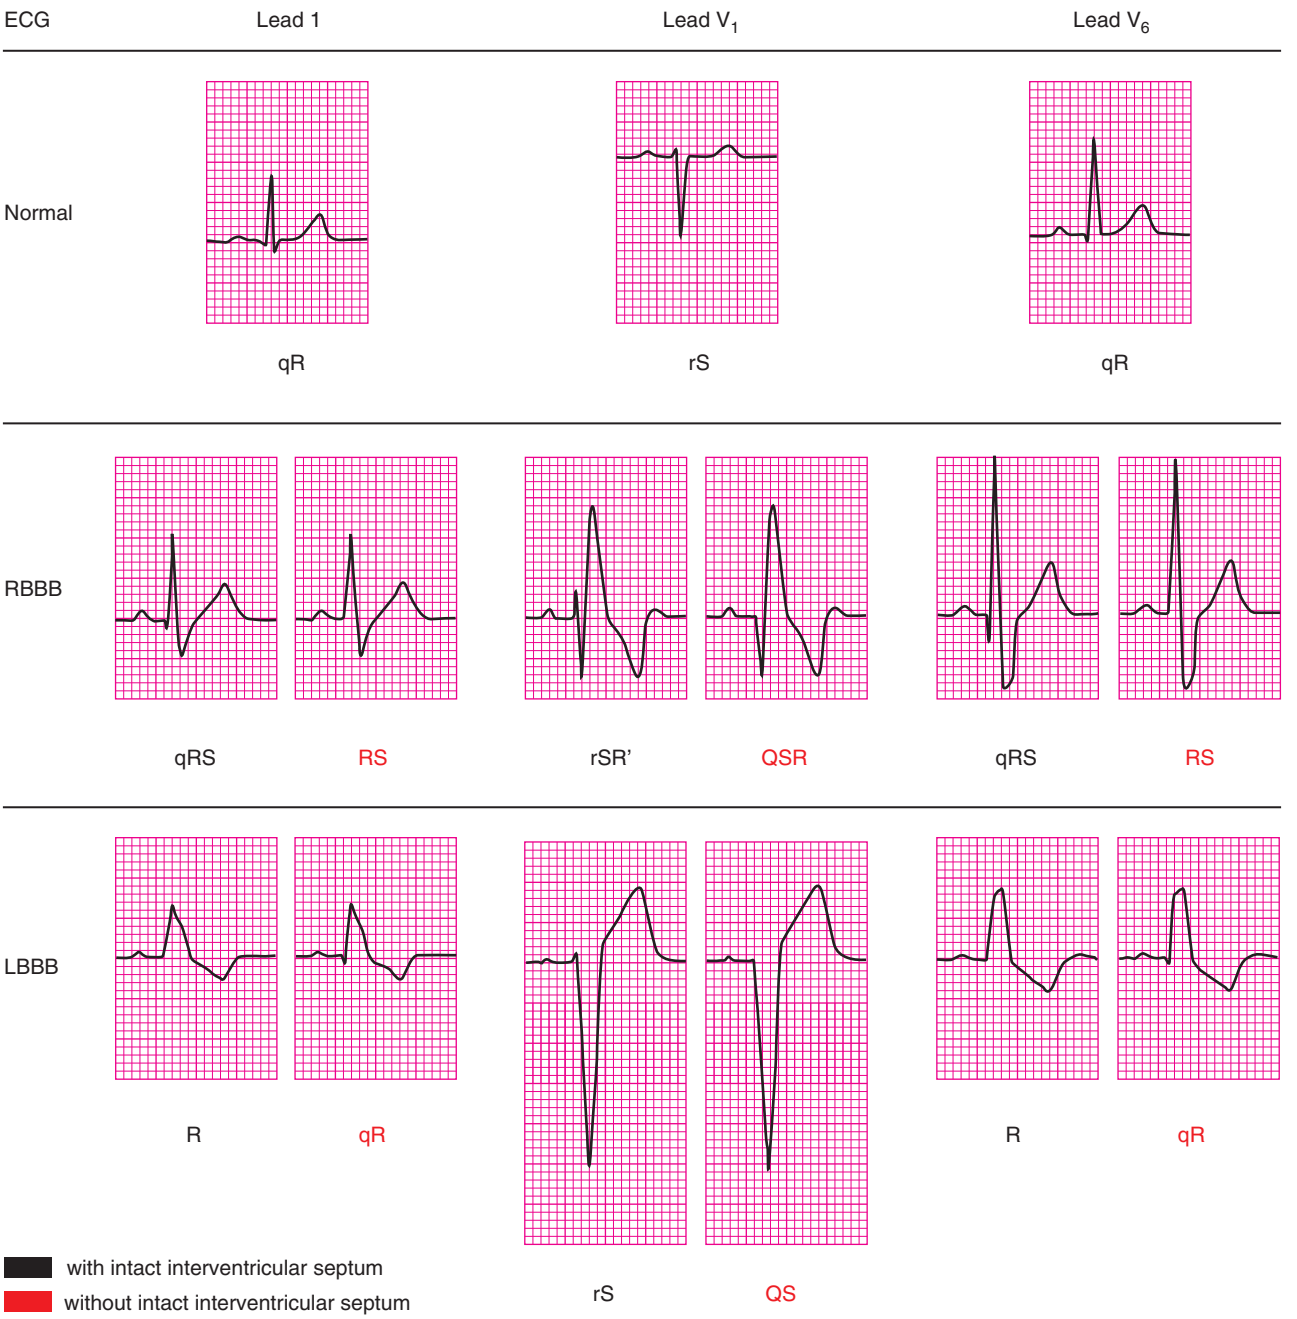

FIGURE 22-96 Comparison of leads I, V_1, and V_6 with normal conduction, right bundle branch block, and left bundle branch block.

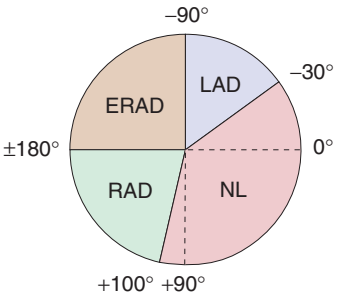

FIGURE 22-97 Frontal plane axes. Normal (NL) = –30 to +100 degrees; left axis deviation (LAD) = –30 to –90 degrees; right axis deviation (RAD) = +100 to +180 degrees; extreme right axis deviation (ERAD) = –90 to ±180 degrees. Mild RAD is considered normal in children, adolescents, and young adults. (Goldman L et al: *Cecil medicine,* ed 23, Philadelphia, 2007, Saunders.)

The QRS vector flows slightly to the left of the ventricular septum. This is because the left ventricle has more and larger cardiac cells. Generally, each person has a unique QRS vector that remains constant throughout life. However, if a person's cardiac status changes, the electrical axis and position of the heart can deviate from normal to right to left of its normal position. Box 22-10 lists common causes of axis deviation.

NOTE
The QRS vector is a representation of the electrical properties of the heart. A 12-lead ECG views the vector from 12 different angles. If the heart is displaced, the QRS vector is displaced in the same direction (right or left of normal). For example, if a patient's left ventricle is enlarged as a result of heart failure, the heart and the QRS vector are pulled to the left.

Axis is calculated automatically by modern 12-lead ECG machines (Figure 22-98). The paramedic then interprets the degree of axis by memorization or by referring to an axis chart. If the ECG machine cannot calculate axis, it can be determined by quadrant or by assessing leads I, II, and III.

Determining Axis by Quadrant

Axis can be approximated quickly by quadrant (Figure 22-99). The two key leads that can be used for approximating axis are leads I and aV_F. Recall that lead I is located at 0 degrees and that lead aV_F is located +90 degrees from lead I. A normal axis lies within the quadrant of 0 degrees and +90 degrees. A deviation of the axis to the left **(left axis deviation)** lies within the quadrant of 0 degrees and –90 degrees. A deviation of the axis to the right **(right axis deviation)** lies within the quadrant of +90 degrees and ±180 degrees. An indeterminate axis exists when the axis lies within the quadrant of –90 degrees and ±180 degrees. By looking at the net deflection of the mean QRS vector in leads I and aV_F, the paramedic can make an approximate determination of axis (Table 22-4).

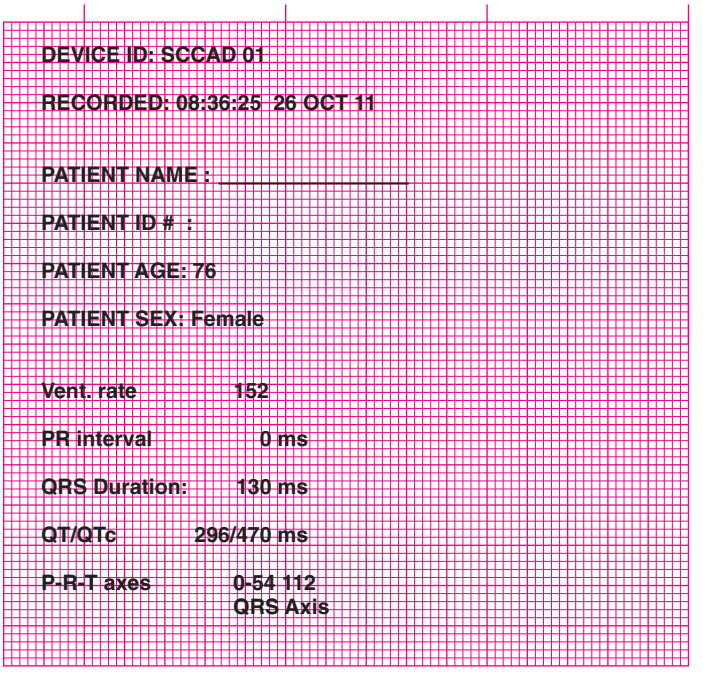

FIGURE 22-98 Axis display on ECG printout.

BOX 22-10 Common Causes of Axis Deviation

Right Axis Deviation
Anterolateral myocardial infarction
Chronic lung disease
Left posterior hemiblock
Left-sided tension pneumothorax
Pulmonary embolism
Right ventricular hypertrophy
Wolff-Parkinson-White syndrome
(May be a normal finding in children and tall, thin adults)

Left Axis Deviation
Aortic stenosis
Hypertension
Left anterior hemiblock
Mitral regurgitation
Inferior myocardial infarction
Right-sided tension pneumothorax
Ventricular pacemaker
Ventricular tachycardia
Wolf-Parkinson-White syndrome

NOTE
If the QRS complex in lead I is upright, then the vector is flowing right to left. If the QRS complex in lead aV_F is upright, the vector is directed top to bottom. If the QRS complex is upright in both lead I and aV_F, the electrical axis must fall into the lower left or normal quadrant (see Table 22-4).

TABLE 22-4 Axis Deviation

	NET QRS DEFLECTION		
Axis	**Lead I**	**aV_F**	**Axis Degrees**
Normal	Positive	Positive	0 to +90
RAD	Negative	Positive	+90 to ±180
LAD	Positive	Negative	0 to –90
Indeterminate	Negative	Negative	–90 to ±180

LAD, Left axis deviation; *RAD,* right axis deviation.

Determining Axis by Leads I, II, and III

Axis can be evaluated by looking at the QRS complexes in leads I, II, and III (Table 22-5):

- *Normal:* QRS deflection is positive (upright) in all bipolar leads
- *Physiological left* (may be normal in some patients): QRS deflection is positive in leads I and II but negative (inverted) in lead III
- *Pathological left:* QRS deflection is positive in lead I and negative in leads II and III (indicating an anterior hemiblock)
- *Right axis:* QRS deflection is negative in lead I, negative or positive in lead II, and positive in lead III (this is

TABLE 22-5 Identifying the Axis by the QRS Complex

		QRS COMPLEX		
Axis	**Lead I**	**Lead II**	**Lead III**	**Indications**
Normal	Upright	Upright	Upright	May be normal
Physiological left	Upright	Upright	Inverted	May be normal
Pathological left	Upright	Inverted	Inverted	Anterior hemiblock
Right axis	Inverted	Inverted or upright	Upright	Posterior hemiblock*
Extreme right	Inverted	Inverted	Inverted	Ventricular in origin

*Chronic obstructive pulmonary disease (COPD) and right ventricular hypertrophy must first be ruled out.

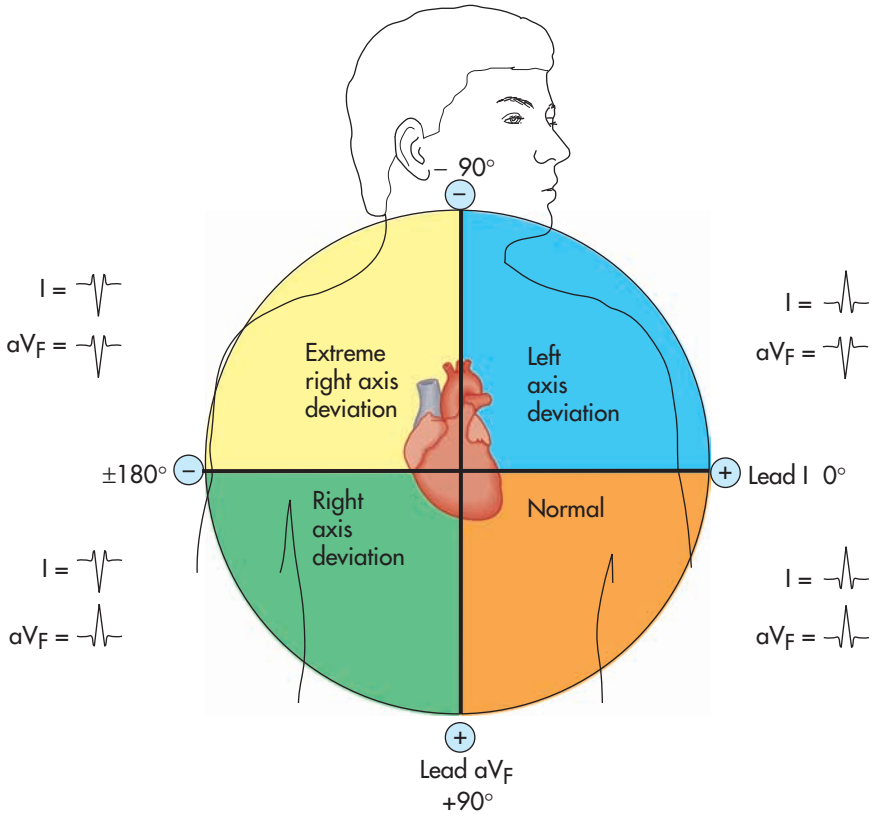

FIGURE 22-99 Approximating axis by quadrant. (Beachey W: *Respiratory care anatomy and physiology,* ed 2, St Louis, 2007, Mosby.)

pathological in any adult and may indicate a posterior hemiblock)

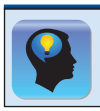
- *Extreme right* ("no man's land"): QRS deflection is negative in all three leads (indicating that the rhythm is ventricular in origin)

AXIS AND HEMIBLOCKS

As described earlier, a hemiblock is a failure in conduction of the cardiac impulse in either of two main divisions of the left bundle branch of the bundle of His. The interruption may occur in either the anterior (superior) or the posterior (inferior) division. Identifying the axis can be useful in determining the presence of hemiblocks.

Anterior Hemiblock

Anterior hemiblock occurs more often than **posterior hemiblock.** The anterior fascicle of the left bundle branch is a longer and thinner structure. Its blood supply comes mainly from the left anterior descending coronary artery. Anterior hemiblock is characterized by left axis deviation in a patient who has a supraventricular rhythm (Figure 22-100). Other ECG findings associated with an anterior hemiblock include a normal QRS complex (less than 0.12 second) or a right bundle branch block, a small Q wave followed by a tall R wave in lead I, and a small R wave followed by a deep S wave in lead III. In a patient who has an anterior hemiblock with a right bundle branch block, impulses can be conducted only through the ventricles by way of the posterior fascicle of the left bundle branch. These patients are at high risk of developing complete heart block.



CRITICAL THINKING

What rhythms are produced by supraventricular activity?

Posterior Hemiblock

The posterior fascicle of the left bundle branch is not blocked as easily as the anterior fascicle. This is because the bundle is much thicker and has a double blood supply (left and right coronary arteries). As a result, posterior hemiblock occurs less often. This conduction disturbance is not commonly seen alone, but rather is more often associated with right bundle branch block. For practical purposes, posterior hemiblock can be assumed in patients with right axis deviation and a QRS complex of normal width or with a right bundle branch block (Figure 22-101). Other ECG findings that indicate the presence of a posterior hemiblock include a small R wave followed by a deep S wave in lead I and a small Q wave followed by a tall R wave in lead III.

Bifascicular Block

Bifascicular block refers to the blockage of two of three pathways (fascicles) for ventricular conduction. This condition generally refers to RBBB with block of either the anterior or posterior division of the left bundle branch. (This is because anterior hemiblock combined with posterior hemiblock is difficult to distinguish from LBBB.) Bifascicular block reduces myocardial contractility and cardiac output. Patients with this condition may develop complete heart block suddenly and without warning. As a rule, the more branches with impaired conduction, the greater the chance the patient will develop complete atrioventricular block (especially in patients with acute myocardial infarction).

12-LEAD STRATEGIES FOR WIDE-COMPLEX TACHYCARDIAS

If an unstable patient's QRS complex is wide (greater than 0.12 second) and fast (greater than 150 beats/minute), immediate cardioversion may be indicated. If the patient is stable, however, the following steps in 12-lead assessment

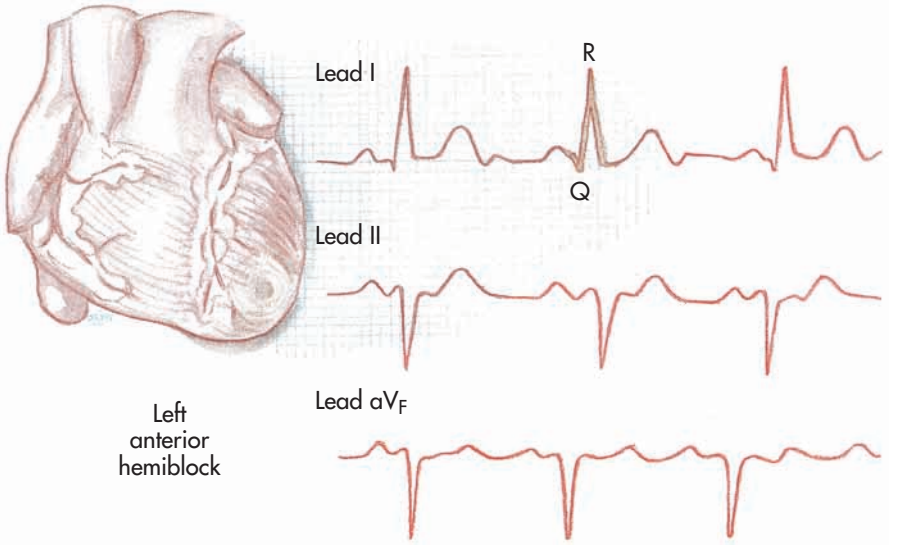


FIGURE 22-100 Anterior hemiblock.

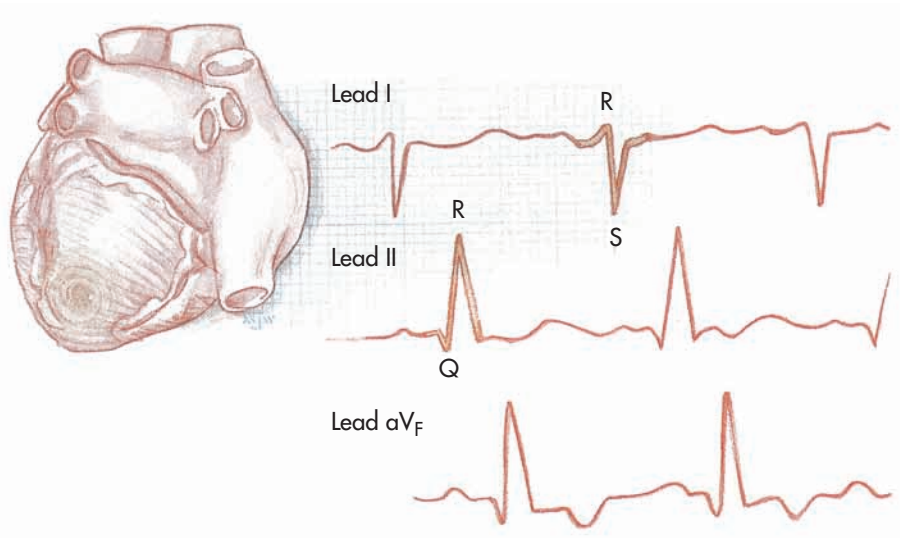

FIGURE 22-101 Left posterior hemiblock.

may help distinguish between ventricular tachycardia and other wide-complex tachycardias[12]:

1. Assess leads I, II, III, V_1, and V_6. If the QRS complex is negative in leads I, II, and III and positive in V_1, the rhythm indicates ventricular tachycardia (Figure 22-102). If these criteria are not met, proceed to step 2.
2. Assess the QRS deflection in V_1 and V_6. Regardless of the QRS deflection in leads I, II, and III, positive QRS deflections with a single peak, a taller left "rabbit ear," or an RS complex with a fat R wave or slurred S wave in V_1 indicates ventricular tachycardia. A negative QS complex, a negative RS complex, or any wide Q wave in V_6 also indicates ventricular tachycardia (Figure 22-103).
3. A negative QRS complex in lead I, a positive QRS complex in leads II and III, and a negative QRS complex in V_1 or MCL_1 indicates ventricular tachycardia (Figure 22-104).
4. If all precordial leads (V leads) are positive or negative *(precordial concordance),* the rhythm indicates ventricular tachycardia (Figure 22-105).
5. If the R-S interval is greater than 0.10 second in any V lead (increased ventricular activation time), the rhythm indicates ventricular tachycardia (Figure 22-106).

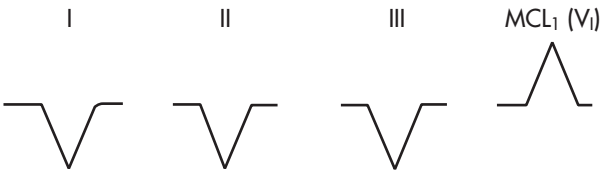

FIGURE 22-102 Criteria for ventricular tachycardia.

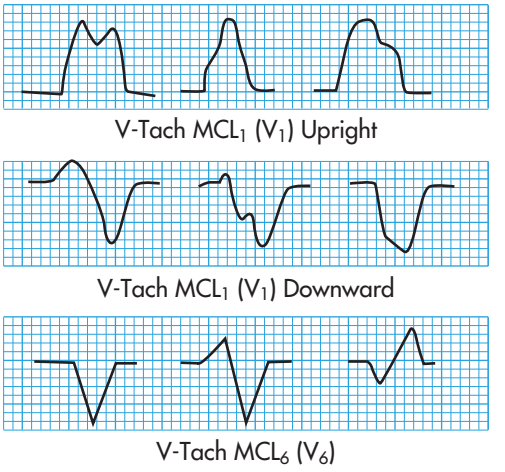

FIGURE 22-103 Step 1: A QRS complex that is negative in leads I, II, and III and positive in MCL_1 (V_1) indicates ventricular tachycardia. Step 2: Assess the QRS complex in MCL_1 (V_1) and MCL_6 (V_6). Step 3: Assess the QRS complex in leads I, II, III, and MCL_1 (V_1). (Courtesy Bob Page, Springfield, Mo.)

NOTE
Nonventricular tachycardia precordial concordance may occur in patients who have Wolff-Parkinson-White syndrome and associated left bundle branch block.

CRITICAL THINKING
Why is it crucial to distinguish between ventricular tachycardia and wide-complex tachycardias in stable patients?

CRITICAL THINKING
How would you manage a patient with ventricular tachycardia, chest pain, or difficulty breathing if you could not establish an IV line?

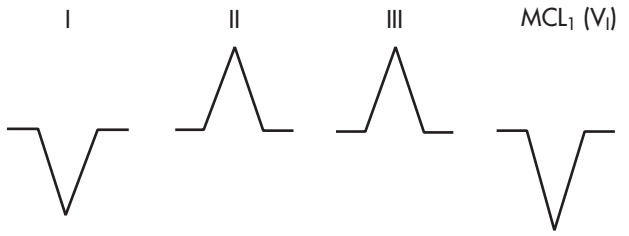

FIGURE 22-104 Right axis deviation with a downward MCL_1 indicates ventricular tachycardia.

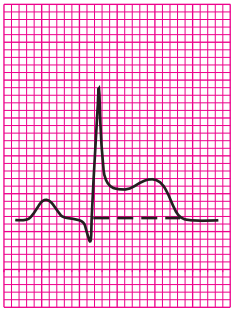

FIGURE 22-107 ST-segment elevation likely to present with acute injury.

BOX 22-11 Contiguous Leads

Contiguous leads are leads that are anatomically close together and that cover the same general area of the heart (specifically, the walls of the left ventricle). Lead aV_R is the only lead that is not considered contiguous with another lead.

I	Lateral	aV_R	---------	V_1	Septal	V_4	Anterior
II	Inferior	aV_L	Lateral	V_2	Septal	V_5	Lateral
III	Inferior	aV_F	Inferior	V_3	Anterior	V_6	Lateral

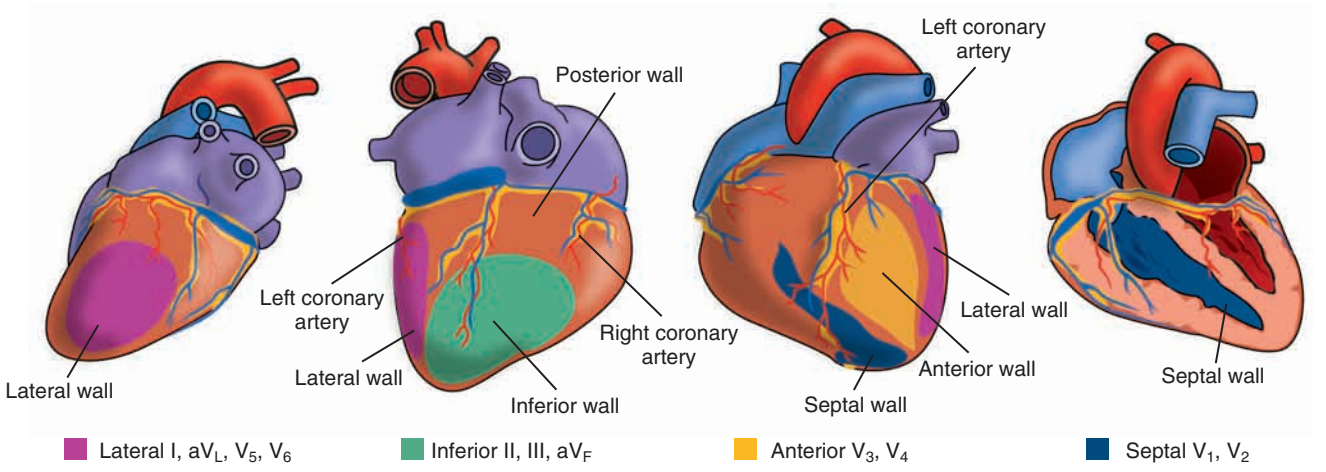
ST-SEGMENT AND T-WAVE CHANGES

When the heart muscle is damaged, the damaged area is unable to contract effectively. The area remains in a constant depolarized state. The flow of current between the pathologically depolarized and normally repolarized areas can produce ST-segment elevation (Figure 22-107), ischemic ST-segment depression, or normal or nondiagnostic changes in the ST segment or T waves. Using these ECG findings, the paramedic can classify the patient into one of three groups[6]:

1. *ST-segment elevation myocardial infarction (STEMI):* ST-segment elevation is characterized by ST-segment elevation greater than 1 mm (0.1 mV) in two or more adjacent limb leads or any two contiguous chest leads (Box 22-11 and Figure 22-108). STEMI also occurs with presumed new LBBB.

NOTE

Numerous methods have been proposed for measuring ST-segment elevation. Some begin the measurement at the J point. Others begin the measurement at one small box (0.04 second) after the J point. More than 1 mm of ST-segment elevation in a standard limb lead or chest lead is an abnormal finding that indicates injury.



I	Lateral	aV_R	---------	V_1	Septal	V_4	Anterior
II	Inferior	aV_L	Lateral	V_2	Septal	V_5	Lateral
III	Inferior	aV_F	Inferior	V_3	Anterior	V_6	Lateral

FIGURE 22-108 Localizing ECG changes by lead with corresponding affected areas of the heart.

2. *High-risk non–ST-elevation myocardial infarction (non-STEMI)*: Ischemic ST-segment depression equal to or greater than 0.5 mm (0.05 mV) or dynamic T-wave inversion with pain or discomfort. Nonpersistent or transient ST-segment elevation equal to or greater than 0.5 mm (0.05 mV) for longer than 20 minutes is included in this category.
3. *Normal or nondiagnostic changes in ST segment or T wave*: These findings are inconclusive. This classification includes patients with normal ECG findings and those with ST-segment deviation of less than 0.5 mm (0.05 mV) or T-wave inversion less than or equal to 0.2 mV. Special cardiac studies and testing are needed for these patients.

NOTE

ST-segment elevation is best measured by drawing a baseline from the end of the T wave to the start of the P wave using either of the methods described previously. The ST segment then is compared with the isoelectrical baseline. However, ST-segment elevation is not always present on an initial ECG tracing. This is true even when a patient is experiencing a myocardial infarction. When ST-segment elevation is present in a symptomatic patient, the paramedic should notify medical direction and transmit an ECG for evaluation (per protocol). Even if infarction is present, ST-segment elevation is a poor indicator of the type or cause of infarction (STEMI or non-STEMI). In addition, ST-segment elevation can be caused by conditions other than acute myocardial infarction, including the following:

- Left bundle branch block
- Some ventricular rhythms
- Left ventricular hypertrophy
- Pericarditis
- Ventricular aneurysm
- Early repolarization

USE OF A 12-LEAD ECG TO ASSESS INFARCTS

Early recognition and management of acute myocardial infarction sometimes can salvage a damaged myocardium ("time is muscle"). Paramedics can play an important role in identifying these patients by using the following five-step analysis for infarct recognition[4]:

Step 1: Identify the rate and rhythm. Manage any life-threatening dysrhythmias.

NOTE

LBBB that impairs repolarization may "look like" STEMI. If LBBB is present, ST-segment elevation measurements will not be diagnostic for infarction.

Step 2: Identify the area of infarct. ST-segment elevation is the most reliable indicator during the first hours of infarction. ST-segment elevation can be present before permanent tissue damage has occurred. If ST-segment elevation is present in a patient with chest pain, the paramedic should identify the degree of elevation and visualize the cardiac anatomy to predict which coronary artery is occluded (Figure 22-109). The paramedic should use a systematic approach for 12-lead assessment. One method is to begin by assessing the inferior leads (II, III, aV_F), followed by the septal leads (V_1, V_2), anterior leads (V_3, V_4), and lateral leads (V_5, V_6, I, aV_L). The paramedic evaluates each lead for ST-segment elevation (the most important sign of injury), deep symmetrically inverted T waves (a sign of ischemia), ST-segment depression (a reciprocal change to ST elevation), and pathological Q waves (Tables 22-6 and 22-7 and Figure 22-110).

TABLE 22-6 ST-Segment Elevation and Location of Infarct

Lead	Location of Infarct	Coronary Artery Involved
II, III, aV_F	Inferior wall (most common)	Right
V_1, V_2	Septal wall	Left
V_3, V_4	Anterior wall (most lethal)	Left
I, aV_L, V_5, V_6	Lateral wall	Left
V_{4R}-V_{6R}	Right ventricle	Right

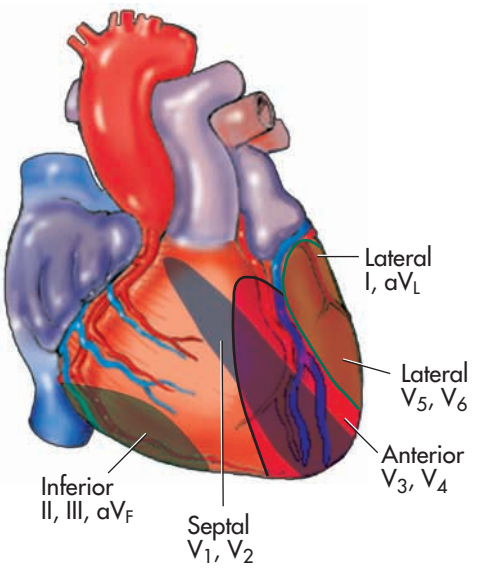


FIGURE 22-109 Multilead assessment of the heart.

TABLE 22-7 Reciprocal Changes Seen With ST-Segment Elevation Myocardial Infarction (STEMI)

Injury Site	ST Elevation	Reciprocal ST Depression
Septal	V_1, V_2	None
Anterior	V_3, V_4	None
Anteroseptal	V_1, V_2, V_3, V_4	None
Lateral	I, aV_L, V_5, V_6	II, III, aV_F
Anterolateral	I, aV_L, V_3, V_4, V_5, V_6	II, III, aV_F
Inferior	II, II, aV_F	I, aV_L
Posterior	None	V_1, V_2, V_3, V_4

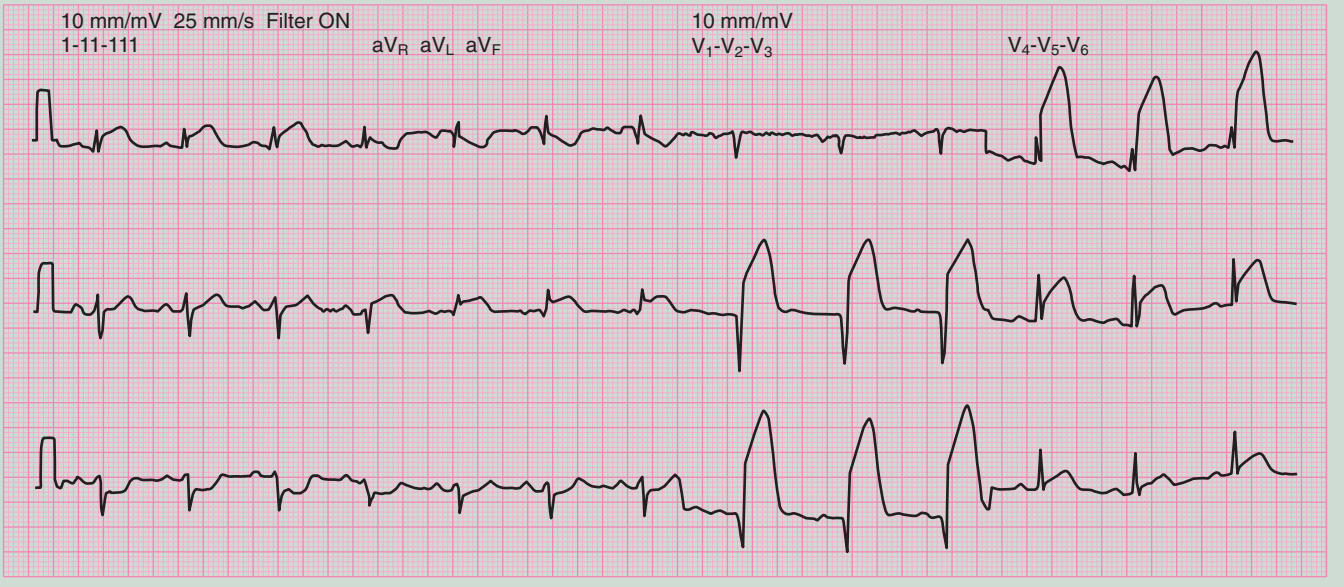

FIGURE 22-110 12-lead ECG showing STEMI and reciprocal ST-segment depression. (Andreoli TE: *Cecil essentials of medicine,* ed 7, Philadelphia, 2008, Saunders.)

In an acute STEMI, reciprocal changes may be seen between leads that face the acute injury and leads that face the lateral boundary of the injury (between ischemic and healthy tissue). Leads that face the injury often show ST-segment elevation. Leads that face the boundary often show ST-segment depression.[13] Reciprocal changes are not always visible on the 12-lead ECG during acute STEMI. However, if they are visible, this confirms the diagnosis.

At times, the extent of the infarction can be gauged by the number of leads showing ST-segment elevation. The degree of ST-segment elevation also is important. For example, large infarcts often show an ST elevation of 7 mm or more in inferior leads and 12 mm or more in anterior leads. ST-segment elevation or new or presumably new left bundle branch block is suspicious for injury.

Step 3: Consider other conditions that could be responsible for ST-segment changes (as described previously). These "infarct impostors" also may be present in a patient experiencing acute myocardial infarction. With the exception of left bundle branch block (which makes the interpretation of myocardial infarction difficult), left ventricular hypertrophy looks less like an infarction. Ventricular rhythms often produce Q waves *and* ST-segment elevation. Ventricular rhythms also do not have reciprocal ST depression. ECG changes with pericarditis are subtle. In addition, early repolarization produces no clinical symptoms.

Step 4: Assess the patient's clinical presentation. This is just as crucial as the ECG findings. Therefore, the findings of a thorough patient history and a physical examination should be incorporated into the ECG interpretation. Not all patients with acute myocardial infarction have classic signs and symptoms. Therefore, the paramedic should maintain a high degree of suspicion in the absence of pain. (This should be the case especially with diabetic patients, older adults, and postmenopausal women.) As many as 50% of patients with acute myocardial infarction have no early ECG changes. The clinical picture therefore is important.

Step 5: Recognize the infarction and initiate care. When all indications point to acute myocardial infarction, the paramedic must take steps to speed the process of data collection, physician evaluation, and definitive care (angioplasty and stent; thrombolysis when appropriate). This helps reduce the time from infarct to treatment. Clinical presentation and ECG findings that suggest an acute myocardial infarction must be confirmed by medical direction to determine appropriate care.

SHOW ME THE EVIDENCE

Eckstein and colleagues compared 234 STEMI patients who arrived at four Los Angeles hospitals where percutaneous coronary angioplasty could be performed. The authors sought to determine whether a difference existed in treatment time based on arrival by private vehicle versus arrival by ambulance with a prehospital 12-lead ECG. Although no statistically significant difference in door-to-balloon time was seen between the two groups, the time from confirmation of STEMI to balloon inflation was significantly shorter in the prehospital group.

From Eckstein M, et al: Impact of paramedic with prehospital 12-lead ECG on door-to-balloon times for patients with ST-segment elevation myocardial infarction, *Prehosp Emerg Care* 32:203-206, 2009.

15- AND 18-LEAD DIAGNOSTICS

The wall of the right ventricle and the posterior wall of the left ventricle are areas of the heart that are difficult to evaluate with the six precordial leads. ECG monitoring that includes 12 leads plus V_{4R}, V_8, and V_9 leads (a 15-lead ECG) increases sensitivity for myocardial infarctions that occur in these areas (e.g., isolated posterior myocardial infarction). For 15-lead ECG monitoring, the V_{4R} lead is placed at the fifth intercostal space in the right anterior midclavicular line. The V_8 lead is placed at the posterior fifth intercostal space in the right midscapular line. The V_9 lead is placed between the V_8 lead and the spinal column at the posterior fifth intercostal space. The 18-lead ECG monitoring (not routinely performed in the prehospital setting) uses the 15-lead ECG along with V_{5R}, V_{6R}, and V_7. These leads are placed in the same horizontal line as V_4 to V_6. V_7 is placed at the posterior axillary line. V_8 is placed at the posterior scapular line (Figure 22-111).

When a 15-lead ECG is obtained, the new 12-lead ECG printout must be labeled to identify the three leads that have been moved. A notation should be made at the top of the ECG printout, "Posterior Chest Leads." Lead V_4 should be relabeled V_{4R}; V_5 should be relabeled V_8; and V_6 should be relabeled V_9 (Figure 22-112). The more leads that reveal acute changes in the heart, the larger the area of infarct is presumed to be.

NOTE

Right ventricular (RV) infarction or ischemia may occur in up to 50% of patients with inferior wall MI. RV infarction should be suspected in patients with inferior wall infarction, hypotension, and clear lung fields. In these cases, a 15-lead ECG should be obtained to confirm the field impression. ST-segment elevation (greater than 1 mm) in lead V_{4R} is sensitive for RV infarction (sensitivity, 88%; specificity, 78%; diagnostic accuracy, 83%). These findings also are a strong predictor of increased in-hospital complications and mortality.[6]

SECTION SEVEN
Assessment of the Patient with Cardiac Disease

ASSESSMENT

A focused evaluation of any patient should identify a chief complaint. It also should cover the history of the event and any significant medical history, and it should include a

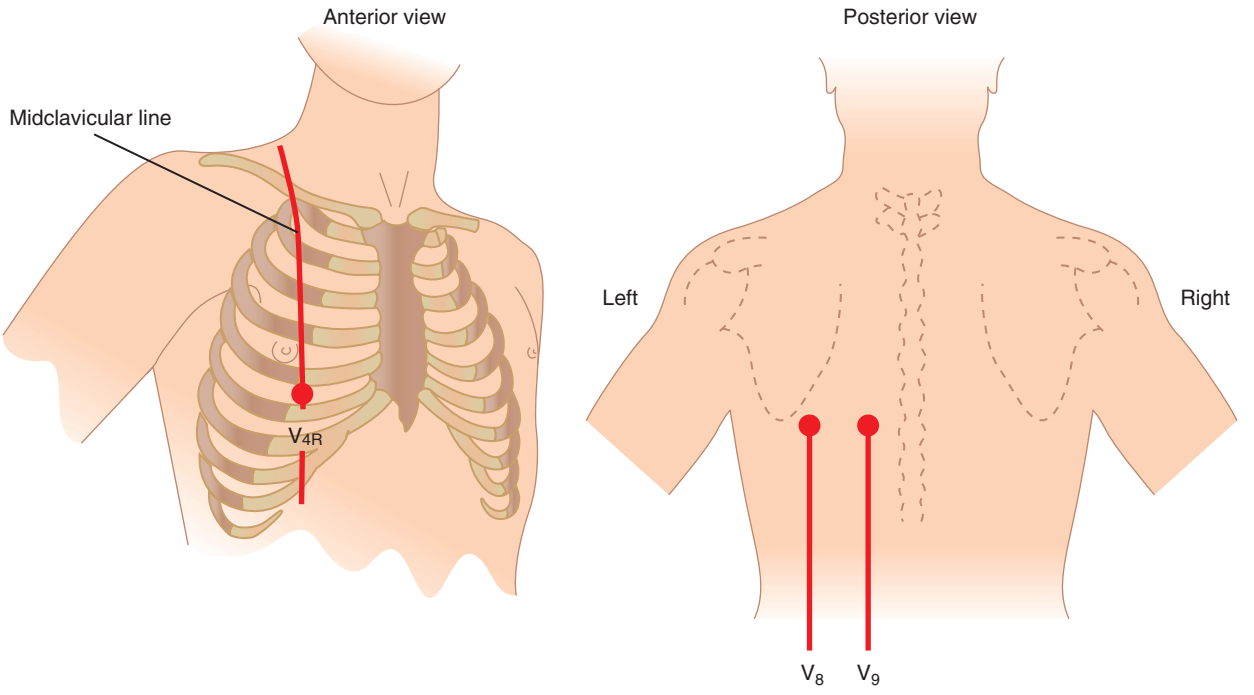

FIGURE 22-111 Lead placement for V_{4R} and V_8 and V_9.

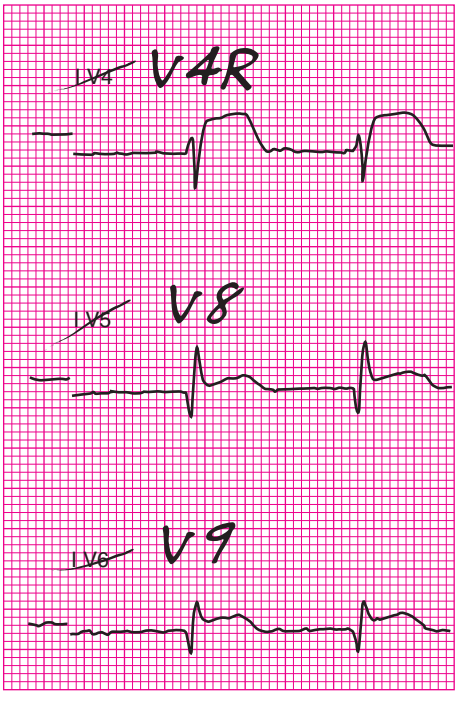

FIGURE 22-112 ECG relabeled to show V_{4R} and V_8 and V_9.

physical examination. These elements are crucial in determining the cause of the emergency. They also help paramedics determine the initial patient care and anticipate potential problems during transport to a medical facility. The following discussion of patient assessment explains the approach to the patient with a cardiovascular emergency.

CRITICAL THINKING

A patient has made an EMS call about a cardiovascular complaint. What emotions might the patient be feeling?

Chief Complaint

Cardiovascular disease may cause a variety of symptoms. Obtaining an appropriate history of each symptom is important to form a diagnostic impression of any patient with a possible coronary event. Common chief complaints include chest pain or discomfort, including shoulder, arm, neck, or jaw pain or discomfort; dyspnea; syncope; and abnormal heartbeat or palpitations.

In some patients (e.g., some women, older adults, and patients with diabetes), cardiovascular problems commonly have atypical symptoms. These include mental status changes, abdominal or gastrointestinal symptoms (including persistent heartburn), and vague complaints of feeling ill.

CHEST PAIN OR DISCOMFORT

Chest pain or discomfort is the most common chief complaint of patients with myocardial infarction. However, many causes of chest pain are not related to cardiac disease (e.g., pulmonary embolus, pleurisy, reflux esophagitis). Therefore, a history of chest pain is a key factor. The OPQRST method (or a similar method) should be used to obtain the following information when possible:

Onset/origin: Ask the patient to describe the pain or discomfort. What does it feel like? What were you doing

when the pain began? Have you ever had this type of pain before? Is it the same as or different from the last time?

Provokes: Try to determine the events surrounding the patient's symptoms. What do you think might have caused this pain? Does anything you do make the pain better or worse? Does the pain go away when you rest? Have you taken ***nitroglycerin*** for the pain, and if so, did it help? Does the pain get worse when you exercise or walk or when you eat certain foods?

Quality: Ask the patient to describe the pain or discomfort in his or her own words. Common descriptions for the quality of chest pain associated with a coronary event include sharp, tearing, burning, heavy, and squeezing.

Region: Ask the patient to localize the pain. With one finger, point to where the pain hurts most. Does the pain move (radiate) to another area of the body or does it stay in one place? If the pain moves, to where does it move? (Cardiac chest pain often radiates to the arms, neck, jaw, and back.)

Severity: Ask the patient to rate the pain or discomfort to establish a baseline. On a scale of 0 to 10, with 10 being the worst pain you have ever had, what number would you use to describe this pain? If you have had pain like this before, is this pain worse than the last time or not as bad as the last time?

Time: Try to determine the duration of the pain episode and document it. How long have you had this pain? Is the pain better or worse than it was when you called for help? Is the pain constant or does it come and go?

CRITICAL THINKING

What factors may influence a person's perception and description of pain?

NOTE

Chest pain is a common complaint of cocaine users. Cocaine can cause serious cardiac toxicity because of the effect of the drug on the heart. It also stimulates the central nervous system, and that also stimulates the cardiovascular system. Although rare, acute myocardial infarction can occur in these patients, even in the absence of risk factors for ischemic heart disease.[1]

DYSPNEA

Dyspnea (difficulty breathing) often is associated with myocardial infarction. It is a main symptom of pulmonary congestion caused by heart failure. Other common causes of dyspnea that may be unrelated to heart disease include chronic obstructive pulmonary disease, respiratory infection, pulmonary embolus, and asthma. Historical factors important in differentiating breathing difficulties include the following:

- Duration and circumstances of onset of dyspnea
- Anything that aggravates or relieves the dyspnea, including medications
- Previous episodes
- Associated symptoms
- Orthopnea
- Previous cardiac problems

SYNCOPE

Syncope is a brief loss of consciousness caused by a sudden decrease in oxygenated blood to the brain. Cardiac causes of syncope result from events that reduce cardiac output. The most common cardiac disorders associated with syncope are dysrhythmias. Other causes of syncope include stroke, drug or alcohol intoxication, aortic stenosis, pulmonary embolism, and hypoglycemia. In older patients, syncope may be the only symptom of a cardiac problem. Young, healthy people may have a syncopal episode. This episode may result from stimulation of the vagus nerve **(vasovagal syncope),** which can produce hypotension and bradycardia. The history of a syncopal event should include the following:

- Presyncope aura (nausea, weakness, lightheadedness)
- Circumstances of occurrence (e.g., patient's position before the event, severe pain, or emotional stress)
- Duration of syncopal episode
- Symptoms before syncopal episode (palpitation, seizure, incontinence)
- Other associated symptoms
- Previous episodes of syncope

NOTE

Cardiac syncope often occurs without warning. By comparison, vasovagal syncope often is preceded by a minute or two of nausea and weakness before the loss of consciousness.

CRITICAL THINKING

Syncopal events often occur in public places, such as a church. How can you ease the feelings of embarrassment the patient may have in this situation?

ABNORMAL HEARTBEAT AND PALPITATIONS

Many patients are aware of their own heartbeat, particularly if it is irregular (skipping beats) or rapid (fluttering). Abnormal heartbeats or **palpitations** (irregular or forceful beating of the heart) sometimes are a normal occurrence. However, they also may indicate a serious dysrhythmia. Important information to obtain with these patients includes the following:

- Pulse rate
- Regular versus irregular rhythm
- Circumstances of occurrence

- Duration
- Associated symptoms (chest pain, diaphoresis, syncope, confusion, dyspnea)
- Previous episodes and frequency
- Medication (drug stimulant) or alcohol use

Significant Medical History

The medical history is a vital part of any patient assessment. If possible, the paramedic should determine the following information.

1. *Is the patient taking prescription medications, particularly cardiac medications?* Common medications that should alert the paramedic to a possible coronary event include ***nitroglycerin, atenolol, metoprolol,*** and other beta blockers; ***digoxin; furosemide*** and other diuretics; antihypertensives; and antihyperlipidemic agents. The paramedic also should ask the patient about his or her compliance in taking medications. The use of any nonprescription drugs, such as over-the-counter (OTC) medications, ***aspirin,*** and herbal supplements, should also be ascertained. Alcohol use or illicit drug use may be a contributing factor in the patient's chief complaint. (For example, this may include the use of cocaine or methamphetamines.)
2. *Is the patient being treated for any other illness?* A medical history that includes angina pectoris, previous myocardial infarction, coronary artery bypass (Box 22-12), or **angioplasty** (described later) increases the likelihood of a significant coronary event. Chronic illness such as heart failure, valvular disease, renal disease, hypertension, aneurysms, diabetes, inflammatory cardiac disease (e.g., endocarditis, myocarditis), and lung disease also are indicators that heart disease may be present.
3. *Does the patient have any allergies?* Medication allergies (e.g., an allergy to ***aspirin*** or radiographic dye) may be important in the course of the patient's care. The paramedic should document these allergies and report them to medical direction.
4. *Does the patient have risk factors for a heart attack?* Examples of risk factors include older age, tobacco use, diabetes, a family history of heart disease, obesity, an increased serum cholesterol level (hypercholesterolemia), and illicit drug use.
5. *Does the patient have an implanted pacemaker or implantable cardioverter-defibrillator?* The presence of these devices (described later in the chapter) indicates a significant coronary history.

Physical Examination

The classic presentation of myocardial infarction is pain or discomfort beneath the sternum that lasts longer than 30 minutes. The pain often is described as crushing, pressure, squeezing, or burning. Associated signs and symptoms may include apprehension, diaphoresis, dyspnea, nausea and vomiting, and a sense of impending doom (e.g., patients feel that they are going to die). However, at times the presentation is atypical. The paramedic's skill in gathering a relevant medical history and performing a focused physical examination directs the patient care. For example, patients with myocardial ischemia may deny that they have chest pain. They may need to be asked specifically about tightness or squeezing in the chest.

BOX 22-12 Coronary Bypass Surgery

Coronary bypass surgery is a commonly performed heart surgery in which blood vessels from another part of the body are used to "bypass" diseased coronary arteries. This improves blood flow in the heart. The goal of improved blood flow is to reduce chest pain and to reduce the risk of myocardial infarction. This surgical procedure is sometimes referred to as *coronary artery bypass grafting* (CABG or cabbage). A patient may have one, two, three, or more bypass grafts, depending on how many coronary arteries are blocked. Three-way and four-way coronary bypass surgery is common.

Coronary bypass surgery may be performed with or without a heart-lung machine ("on-pump" or "off-pump" surgery). During surgery, an artery is removed from the patient's chest wall or arm (internal mammary artery or radial artery) and is sewn to the coronary artery below the site of the blockage. If a vein is used (usually the saphenous vein, taken from the patient's leg), it is attached to the aorta and then grafted to the coronary artery below the blocked area. In either case, the surgery allows blood to flow more freely through the grafts to nourish the heart muscle. Grafts normally remain open and function well for 10 to 15 years, after which bypass surgery may be needed again.

Several alternatives to CABG are available, which may be appropriate for some patients. Two alternatives are specific drug therapy (e.g., thrombolytics) and atherectomy (plaque removal). Another is balloon angioplasty. In this procedure, a balloon catheter is placed over a guide wire. The catheter is used to insert a meshlike stent into a narrowed section of a coronary artery. Once positioned, the balloon is inflated. This opens the stent and pushes it against the arterial wall. The balloon then is deflated and removed, leaving the stent permanently in place to keep the artery open. Some stents are coated with a medication (drug-eluting stents) that prevents the growth of cells around the stent. This reduces the chance of the artery closing again (restenosis). Stents also may be placed without angioplasty.

CRITICAL THINKING

Think of a way to ask a patient a question about chest pain that cannot be answered with a simple yes or no.

When caring for a patient who has chest pain caused by heart problems, the paramedic should understand that the patient is frightened. Chest pain is associated with life-threatening consequences. These patients should be calmed and reassured to reduce their anxiety.

PRIMARY SURVEY

In most medical emergencies involving conscious patients, the main elements of the primary survey (level of consciousness, airway, breathing, and circulation) can be evaluated during the initial paramedic-patient encounter. For example, an appropriate verbal exchange between the paramedic and the conscious patient establishes that the patient is alert, oriented, and has adequate cardiorespiratory function. However, the primary survey for a patient with a possible coronary event should include a more in-depth evaluation of the patient's level of consciousness, respirations, pulse, and blood pressure.

A change in the patient's level of consciousness (e.g., lightheadedness or confusion) may indicate decreased cerebral perfusion caused by poor cardiac output. If possible, the paramedic should determine the patient's normal level of functioning by interviewing the patient, family members, or others who are familiar with the patient (e.g., neighbors and nursing staff). In addition, the paramedic should evaluate the patient's vital signs and include a respiratory assessment, an assessment of the patient's pulse for rate and regularity, and an initial measurement of the patient's blood pressure. These findings give the paramedic a baseline. They also are important during reassessment to identify trending and to guide patient care.

PHYSICAL EXAMINATION

The physical examination of a patient with cardiac disease should be organized and complete. The paramedic should use the following look-listen-feel approach. (Chapter 20 presents a more detailed discussion of this approach.)

LOOK AGAIN
See Chapter 20: Secondary Assessment, pp. 540-542.

Look

- *Skin:* Pale and diaphoretic skin may indicate peripheral vasoconstriction and sympathetic stimulation. Cyanosis is an indicator of poor oxygenation. The paramedic should use pulse oximetry to measure hemoglobin oxygenation.
- *Jugular veins:* An increase in central venous pressure from heart failure and cardiac tamponade can produce distention of internal jugular veins. **Jugular vein distention** is best evaluated with the patient's head elevated at 45 degrees. Distention may be difficult to assess in obese patients.
- *Peripheral and presacral edema:* Edema can result from chronic back pressure in the systemic venous circulation. It may be related to right heart failure. Edema is most obvious in dependent areas. (These areas may include the ankles and the sacral region in bedridden patients.) Edema can be classified as *nonpitting* (minimal or no depression of tissue after removal of finger pressure) or *pitting* (depression of tissue remains after removal of finger pressure).
- *Additional indicators of cardiac disease:* More subtle signs of cardiac disease that may be found on a visual inspection include a midsternal scar from coronary surgery (Figure 22-113), a ***nitroglycerin*** patch on the skin, an implanted pacemaker or implantable cardioverter-defibrillator in the left upper chest or abdominal wall, and medical alert identification necklaces or bracelets.

Listen

- *Lung sounds:* The paramedic should assess the patient's chest visually for accessory muscle use in breathing before listening to lung sounds. Lung sounds should be clear and equal bilaterally. As described in Chapter 20, crackles may indicate pulmonary congestion or edema.

LOOK AGAIN
See Chapter 20: Secondary Assessment, pp. 536-540.

CRITICAL THINKING
What breath sounds might you hear if the patient has congestive heart failure or pulmonary edema?

- *Heart sounds:* Abnormal heart sounds may indicate congestive heart failure in adult patients (Box 22-13). Heart sounds are best heard at the **point of maximum impulse.** The point of maximum impulse is the location where the apical impulse is most readily visible or palpable. This often is in the fifth intercostal space, just medial to the left midclavicular line. Although abnormal heart sounds are difficult to detect in the prehospital setting, they can be useful for confirming the paramedic's field impression. Even so, abnormal heart sounds do not alter prehospital care. This evaluation should never delay other patient care measures or transportation.

FIGURE 22-113 Midsternal scar and implanted cardiac device.

BOX 22-13 Heart Sounds

Heart sounds typically can be auscultated with a stethoscope during ventricular systole and diastole. When the ventricles contract, both atrioventricular valves close at nearly the same time. This closure causes a vibration of the valves and surrounding fluid. Vibration results in a low-pitched sound (often described as a "lubb"). Closing of the aortic and pulmonary semilunar valves at the end of ventricular systole produces a higher pitched sound (described as "dub"). These normal heart sounds are referred to as S_1 and S_2, respectively.

In rare cases a third heart sound can be heard near the end of the first third of diastole (S_3). The third heart sound is caused by turbulent blood flow into the ventricles. It may be normal, but it also may be an indicator of congestive heart failure. A fourth heart sound (S_4) may be heard during the end of diastole. This sound is thought to result from turbulence and chamber stretching caused by the atrial contraction during this part of the cardiac cycle. S_4 often is a sign of congestive heart failure in adults. S_3 and S_4 contribute to "gallop" rhythms, which are useful clinical indicators of congestive heart failure. Although heart sounds can help define the clinical picture, evaluation of these sounds should never delay emergency care or transport. To summarize:

- *S_1:* First heart sound, which occurs with closure of the atrioventricular valves during ventricular systole.
- *S_2:* Second heart sound, which occurs with closure of the aortic and pulmonic valves. It signifies the beginning of ventricular diastole.
- *S_3:* Extra heart sound heard after S_2 (although it is not always present). It may be a normal finding in some patients, or it may indicate heart failure.
- *S_4:* Extra heart sound heard in late diastole (just before S_1) It is associated with atrial contractions and often is heard in patients with congestive heart failure.

- *Carotid artery bruit:* **Bruits** are murmurs that indicate turbulent blood flow through a vessel. (This is most commonly caused by atherosclerosis.) The presence of a bruit in a patient with cardiac disease is evaluated at the carotid artery with a stethoscope and should always be assessed before carotid sinus massage (described later in this chapter) is performed. If a carotid artery bruit is present, carotid sinus massage is contraindicated. The procedure may dislodge plaque in the artery and cause a stroke.

Feel

- *Skin:* The paramedic should assess the patient's skin with the back of the hand for diaphoresis or fever. Normal skin is warm and dry.
- *Pulse:* The paramedic should assess the pulse for rate, regularity, and equality. A **pulse deficit** is a radial pulse that is less than the ventricular rate. A pulse deficit in peripheral and apical pulse sites may indicate a rhythm disturbance or vascular disease. The paramedic should note any pulse deficit and report it to medical direction.
- *Thorax and abdomen:* The paramedic should check the thorax and abdomen of a patient with cardiac disease for chest wall tenderness and pulsating masses. Chest wall tenderness is not uncommon in patients with acute myocardial infarction. A pulsating mass or distention in the abdomen or epigastric area may indicate an abdominal aneurysm (described later in this chapter).

SECTION EIGHT
Specific Cardiovascular Diseases

PATHOPHYSIOLOGY AND MANAGEMENT OF CARDIOVASCULAR DISEASE

Many true medical emergencies are cardiovascular in nature. Cardiovascular emergencies often result from atherosclerosis of the coronary arteries or peripheral arteries. The following specific medical conditions are discussed in this section:

- Acute coronary syndromes
- Atherosclerosis
- Angina pectoris
- Myocardial infarction
- Left ventricular failure and pulmonary edema
- Right ventricular failure
- Cardiogenic shock
- Cardiac tamponade
- Thoracic and abdominal aortic aneurysm
- Acute arterial occlusion
- Noncritical peripheral vascular disorders
- Hypertension

ACUTE CORONARY SYNDROMES

Acute myocardial infarction (AMI) and unstable angina (UA) are part of a spectrum of clinical disease, collectively known as **acute coronary syndromes** (ACS). ACS is the most common cause of sudden cardiac death. The pathophysiology of both AMI and UA is a ruptured or eroded atheromatous plaque. ECG findings common to ACS include ST-segment elevation, ST-segment depression, and T-wave abnormalities. As with other life-threatening conditions, time is of the essence in managing these patients. Rapid transport is indicated for any patient with chest pain of cardiac origin. Other indications for rapid transport include a sense of urgency for reperfusion; no relief of pain with medications; hypotension or hypoperfusion with central nervous system (CNS) involvement; and significant changes in the patient's ECG.[14]

The primary goals of therapy for patients with ACS include the following[1]:

- Reducing the amount of myocardial necrosis that occurs in patients with myocardial infarction, preserving left ventricular function, and preventing heart failure

- Preventing major adverse cardiac events (death, nonfatal myocardial infarction, and the need for urgent revascularization)
- Treating acute, life-threatening complications of ACS (e.g., ventricular fibrillation, pulseless ventricular tachycardia, symptomatic bradycardias, and unstable tachycardias)

Atherosclerosis

Atherosclerosis is a disease process characterized by progressive narrowing of the lumen of medium and large arteries (e.g., the aorta and its branches, cerebral arteries, and coronary arteries). The process results in the development of thick, hard atherosclerotic plaque. This plaque is referred to as *atheromata* or *atheromatous lesions*. These lesions most often are found in areas of turbulent blood flow. Such areas include vessel bifurcations or occur in vessels with a decreased lumen diameter.

Atherosclerosis is thought to result from damage to the endothelial cell from mechanical or chemical injury and perhaps inflammation (Box 22-14). This response includes platelet adhesion and clotting. Smooth muscle cells may move from the middle muscle layer into the lining of the artery. In the lining, the muscle cells form an atheroma. Over time, the atheromata become fibrous and hardened. In time, they partly or fully obstruct the opening of the arteries. In most cases, some collateral circulation develops to make up for the narrowed vessels.

MAJOR RISK FACTORS

Atherosclerosis occurs to some extent in all middle-aged and older people. The disease also occurs in some young people. Atherosclerosis is thought to be inherited. It usually is seen at a younger age in men than in women. Associated risk factors include age, a family history of heart disease, and diabetes. Some other risk factors can be reduced or eliminated. These include cigarette smoking, obesity, hypertension, and hypercholesterolemia. Some research has shown that plaque formation is not only preventable but also reversible.[1]

EFFECTS

Atherosclerosis has two major effects on blood vessels. First, it disrupts the innermost lining of the vessels. This causes loss of vessel elasticity and an increase in the formation of clots. Second, the atheroma reduces the diameter of the vessel lumen. This reduces the blood supply to tissues. Both effects result in an insufficient supply of nutrients to the tissue. This is especially true under conditions of increased tissue demand for nutrients and oxygen.

The severity of this insufficiency is related to the extent of narrowing (stenosis) of the blocked artery. The severity also depends on how long the atheroma took to develop, and the patient's ability to develop collateral circulation around the obstruction. For example, a patient who gradually develops an atherosclerotic occlusion in an artery of a lower extremity may compensate well through collateral circulation. The patient may experience only mild, intermittent pain during periods of exercise. In contrast, sudden-onset occlusion in a coronary artery (after an acute thrombus) almost always results in ischemia, injury, and necrosis to the area of the myocardium supplied by the affected artery.

Angina Pectoris

Angina pectoris is a symptom of myocardial ischemia; the term literally means "choking pain in the chest." Angina is caused by an imbalance between myocardial oxygen supply and demand. The result is a buildup of lactic acid and carbon dioxide in ischemic tissues of the myocardium. These metabolites irritate nerve endings that produce anginal pain. The most common cause of angina pectoris is atherosclerotic disease of the coronary arteries. A temporary occlusion caused by spasm of a coronary artery with or without atherosclerosis *(Prinzmetal's angina)* also can cause angina pectoris (Box 22-15). Emotional stress and any activity that increases myocardial oxygen demand may cause anginal pain, particularly in patients with atherosclerosis. Myocardial ischemia in turn puts the patient at risk for cardiac dysrhythmias.

BOX 22-14 Role of Inflammation in Heart Attack

Studies have suggested that painless inflammation deep in the body plays an important role in triggering heart attacks.[15] The inflammation may arise from such sources as chronic gum disease, lingering urinary tract infections, and others. Inflammation may weaken the walls of the blood vessels, allowing fatty buildups to burst. Inflammation can be assessed in those at risk for heart disease by testing the blood for an elevated white blood cell count and by measuring the C-reactive protein level. C-reactive protein is a chemical in the blood that is necessary for fighting injury and infection. It can be lowered with cholesterol-lowering drugs, aspirin, and other medications and through diet and exercise.

NOTE

A number of conditions can mimic the signs and symptoms of heart disease and angina pectoris (see Box 22-15). These include cholecystitis, peptic ulcer disease, aneurysm, hiatal hernia, pulmonary embolism, pancreatitis, pleural irritation, respiratory infection, and others. These conditions should be considered as part of the differential diagnosis when a patient presents with signs and symptoms of an acute coronary syndrome.

STABLE ANGINA

Angina pectoris generally is classified as *stable* or *unstable*. Stable angina usually is precipitated by physical exertion or emotional stress. The pain usually lasts 1 to 5 minutes but

BOX 22-15 Conditions That May Mimic Acute Coronary Syndrome

Acromioclavicular disease
Chest wall syndrome
Chest wall trauma
Chest wall tumors
Cholecystitis
Costochondritis
Dyspepsia
Esophageal disease
Gastric reflux
Herpes zoster
Hiatal hernia
Pancreatitis
Peptic ulcer disease
Pericarditis
Pleural irritation
Pneumothorax
Pulmonary embolism
Respiratory infection
Thoracic aortic dissection

may last as long as 15 minutes. Angina is relieved by rest, ***nitroglycerin,*** or oxygen. Stable angina attacks usually are similar and are always relieved by the same mode of therapy.

UNSTABLE ANGINA

Unstable angina *(preinfarction angina)* denotes an anginal pattern that has changed in its ease of onset, frequency, intensity, duration, or quality. (This includes any new-onset anginal chest pain.) Unstable angina may occur during periods of light exercise or at rest. The pain usually lasts 10 minutes or longer. The pain is relieved less promptly by cessation of activity or ***nitroglycerin*** than in stable angina. Unstable angina mimics acute myocardial infarction. The two sometimes are difficult to differentiate in the prehospital setting. Patients with unstable angina are at increased risk of acute myocardial infarction and sudden death.

The pain of angina usually is described by the patient as a pressure, squeezing, heaviness, or tightness in the chest. Although 30% of patients with angina feel pain only in the chest, others describe the pain as radiating to the shoulders, arms, neck, and jaw and through the chest to the back. Associated signs and symptoms include anxiety, shortness of breath, nausea or vomiting, and diaphoresis. The patient history often reveals previous attacks of angina. Often the patient will have taken ***nitroglycerin*** before paramedics arrive. If so, the paramedic should determine the age of the nitroglycerin prescription (***nitroglycerin*** is unstable and quickly loses its strength), the amount of ***nitroglycerin*** taken, and its effect. If the pain is not relieved by rest and medication, the paramedic should suspect a myocardial infarction.

MANAGEMENT

All patients with chest pain and signs and symptoms of myocardial ischemia should be managed as though an acute myocardial infarction were evolving (Table 22-8). The goal of management is to increase the coronary blood supply, reduce the myocardial oxygen demand, or both.

Management guidelines include the following:

1. Place the patient at rest physically and emotionally.
2. Administer oxygen if the patient is dyspneic, has signs of CHF or has an SaO_2 <94%.[1]
3. Administer ***aspirin*** (per protocol).
4. Initiate intravenous therapy.
5. If pain is present on paramedics' arrival, use pharmacological therapy. This may include sublingual ***nitroglycerin*** followed by ***morphine*** (IIa).
6. Monitor the ECG for dysrhythmias. Monitor a 3-lead ECG continuously and record serial 12-lead ECGs during transport. Also measure, record, and communicate any ST-segment changes. (Measurable ST-segment changes are most reliable when viewed in 12-lead mode.)
7. Transport the patient to an appropriate hospital for evaluation by a physician.

Myocardial Infarction

Acute myocardial infarction occurs with a sudden and total blockage or near blockage of blood flowing through an affected coronary artery to an area of heart muscle. This blockage results in ischemia, injury, and necrosis to the area of the myocardium distal to the occlusion. Acute myocardial infarction most often is associated with atherosclerotic heart disease.

PRECIPITATING EVENTS

The process of myocardial infarction is complex. It generally begins with the formation of an atherosclerotic plaque involving the intimal layer of a coronary artery. The plaque disrupts the smooth arterial lining and results in an uneven surface. This creates turbulent blood flow. The plaque may rupture. If rupture occurs, the injured tissue is exposed to circulating platelets. This results in the formation of a thrombus that occludes the artery. As the thrombus enlarges, it further reduces blood flow in the coronary vessel.

Acute thrombotic occlusion generally is accepted as the cause of most myocardial infarctions. Other factors that may lead to acute myocardial infarction include coronary spasm, coronary embolism, severe hypoxia, hemorrhage into a diseased arterial wall, and reduced blood flow after any form of shock. All of these may result in an inadequate amount of blood reaching the myocardium.

TYPES AND LOCATIONS OF INFARCTS

The myocardial cells beyond the occluded artery die (infarct) from lack of oxygen. The size of the infarct is determined by the needs of the tissue supplied by the occluded vessel, by the presence of collateral circulation, and by the time

TABLE 22-8 Likelihood of Ischemic Origin of Chest Pain and Short-Term Risk

Part I. Patient With Chest Pain Without ST-Segment Elevation: Likelihood of Ischemic Origin

	A. High Likelihood	B. Indeterminate Likelihood	C. Low Likelihood
	High likelihood that chest pain has ischemic origin if patient has *any* of the findings in the column below:	Indeterminate likelihood that chest pain has ischemic origin if patient has NO findings in column A and *any* of the findings in the column below:	Low likelihood that chest pain has ischemic origin if patient has NO findings in column A or B. Patients may have any of the findings in the column below:
History	• Chief symptom is chest or left arm pain or discomfort *plus* current pain that reproduces pain of previous documented angina *and* known CAD, including MI	• Chief symptom is chest or left arm pain or discomfort • Age >70, male	• Probably ischemic symptoms • Recent cocaine use
Physical exam	• Transient mitral regurgitation • Hypotension • Diaphoresis • Pulmonary edema or rales	• Diabetes mellitus • Extracardiac vascular disease	• Age >70 years • Male gender • Chest discomfort reproduced by palpation
ECG	• New (or presumed new) transient ST deviation (≥0.5 mm) or T-wave inversion (≥2 mm) with symptoms	• Fixed Q waves • Normal ECG *or* T-wave flattening *or* T-wave inversion in leads with dominant R waves	• Abnormal ST segments *or* T waves that are not new
Cardiac markers	• Elevated troponin I or T • High (A) or indeterminate (B) likelihood of ischemia	*Any finding in column B above PLUS* • Elevated CK-MB	• Normal

Part II. Risk of Death or Nonfatal MI Over the Short Term in Patients With Chest Pain With High or Indeterminate Likelihood of Ischemia (Columns A and B in Part I)

	High Risk	Indeterminate Risk	Low Risk
	Risk is high if patient has *any* of the following findings:	Risk is indeterminate if patient has any of the following findings:	Risk is low if patient has NO high- or indeterminate-risk features; may have any of the following:
History	• Accelerating tempo of ischemic symptoms over previous 48 hours	• Previous MI *or* • Cerebrovascular disease *or* • CABG, previous aspirin use	• Peripheral-artery disease *or*
Character of pain	• Prolonged, continuing rest pain (>20 min)	• Prolonged rest angina (>20 min) now resolved (moderate to high likelihood of CAD) • Rest angina (<20 min) or pain relieved by rest or sublingual nitrates	• New-onset functional angina (class III or IV) in past 2 weeks without prolonged rest pain (but with moderate or high likelihood of CAD)
Physical exam	• Pulmonary edema secondary to ischemia • New or worse mitral regurgitation murmur • Hypotension, bradycardia, tachycardia • S_3 gallop or new or worsening rales • Age >75 years	• Age >70 years	
ECG	• Transient ST-segment deviation (≥0.5 mm) with rest angina • New or presumably new bundle branch block • Sustained VT	• T-wave inversion ≥2 mm • Pathologic Q waves or T waves that are not new	• Normal or unchanged ECG during an episode of chest discomfort
Cardiac markers	• Elevated cardiac troponin I or T	*Any of the above findings PLUS* • Elevated CK-MB	• Normal

Modified from Braunwald E, et al: ACC/AHA guideline update for the management of patients with unstable angina and non-ST segment elevation myocardial infarction-2002: Summary Article: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients with Unstable Angina). *Circulation* 106:1893-1900, 2002.

CABG, Coronary artery bypass grafting; *CAD,* coronary artery disease; *CK-MB,* creatine kinase, myocardial bound; *MI,* myocardial infarction.

required to reestablish blood flow. Therefore emergency care is directed at the following:

- Increasing the oxygen supply by administering supplemental oxygen
- Decreasing the metabolic needs and providing collateral circulation
- Reestablishing perfusion to the ischemic myocardium as quickly as possible after the onset of symptoms

Most acute myocardial infarctions involve the left ventricle or interventricular septum. These areas are supplied by either of the two major coronary arteries. (However, some patients sustain damage to the right ventricle.) If the occlusion is in the left coronary artery, the result is an anterior, lateral, or septal wall infarction. Inferior wall infarction (of the inferior-posterior wall of the left ventricle) usually is a result of right coronary artery occlusion.

Infarction also can be classified into one of three ischemic syndromes based on the rupture of an unstable plaque in an epicardial artery: **unstable angina, non-STEMI,** and **STEMI.**[1] These three acute coronary syndromes share common risk factors, and their management overlaps a good deal. Sudden cardiac death may occur with any of these syndromes.

- In *unstable angina,* the early thrombus has not obstructed coronary blood flow completely. This partial occlusion produces symptoms of ischemia. The blockage eventually may result in complete occlusion and produce a non-STEMI. Fibrinolytic therapy (described later in this chapter) is not effective in unstable angina. In fact, such therapy may accelerate the occlusion. Therapy with antiplatelet agents is most effective at this time because the thrombus is rich in platelets.
- *Non-STEMI* occurs as microemboli from the thrombus become lodged in the coronary arteries. This produces minimal damage to the myocardium. However, these patients are at highest risk for progression to myocardial infarction. Non-STEMIs are evident only with ST-segment depression or T-wave abnormalities.
- *STEMI* occurs when the thrombus occludes the coronary vessel for a prolonged period. The infarct is diagnosed by the development of elevated ST segments in two or more contiguous (adjacent) leads. (Figure 22-114). The clot is rich in thrombin; therefore, early management with fibrinolytics may help limit the size of the infarct.

DEATH OF MYOCARDIUM

When blood flow to the myocardium stops, a series of events begins. Cells switch from aerobic to anaerobic metabolism. This results in the release of lactic acid and an increase in tissue carbon dioxide levels. These changes contribute to ischemic pain (angina). As cells lose their ability to maintain their electrochemical gradients, they begin to swell and depolarize. These initial changes are reversible.

FIGURE 22-114 ST elevation and pathological Q waves. (Aehlert B: *ACLS quick review study guide,* ed 3, St Louis, 2006, Mosby.)

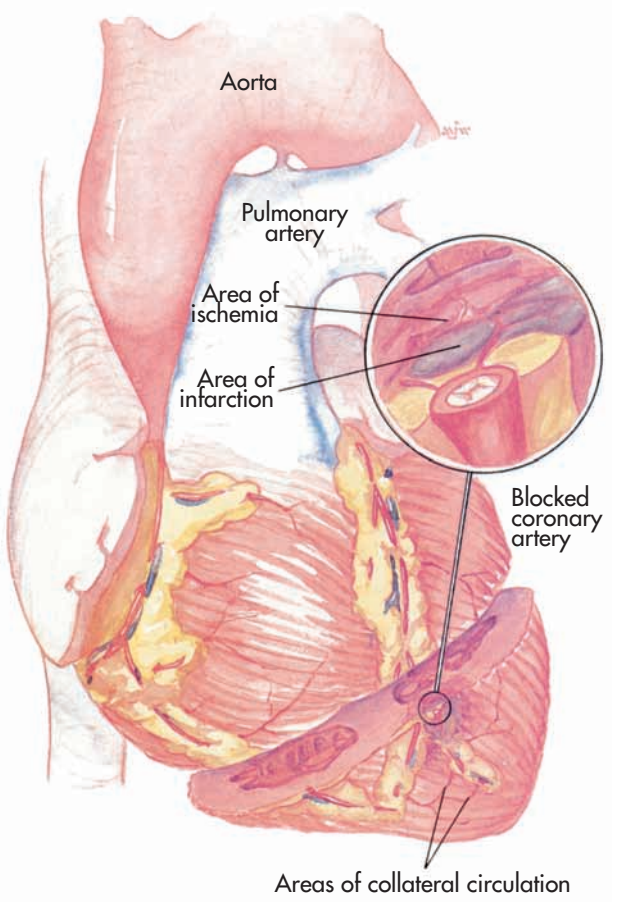

FIGURE 22-115 Areas of infarct.

However, within a few hours, if collateral flow and reperfusion are inadequate, much of the muscle distal to the occlusion dies. The area surrounding the necrotic tissue may survive because of collateral circulation. However, surviving tissue may become the origin of dysrhythmias (Figure 22-115).

Scar tissue replaces the infarcted area in a process that takes about 8 weeks. The process starts with deposits of connective tissue on about the twelfth day. Scar tissue is durable. However, it lacks elasticity, does not contract, and conducts electrical impulses poorly in the damaged area of the myocardium. The left ventricle can lose as much as 25% of its muscle and still function as an effective pump. Areas

with poor perfusion after a large myocardial infarction may not develop strong scar tissue. This may result in an aneurysm. Such an aneurysm can greatly reduce the effective ventricular contractility. An aneurysm also may lead to the development of serious dysrhythmias.

The damaged myocardium is most susceptible to rupture during the first 1 to 2 weeks after a myocardial infarction, because the scar tissue has not reached adequate strength. For this reason, patient activity is limited. Prevention of hypertension and excitement during this period also is usually necessary. Even so, the hospital stay of patients with uncomplicated myocardial infarctions has been shortened. Today, most patients resume activity within 2 to 3 days, and most leave the hospital within 7 to 10 days. Many patients have a stress test before they are discharged. This test determines the patient's exercise tolerance level and whether ischemia or dysrhythmias are present during exercise. The result of this test helps determine the activities the patient may resume after discharge.

DEATH FOLLOWING MYOCARDIAL INFARCTION

Death after myocardial infarction usually results from lethal dysrhythmias (ventricular tachycardia, ventricular fibrillation, and cardiac standstill), pump failure (cardiogenic shock and congestive heart failure), or myocardial tissue rupture (rupture of the ventricle, septum, or papillary muscle). Fatal dysrhythmias are the most common cause of death from myocardial infarction. Deaths that occur within the first 2 hours after the onset of illness or injury are *sudden deaths*. Most patients who suffer sudden death have no immediate warning symptoms.

NOTE

Sudden death is defined as a sudden dysrhythmic death that occurs within the first 2 hours of cardiac ischemic symptoms.[6] More than 50% of cardiac deaths occur with no evidence of infarction on autopsy when resuscitation attempts fail. Sudden death without infarction is a main reason for the widespread availability of automated external defibrillators. (Another reason is that the most common death-producing dysrhythmia is ventricular fibrillation.)

SIGNS AND SYMPTOMS

Some patients with acute myocardial infarction—particularly diabetic patients, some women, and those in the older age groups—may have only symptoms of dyspnea, syncope, or confusion. However, substernal chest pain is present in 70% to 90% of patients with acute myocardial infarction. The pain generally has the same characteristics and locations as anginal pain. The pain also may radiate to the arms, neck, jaw, or back. The following signs and symptoms may accompany the pain and occasionally are present even in the absence of pain *(silent myocardial infarction):*

- Agitation
- Anxiety
- Cyanosis
- Diaphoresis
- Dyspnea
- Nausea and vomiting
- Palpitations
- Sense of impending doom
- Weakness

CRITICAL THINKING

How can prehospital recognition of an acute myocardial infarction affect the care of the patient at the hospital?

The chest pain associated with acute myocardial infarction often is constant. Also, the pain often is not altered or alleviated by ***nitroglycerin*** or other cardiac medications, rest, changes in body position, or breathing patterns. With angina pectoris, the onset often occurs during periods of activity. In contrast, the onset of pain in more than half of all patients with acute myocardial infarction occurs during rest. Most patients have had warning anginal pains (preinfarction angina) hours or days before the attack. Many patients deny the possibility of an evolving myocardial infarction. They may blame the chest pain or discomfort on unrelated causes, such as fatigue or indigestion. Denial delays the request for EMS assistance during the most critical phase of the illness. According to the American Heart Association, more than 50% of deaths from ischemic heart disease occur outside the hospital within the first 4 hours after the onset of pain.[1]

CRITICAL THINKING

Why do you think patients deny that their signs and symptoms may be due to a heart attack?

Vital signs vary with an acute myocardial infarction. They depend on the extent of damage to the heart muscle and conduction system. They also depend on the degree and type of autonomic nervous system response. (Inferior myocardial infarctions often show a mainly parasympathetic response. In contrast, anterior myocardial infarctions commonly show a mainly sympathetic response.) For example, the patient's blood pressure may be normal, elevated (sympathetic discharge), or low (parasympathetic discharge or pump failure). The pulse rate depends on the presence or absence of dysrhythmias. The pulse rate may be normal, tachycardic, bradycardic, regular, or irregular. Respirations may be normal or increased.

NOTE

Sulfonylurea drugs (drugs for treating diabetes), such as glyburide or glipizide, may lessen the magnitude of ST-segment elevation in the presence of an infarct. Therefore, it is crucial that paramedics obtain a diabetes history for all patients with a cardiac event. Research has shown that diabetes drugs can mask the severity of a heart attack.[17]

MANAGEMENT OF AN UNCOMPLICATED ACUTE MYOCARDIAL INFARCTION

All patients with anginal chest pain are assumed to have an acute myocardial infarction until it is proved otherwise (Figure 22-116). Any patient with chest pain should be transported to a medical facility for evaluation by a physician, regardless of the apparent severity on the arrival of EMS providers, the patient's age, gender, or associated complaints. The primary goals of prehospital care are to identify a patient with possible myocardial infarction; to relieve pain and apprehension; to prevent the development of serious dysrhythmias; and to limit the size of the infarct. The paramedic should obtain a full patient history while performing the physical examination and during initial patient care. Because time is of the essence, the following aspects of patient care are a high priority:

1. Place the patient at rest or in a comfortable position. This helps reduce anxiety and the heart rate and thus oxygen demand.
2. Monitor pulse oximetry.
3. Administer low-concentration oxygen (4 L/minute) via the nasal cannula if SaO_2 is <94%. Patients with respiratory compromise need a higher oxygen concentration.
4. Initiate transport quickly. (If the patient is stable, do not use audible or visual warning devices, to help reduce the patient's anxiety.)
5. Administer ***aspirin*** (per protocol).
6. Establish an IV line with normal saline or lactated Ringer solution to keep the vein open or to supply fluid boluses (if needed).
7. Obtain baseline vital signs. Repeat the assessment often. Vital sign assessment should include auscultation of the lungs for heart failure indicators (e.g., presence of crackles).
8. Attach ECG electrodes, obtain a 12-lead ECG, document the initial rhythm, and monitor for dysrhythmias (repeat if possible during transport).
9. Administer medications (per protocol) to relieve pain and manage dysrhythmias:
   a. Medications that may be used for analgesia and to reduce preload and afterload include ***nitroglycerin*** followed by ***morphine.***
   b. Medications that may be used to manage the various dysrhythmias include ***procainamide, atropine,*** diltiazem, ***verapamil, adenosine, magnesium, metoprolol, amiodarone,*** and others. (Refer to the appropriate treatment algorithm.)

NOTE

Nitroglycerin is a vasodilating agent that has beneficial hemodynamic effects. These include dilation of arterioles and veins in the periphery (thereby reducing preload) and dilation of the coronary arteries. This reduces the workload of the heart, lowers myocardial oxygen demand, and may relieve ischemic chest pain. Because of these hemodynamic effects, ***nitroglycerin*** should not be used in patients with the following conditions[4]:

- Hypotension (systolic blood pressure lower than 90 mm Hg or more than 30 mm Hg below baseline)
- Extreme bradycardia (heart rate slower than 50 beats/minute)
- Tachycardia (heart rate faster than 100 beats/minute) unless the patient has heart failure[1]

Nitroglycerin also should be given with extreme caution (if at all) to patients with suspected inferior wall myocardial infarction with possible right ventricular involvement (patients who require adequate right ventricular preload). In these patients, nitroglycerin can cause profound hypotension. ***Nitroglycerin*** also is contraindicated in patients who have taken medication for erectile dysfunction within the previous 24 hours (longer for some preparations).

FIBRINOLYTIC THERAPY

Studies have shown that an acute intracoronary thrombus can be dissolved (thereby restoring blood flow to the ischemic area) with salvage of ischemic myocardium if a fibrinolytic agent is administered within 12 hours after the onset of symptoms when percutaneous angioplasty (PCA) is not available within 90 minutes of first medical patient contact.[1] Some emergency medical services are authorized by medical direction to administer these agents in the prehospital setting. The American Heart Association recommends that prehospital systems focus on early diagnosis and the field administration of fibrinolytics as soon as possible after the onset of ischemic-type chest discomfort in patients with confirmed STEMI or new or presumably new left bundle branch block.[1] The AHA strongly recommends the following for EMS systems that administer fibrinolytics in the prehospital setting[1]:

- Protocols using fibrinolytic checklists
- 12-lead ECG acquisition and interpretation
- Experience in advanced life support
- Communication with the receiving institution
- Medical director with training and experience in STEMI management
- Continuous quality improvement

Common fibrinolytic agents include ***streptokinase, tissue plasminogen activator,*** tenecteplase, anistreplase, and ***reteplase.*** All these agents work through activation of the plasma protein plasminogen to dissolve the coronary thrombus. Plasminogen is converted to plasmin (the active form). Plasmin degrades fibrin, the basic component of a clot (thrombus). ***Aspirin*** and ***heparin*** are part of the "fibrinolytic package."

A fibrinolytic agent can dissolve both beneficial and pathological thrombi. Therefore, the drug is administered selectively. Most EMS systems that use fibrinolytic agents establish inclusion-exclusion criteria similar to those in Box 22-16.[6]

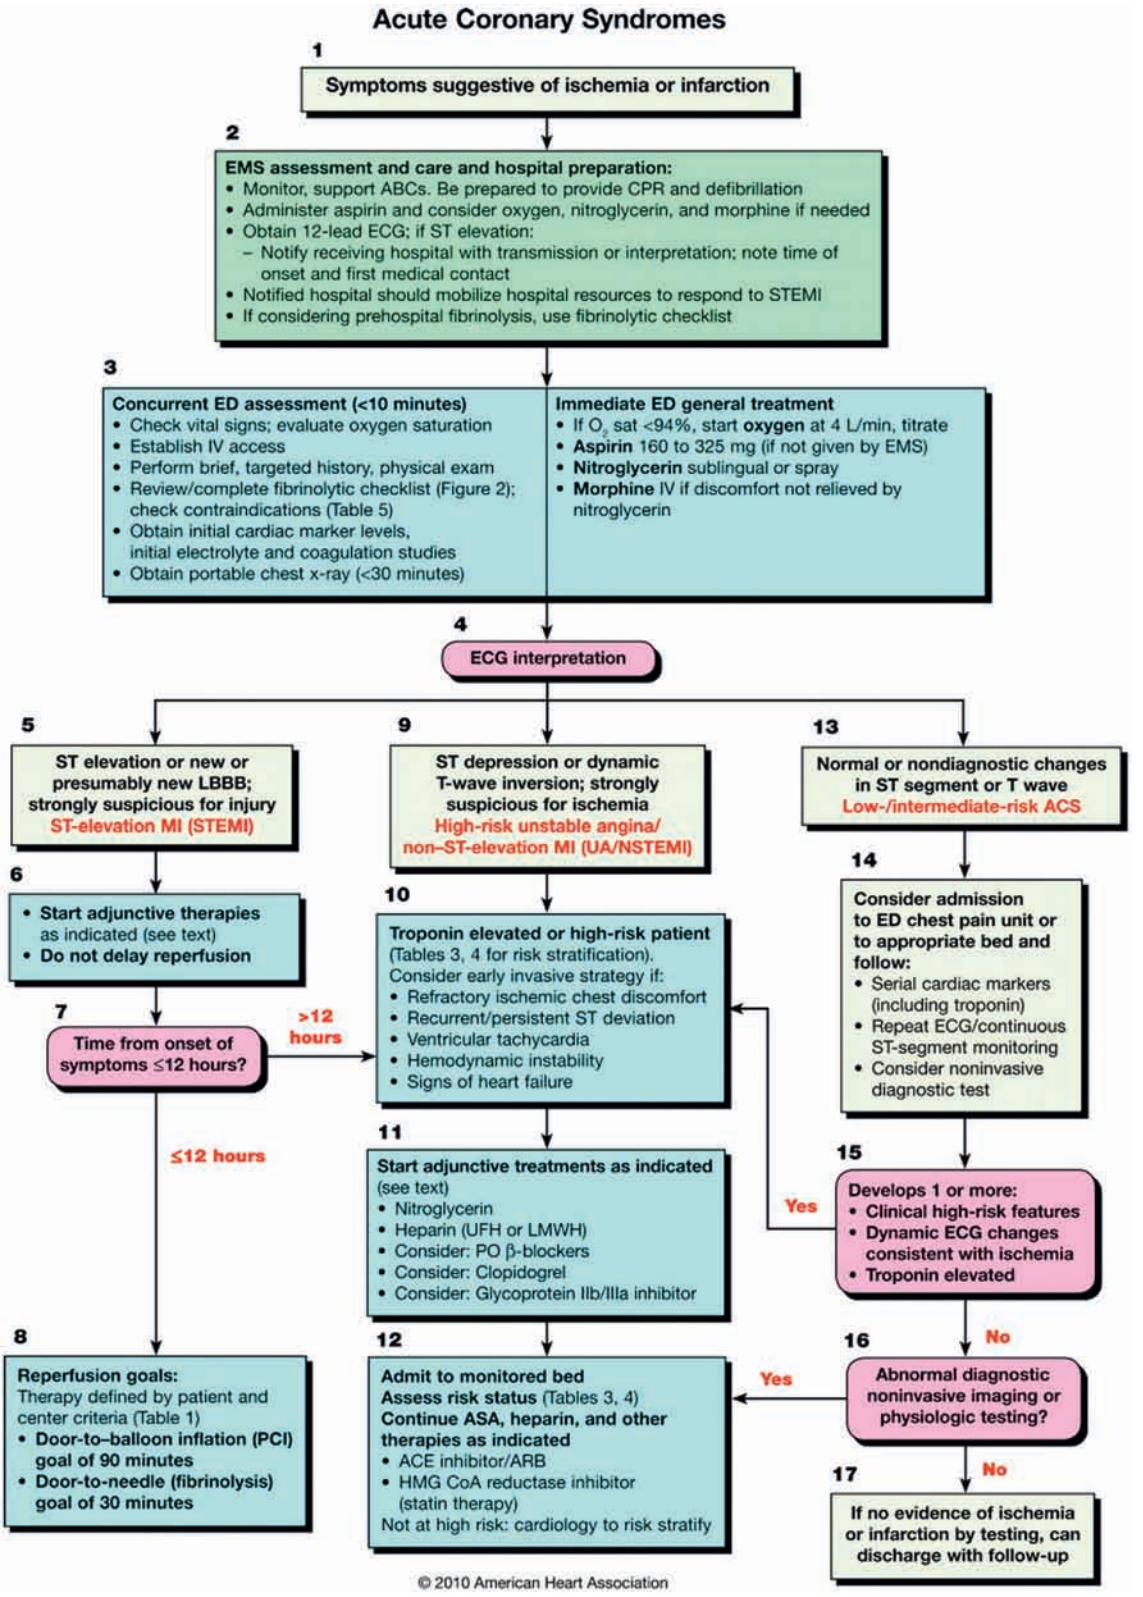

FIGURE 22-116 Acute coronary syndrome algorithm. (Reprinted with permission, American Heart Association Guidelines For CPR and ECC, *Circulation 122* [suppl 3]:S685-S919, American Heart Association, Inc, 2010.)

BOX 22-16 Possible Contraindications to Fibrinolytic Therapy

- Systolic BP >180-200 mm Hg OR diastolic BP >100-110 mm Hg
- Right vs. left arm systolic BP difference >15 mm Hg
- History of structural central nervous system disease
- Significant closed head/facial trauma within the previous 3 weeks
- Stroke >3 hours OR <3 months
- Recent (within 2 to 4 weeks) major trauma, surgery (including laser eye surgery), GI/GU bleed
- Any history of intracranial hemorrhage
- Bleeding, clotting problem, or blood thinners
- Pregnant female
- Serious systemic disease (e.g., advanced cancer, severe liver or kidney disease)

From American Heart Association. 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*, 122(18 Supplement 3), S639-S946, 2010.

BOX 22-17 Classification of Heart Failure

Heart failure can be classified as high-output failure or low-output failure. With **low-output heart failure,** cardiac output is decreased. This is the most common type of heart failure seen with most forms of heart disease. Low-output failure leads to manifestations of impaired peripheral circulation and vasoconstriction. With **high-output heart failure,** cardiac output remains high but is unable to meet the metabolic needs of the body. This type of heart failure is associated with hyperthyroidism, anemia, pregnancy, Paget's disease, arteriovenous fistulas, beriberi, and sepsis. In practice, differentiating between low-output and high-output heart failure sometimes is difficult and does not affect prehospital care.

Heart failure can also be classified as chronic or acute. *Chronic heart failure* typically is observed in patients with dilated cardiomyopathy or multivalvular heart disease that develops or progresses slowly. In chronic heart failure, arterial pressure tends to be well maintained until very late in the course, but peripheral edema often accumulates (these patients often have multiple events of failure). *Acute heart failure* is associated with a sudden reduction in cardiac output that often results in systemic hypotension without peripheral edema. Patients with acute heart failure usually have been entirely well but then suddenly develop a large myocardial infarction or valvular rupture in the heart (this often is a first-time event).

Congestive Heart Failure

Congestive heart failure is a condition in which the heart is unable to pump blood at a rate that meets the metabolic needs of the tissues. The condition affects about 5 million Americans and is responsible for 7000 to 10,000 hospital admissions each year.[17] Congestive heart failure most often is caused by volume overload, pressure overload, loss of myocardial tissue, and impaired contractility. All of these can impair left ventricular function. Precipitating causes of heart failure include myocardial infarction, pulmonary embolism, and enlarged heart *(cardiomegaly)*. This text discusses congestive heart failure in terms of left ventricular failure and pulmonary edema and also right ventricular failure (Box 22-17).

LEFT VENTRICULAR FAILURE AND PULMONARY EDEMA

Left ventricular failure occurs when the left ventricle fails to work as an effective forward pump. This causes a back pressure of blood into the pulmonary circulation. This condition may be caused by a number of forms of heart disease, such as ischemic, valvular, and hypertensive heart disease. If left unmanaged, significant left ventricular failure results in pulmonary edema.

In left ventricular failure, blood is delivered to the left ventricle, but the blood is not fully ejected from the ventricle. The increase in end-diastolic blood volume increases left ventricular end-diastolic pressure. This pressure is transmitted to the left atrium. Pressure then is transmitted to the pulmonary veins and capillaries. As pulmonary capillary hydrostatic pressure increases, the plasma portion of blood is forced into the alveoli. There plasma mixes with air. This results in the typical finding in pulmonary edema: foamy, blood-tinged sputum. If left unmanaged, the progressive fluid buildup can result in death from hypoxia. Myocardial infarction is a common cause of left ventricular failure. Therefore, in all patients with pulmonary edema (particularly those with an abrupt onset), an acute myocardial infarction also should be suspected.

NOTE

Paroxysmal nocturnal dyspnea is an abnormal condition of the respiratory system. It is characterized by sudden attacks of shortness of breath, profuse sweating, tachycardia, and wheezing that awaken a person from sleep. The condition often is associated with left ventricular failure and pulmonary edema.

Left ventricular failure results in a reduction of stroke volume. This in turn initiates several compensatory mechanisms that restore cardiac output and organ perfusion (tachycardia, vasoconstriction, and activation of the renin-angiotensin-aldosterone system). However, these mechanisms often increase myocardial oxygen demand. They therefore further decrease the myocardium's ability to contract. Box 22-18 lists the signs and symptoms of left ventricular failure and pulmonary edema.

Management. Pulmonary edema is an acute and critical emergency (Figure 22-117). It may lead to death unless it is treated rapidly. Emergency management is directed at reducing the venous return to the heart, improving

BOX 22-18 Signs and Symptoms of Left Ventricular Failure

- Severe respiratory distress
  - Orthopnea
  - Spasmodic cough that may produce foamy, blood-tinged sputum
  - History of paroxysmal nocturnal dyspnea (a sudden episode of dyspnea that occurs after lying down)
- Severe apprehension, agitation, confusion
- Cyanosis (if severe)
- Diaphoresis
- Adventitious lung sounds
  - Bilateral crackles that do not clear with coughing (usually present at the base of the lungs and up to the level of the scapulae)
  - Rhonchi (fluid in the upper airways)
  - Wheezes (reflex airway spasm, sometimes referred to as *cardiac asthma*)
- Jugular vein distention (indicative of back pressure through the right heart and into the venous system)
- Abnormal vital signs
  - Blood pressure: Possibly elevated
  - Pulse rate: Rapid to compensate for low stroke volume; possibly irregular if dysrhythmias are present
- Regular alterations of weak and strong beats without changes in the length of the cycle (pulsus alternans); rapid, labored respirations
- Altered level of consciousness (patient may be anxious, agitated, uncooperative, or obtunded because of poor cerebral perfusion or hypoxia)
- Chest pain
  - Presence or absence of pain
  - May be masked by respiratory distress

myocardial contractility, decreasing myocardial oxygen demand, improving ventilation and oxygenation, and rapidly transporting the patient to a medical facility.

Emergency care entails patient positioning, oxygenation, continuous positive airway pressure (CPAP), ventilatory support as needed, and pharmacological therapy. As in any other true emergency, the paramedic should perform a full but focused patient history and examination while initiating treatment. No characteristic ECG changes are associated with pulmonary edema. However, the paramedic should obtain an initial tracing. The paramedic also should monitor the patient's rhythm continuously for evidence of myocardial irritability and dysrhythmias.

The paramedic should place the patient in a sitting position with the legs dependent. This position increases lung volume and vital capacity. It also diminishes the work of respiration and reduces venous return to the heart.

The paramedic should administer high-concentration oxygen using a well-fitted face mask. Preferably the mask should be a nonrebreathing mask to optimize the amount of inspired oxygen. Some patients may require (and will tolerate) positive pressure assistance (including CPAP or biphasic positive airway pressure [BiPAP]). Positive pressure assistance is one of the highest priorities in caring for these patients, and it reduces the need for high levels of inspired oxygen. A pulse oximeter should be used to ensure an arterial oxygen saturation of at least 90%. If this cannot be achieved with 100% oxygen or if signs of cerebral hypoxia or progressive hypercapnia are seen, tracheal intubation and assisted ventilations may be indicated.

Nitroglycerin and ***morphine*** may be used to reduce venous return, enhance contractile function of the myocardium, and reduce dyspnea. It should be noted that both of these drugs can lower blood pressure. Therefore, care must be taken in patients with pulmonary edema and hypotension (a systolic blood pressure less than 100 mm Hg).

In some cases of pulmonary edema, the patient will have fluid overload. In these situations, medical direction may recommend administration of furosemide[18,19].

NOTE

Some medical authorities do not recommend the administration of morphine in patients with decompensated heart failure. Studies have suggested that the use of morphine may be associated with increased adverse events in these patients. These events include a greater frequency of mechanical ventilation, prolonged hospitalization, more intensive care unit (ICU) admissions, and higher mortality.[20] The use of loop and thiazide diuretics in this patient group as part of initial stabilization also is under review.[21] The paramedic should follow local protocol established by medical direction.

The effects of ***nitroglycerin*** and ***morphine*** are:

1. Nitroglycerin
   a. Induction of peripheral vasodilation
   b. Possible reduction of preload and afterload, thereby reducing the myocardial workload and improving cardiac function
2. Morphine
   a. Decrease of venous return by dilation of the capacitance vessels of the peripheral venous bed (reduces preload)
   b. Reduction of myocardial work
   c. Reduction of anxiety

NOTE

Furosemide may be indicated in some patients with pulmonary edema who also have fluid overload. ***Furosemide*** has a direct relaxant (dilating) effect on the venous system and a diuretic effect that reduces intravascular volume. In these patients, ***furosemide*** can reduce venous return and improve breathing.

CRITICAL THINKING

What happens to the diffusion of oxygen and carbon dioxide in the lungs during this process?

Management of Acute Pulmonary Edema

Perform Primary ABCD Survey (Basic Life Support)

(Correct critical problems IMMEDIATELY as they are identified)

- Assess responsiveness, **A**irway, **B**reathing, **C**irculation, ensure availability of monitor/**D**efibrillator

Perform Secondary ABCD Survey (Advanced Life Support)

(Obtain arterial blood gas before oxygen administration if possible)

- Administer oxygen, establish IV access, attach cardiac monitor (O_2, IV, monitor)
- Assess vital signs, attach pulse oximeter, & monitor blood pressure
- Obtain & review 12-lead ECG
- Perform a focused history and physical exam

If feasible and BP permits, place patient in sitting position with feet dependent

- Increases lung volume and vital capacity
- Decreases work of respiration
- Decreases venous return, decreases preload

If systolic BP > 100 mm Hg:

- Sublingual nitroglycerin–1 tablet or 2 sprays every 5 minutes (max 3 tablets) until IV nitroglycerin or nitroprusside can take effect
- Furosemide IV 0.5 to 1.0 mg/kg (typically 20 to 80 mg) can repeat in 30 minutes if symptoms persist and BP stable
- Consider morphine IV 2-4 mg
- Consider continuous positive airway pressure (CPAP)

Consider additional preload/afterload reduction–nitroglycerin or nitroprusside IV, ACE inhibitors

- Nitroglycerin IV–start at 5 mcg/min and increase gradually until mean systolic pressure falls by 10% to 15%, avoid hypotension (SBP <90 mm hg)" **OR**
- Nitroprusside IV (If SBP > 100 mm Hg)–0.1 to 5 mcg/kg/min

Evaluate early for:

- Readily reversible cause and institute appropriate intervention (e.g., cardiac dysrhythmias, tamponade)
- Myocardial ischemia/infarction (Institute appropriate intervention–candidate for fibrinolytic therapy? PTCA?

If patient is refractory to above therapies, hypotensive, or in cardiogenic shock:

- Consider fluid or IV inotropic and/or vasopressor agents (e.g., dobutamine, dopamine, norepinephrine)

In-hospital therapy

- Consider pulmonary and systemic arterial catheterization
- Obtain echocardiogram to assist in diagnosis, evaluation, and reparability of culprit lesion or condition
- Consider need for mechanical circulatory assistance (balloon pump)

FIGURE 22-117 Acute pulmonary edema/hypotension/shock algorithm. (Aehlert B: *ACLS quick review study guide,* ed 3, St Louis, 2006, Mosby.)

Continued

RIGHT VENTRICULAR FAILURE

Right ventricular failure most often results from left ventricular failure that produces elevated pressure in the pulmonary vascular system. This pressure causes resistance to pulmonary blood flow. It also increases the workload of the right side of the heart to overcome the resistance. Over time, the right ventricle fails as an effective forward pump. This causes back pressure of blood into the systemic venous circulation. When the pressure in the systemic venous circulation becomes too high, the plasma portion of the blood is forced out into the interstitial tissues of the body. This results in edema, particularly in the dependent areas of the body. (For example, edema occurs in the lower extremities and sacrum of bedridden patients.) Right ventricular failure can result from several diseases. These include chronic hypertension (in which left ventricular failure usually precedes right ventricular failure), chronic obstructive pulmonary disease, pulmonary embolism, valvular heart disease, and infarction of the right ventricle.

Box 22-19 lists the signs and symptoms of right ventricular failure. When left and right ventricular failure occur at the same time, the signs and symptoms of each may be present. Table 22-9 can help the paramedic differentiate between the two.

Management. Right ventricular failure often is a chronic condition. It usually is not a medical emergency in itself.

Management of Hypotension/Shock–Suspected Pump Problem

Perform Primary ABCD Survey (Basic Life Support)

(Correct critical problems IMMEDIATELY as they are identified)

- Assess responsiveness, **A**irway, **B**reathing, **C**irculation, ensure availability of monitor/**D**efibrillator

Perform Secondary ABCD Survey (Advanced Life Support)

- Administer oxygen, establish IV access, attach cardiac monitor, administer fluids as needed (O_2, IV, monitor, fluids)
- Assess vital signs, attach pulse oximeter, and monitor blood pressure
- Obtain and review 12-lead ECG, portable chest x-ray,
- Perform a focused history and physical exam

Hypotension–suspected pump problem

If breath sounds are clear, consider fluid challenge of 250 to 500 -mL NS to ensure adequate ventricular filling pressure before vasopressor administration

Marked hypotension (systolic BP < 70 mm Hg)/cardiogenic shock

Pharmacologic management:

- Norepinephrine infusion (0.5 to 1 mcg/min titrated to effect) until SBP 80 mm Hg
- Then attempt to change to dopamine 2-20 mcg/kg/min until SBP 90 mm Hg
- IV dobutamine (2 to 20 mcg/kg/min) can be given simultaneously in an attempt to reduce magnitude of dopamine infusion

In-hospital therapy

Consider balloon pump left ventricular assist device or patient transfer to a cardiac interventional facility

Moderate hypotension (systolic BP 70 to 90 mm Hg)

- Dopamine 5 to 15 mcg/kg/min
- If BP remains low despite dopamine doses > 20 mcg/kg/min, may substitute norepinephrine in doses of 0.5 to 30 mcg/min
- Once SBP ≥ 90 with dopamine, add dobutamine 2 to 20 mcg/kg/min and attempt to taper off dopamine

Systolic BP 90 mm Hg

- Dobutamine 2 to 20 mcg/kg/min

Dosing:

Norepinephrine IV	0.5 to 30 mcg/min
Dopamine IV	5 to 15 mcg/kg/min
Dobutamine IV	2 to 20 mcg/kg/min

FIGURE 22-117, cont'd

BOX 22-19 Signs and Symptoms of Right Ventricular Failure

- Tachycardia
- Venous congestion
  - Engorged liver or spleen or both
  - Venous distention: Distention and pulsation of the neck veins
- Peripheral edema
  - Lower extremities or entire body (anasarca)
  - Sacral region in bedridden patients
  - Pitting edema
- Fluid accumulation in serous cavities
  - Abdominal cavity (ascites)
  - Pericardium (pericardial effusion)

  Note: Patients often can tolerate large amounts of effusion without compromise when the effusion develops over an extended period.
- History
  - Often previous myocardial infarction in patients with chronic congestive failure
  - Frequent medication history of digitalis and diuretics to control heart failure

Management of Hypotension/Shock–Suspected Volume Problem

Perform Primary ABCD Survey (Basic Life Support)

(Correct critical problems IMMEDIATELY as they are identified)

- Assess responsiveness, **A**irway, **B**reathing, **C**irculation, ensure availability of monitor/**D**efibrillator

Perform Secondary ABCD Survey (Advanced Life Support)

- Administer oxygen, establish IV access, attach cardiac monitor, administer fluids as needed (O_2, IV, monitor, fluids)
- Assess vital signs, attach pulse oximeter, and monitor blood pressure
- Obtain and review 12-lead ECG, portable chest x-ray,
- Perform a focused history and physical exam

Hypotension–suspected volume (or vascular resistance) problem

Volume replacement

- Fluid challenge (250 to 500-mL IV boluses–reassess)
- Blood transfusion (if appropriate)
- If cause known, institute appropriate intervention (e.g., septic shock, anaphylaxis)
- Consider vasopressors, if indicated, to improve vascular tone if no response to fluid challenge(s)

Note: Aggressive fluid resuscitation is not required for trauma patients with no evidence of hemodynamic compromise. Volume resuscitation in patients with hypovolemic shock should be guided by the type of trauma (penetrating vs. blunt) and by the setting (urban vs. rural). Regardless of the setting, IVs should be established while en route to the emergency department or trauma center. There should be no delay at the scene to establish IV access.

Management of Hypotension/Shock–Suspected Volume Problem

Perform Primary ABCD Survey (Basic Life Support)

(Correct critical problems IMMEDIATELY as they are identified)

- Assess responsiveness, **A**irway, **B**reathing, **C**irculation, ensure availability of monitor/**D**efibrillator

Perform Secondary ABCD Survey (Advanced Life Support)

- Administer oxygen, establish IV access, attach cardiac monitor, administer fluids as needed (O_2, IV, monitor, fluids)
- Assess vital signs, attach pulse oximeter, and monitor blood pressure
- Obtain and review 12-lead ECG, portable chest x-ray,
- Perform a focused history and physical exam

If rate too slow, use bradycardia algorithm

If rate too fast, use appropriate tachycardia algorithm

FIGURE 22-117, cont'd

TABLE 22-9 Symptoms and Signs of Chronic Heart Failure

RIGHT VENTRICULAR DYSFUNCTION		LEFT VENTRICULAR DYSFUNCTION		NONSPECIFIC FINDINGS	
Symptoms	**Signs**	**Symptoms**	**Signs**	**Symptoms**	**Signs**
Abdominal pain	Peripheral edema	Dyspnea on exertion	Bibasilar crackles	Exercise intolerance	Tachycardia
Anorexia	Jugular venous distention	Paroxysmal nocturnal dyspnea	Pulmonary edema	Fatigue	Pallor
Nausea	Engorged liver	Orthopnea	S_3 gallop	Weakness	Cyanosis of digits
Bloating	Engorged spleen	Tachypnea	Pleural effusion	Nocturia	Cardiomegaly
Constipation	—	Cough	Chest pain	Central nervous system symptoms	Agitation
Ascites	—	Hemoptysis	Diaphoresis		

However, if right ventricular failure is associated with pulmonary edema or hypotension, it may be a medical emergency. The paramedic should be prepared to manage the patient for either of these situations. Patient management for right ventricular failure includes the following:

1. Placing the patient at rest in a sitting or semi-Fowler position (head elevated)
2. Administering high-concentration oxygen
3. Obtaining baseline vital signs and an ECG tracing
4. Initiating an IV line to keep the vein open or to manage hypotension
5. Monitoring the ECG and oxygen saturation
6. Managing symptoms of left ventricular failure if present

NOTE

Hypotension caused by right ventricular failure (often seen in right ventricular infarction) can mimic cardiogenic shock. In this case, fluid administration helps normalize left ventricular filling. Administration of fluids is crucial and helps restore a normal blood pressure. (This is just the opposite of the hypotension associated with cardiogenic shock, in which administration of fluids worsens the condition.) Management may include 250 mL IV boluses of normal saline over 5 to 10 minutes. This helps increase myocardial strength (Starling's law). Fluid administration also improves contractility. Close observation of the patient and the vital signs is crucial.

Cardiogenic Shock

Cardiogenic shock is the most extreme form of pump failure. It occurs when left ventricular function is so compromised that the heart cannot meet the metabolic needs of the body. The result is a significant decrease in stroke volume (resulting from ineffective myocardial contraction), cardiac output, and blood pressure. All of these result in an inadequate supply of blood to the organs. Cardiogenic shock occurs in 5% to 10% of patients with acute myocardial infarction. It may be the result of acute left- or right-sided heart failure.

By definition, cardiogenic shock is present when shock persists after correction of existing dysrhythmias, volume deficit, or decreased vascular tone. Cardiogenic shock usually is caused by extensive myocardial infarction (often involving more than 40% of the left ventricle) or by diffuse ischemia. Even with aggressive therapy, cardiogenic shock has a mortality rate of 70% or higher.[22]

In addition to the signs and symptoms of myocardial infarction, patients in cardiogenic shock show clinical evidence of hypoperfusion to vital organs and significant systemic hypotension similar to that found in other forms of shock. (This makes it difficult to determine the exact cause of shock.) This evidence includes the following:

- Acidosis
- Altered level of consciousness
- Cool, clammy, cyanotic, or ashen skin
- Hypoxemia
- Profound hypotension (systolic blood pressure usually less than 80 mm Hg)
- Pulmonary congestion (crackles)
- Sinus tachycardia or other dysrhythmias
- Tachypnea

In the early stages of cardiogenic shock, the patient's heart tries to compensate. The heart rate increases. If possible, the heart also increases contractility and cardiac output. If the condition is managed inadequately, the heart progresses toward hypodynamic failure with depressed contractility, reduced stroke volume, and subsequent hypoperfusion (see Chapter 37).

MANAGEMENT

Patients in cardiogenic shock are ill (see Figure 22-117). These patients need rapid transport to a medical facility. Transport should not be delayed by attempting field treatment. Prehospital care should include airway management and ventilatory support with high-concentration oxygen, placement of the patient in a supine position (or semi-Fowler position, if the patient is dyspneic), insertion of an IV line with normal saline or lactated Ringer solution to keep the vein open, ECG monitoring, correction of dysrhythmias, and frequent evaluation of vital signs (including auscultation of the lungs and observation for jugular venous distention). A patient in respiratory failure may require intubation and ventilatory support.

CRITICAL THINKING

You have an unstable patient with signs and symptoms indicating cardiogenic shock. How should you respond when the patient asks, "Am I going to die?"

Drug therapy may include drugs that strengthen the force of contraction (inotropic agents) to improve cardiac output. Such agents include ***dopamine*** or ***dobutamine.*** The use of vasodilator drugs to reduce afterload generally is reserved for in-hospital coronary care. In such settings, the blood pressure can be evaluated more accurately. If left-sided heart failure and pulmonary edema also are present, they should be treated at the same time.

CRITICAL THINKING

What dose of each of these drugs should be given for this condition?

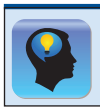
Cardiac Tamponade

Cardiac tamponade (described in Chapter 42) is defined as impaired diastolic filling of the heart caused by increased intrapericardial pressure and volume.[20] As the pressure of the buildup in pericardial fluid compresses the atria and ventricles, they are unable to fill adequately. This results in a decrease in ventricular filling, and stroke volume is decreased. The condition may have a gradual onset. This

may result from a cancerous growth or infection, or the condition may be acute, resulting from trauma to the chest, including cardiopulmonary resuscitation. Cardiac tamponade also may result from renal disease or hypothyroidism. Signs and symptoms of cardiac tamponade include the following:

- Chest pain
- Decreased systolic pressure (a late sign)
- Ectopy
- ECG changes (usually inconclusive)
- Elevated venous pressure (an early sign) with associated jugular vein distention
- Faint or muffled heart sounds
- Shortness of breath
- Low-voltage QRS complexes and T waves
- Alternating amplitude and vector of P waves, QRS complexes, and T waves *(electrical alternans)*
- Pulsus paradoxus
- ST-segment elevation or nonspecific T-wave changes
- Tachycardia

As described in Chapter 42, the most important reliable signs of cardiac tamponade are elevated venous pressure, hypotension, and distant heart sounds (Beck's triad).

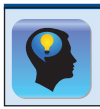


CRITICAL THINKING

Why would fluid resuscitation with large amounts of fluid not be indicated in this situation?

MANAGEMENT

First, the paramedic must obtain a thorough history to attempt to identify the cause of the cardiac tamponade. Then the paramedic should perform a physical examination. Prehospital care is directed at ensuring an adequate airway and ventilatory support and providing rapid transport for evaluation by a physician and possible drainage of the pericardial sac (pericardiocentesis). A fluid bolus may help support the circulatory system temporarily if the patient becomes hypotensive. However, definitive management requires drainage of the pericardial sac. Cardiac tamponade may result in death if the condition is not relieved.



CRITICAL THINKING

Why is drainage of the pericardial sac not done routinely in the prehospital setting?

Thoracic and Abdominal Aortic Aneurysms

Aneurysm is a nonspecific term that means "dilation of a vessel." An aneurysm may result from atherosclerotic disease (most common), infectious disease (primarily syphilis), traumatic injury, or certain genetic disorders (e.g., Marfan syndrome). Figure 22-118 shows the branches of the aorta. Abdominal aortic aneurysm and dissecting aneurysm of the aorta are presented here.

Most aneurysms develop at a weak point in the wall of an artery. This weak point results from degenerative changes in the medial layer. Weakening of the supportive elements of the vessel wall allows dilation. This causes turbulence and increasing lateral pressure. The aneurysm tends to enlarge over time as the lateral pressure increases in the dilated segment. Eventually the aneurysm may rupture. This, in turn, may produce life-threatening hemorrhage.

ABDOMINAL AORTIC ANEURYSM

Abdominal aortic aneurysm affects about 2% of the population.[22] The most common site for an abdominal aortic aneurysm is below the renal arteries and above the branching of the common iliac arteries. Abdominal aortic aneurysms are 10 times more common in men. They also are most prevalent between the ages of 60 and 70 years. An abdominal aneurysm usually is asymptomatic as long as it is stable. However, if the aneurysm begins to expand or leak, symptoms indicate impending rupture (Box 22-20).

Rupture of an abdominal aortic aneurysm may begin with a small tear in the intima. This small tear allows blood to leak into the wall of the aorta. As the process continues with increasing pressure, the tear may extend through the outer layer of the vessel. The tear then may cause bleeding into the retroperitoneal space. If bleeding is tamponaded by the retroperitoneal tissues, the patient may be normotensive on the arrival of emergency medical services. If the rupture opens into the peritoneal cavity, however, massive fatal hemorrhage may follow. In either case, major blood loss results, and hypovolemic shock ensues.

Often a patient with a rupturing aneurysm has syncope followed by hypotension with bradycardia despite the loss of a large amount of blood. The reason for bradycardia is stimulation of the vagus nerve. Fibers of the vagus nerve wrap around the aorta. When the aorta tears, the tear stretches these fibers, causing bradycardia. The bradycardia is present despite the hemorrhagic shock condition, which usually causes hypotension and tachycardia in the patient.

Management. Patients with a leaking or ruptured abdominal aneurysm appear ill. They usually need immediate surgery to repair the vessel. In 20% of patients with a leaking abdominal aortic aneurysm, the aneurysm ruptures before the patient reaches the hospital, and 80% of these patients die.[23] Therefore early recognition and rapid transport can prevent the death of these patients.

In most cases prehospital care should be limited to gentle handling, oxygen administration, cardiac monitoring (myocardial infarctions may be associated with advanced aneurysms), initiation of volume-expanding IV fluids en route to the receiving hospital, and alerting the receiving facility to prepare for imminent surgery.

Pulsatile masses (if present) are fragile and in most cases are membrane thin. The paramedic should avoid aggressive examination or deep palpation of the mass. Palpation may cause the mass to rupture. Examination, if needed, can be

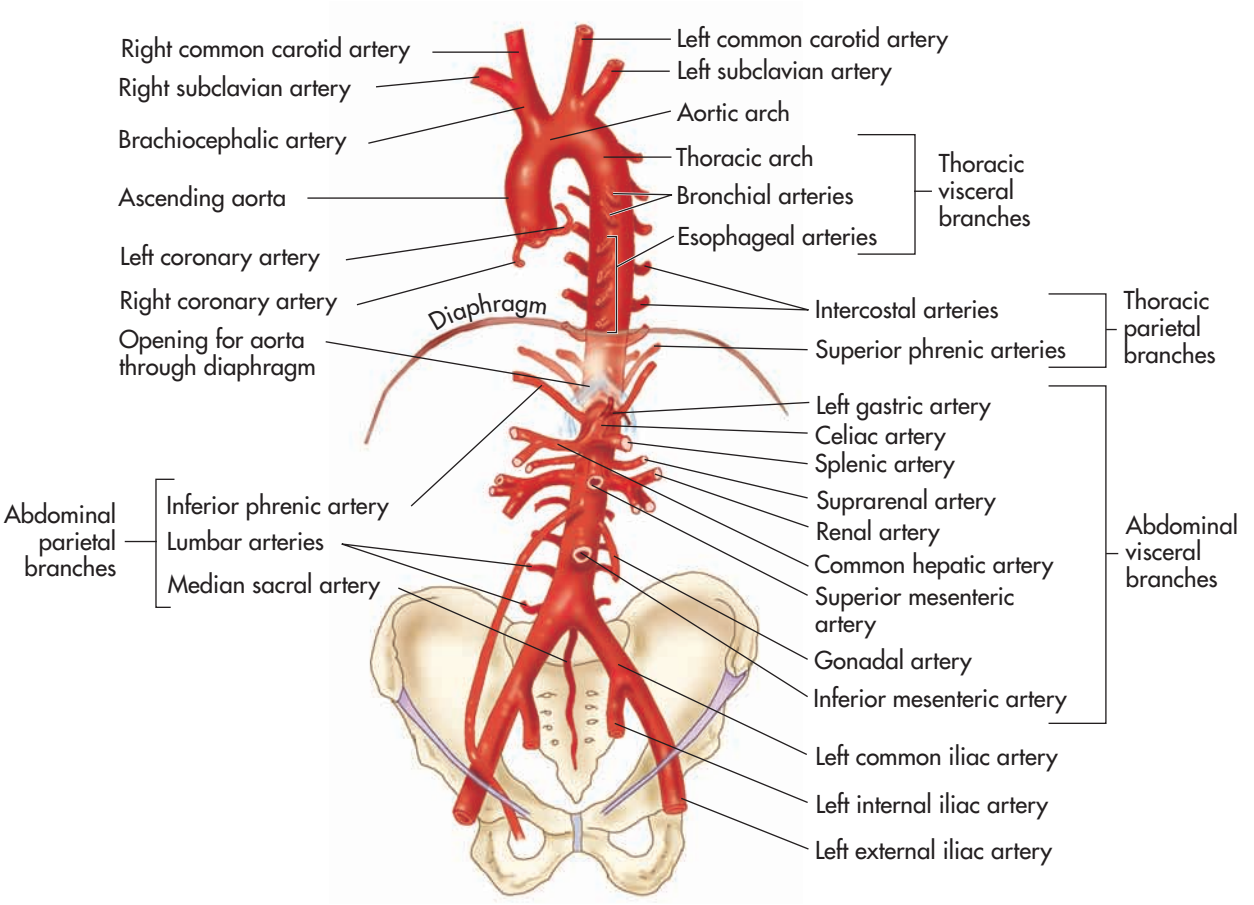


FIGURE 22-118 Branches of the aorta. Aortic arch, thoracic aorta, abdominal aorta, and their branches.

BOX 22-20 Signs and Symptoms of a Leaking or Ruptured Abdominal Aortic Aneurysm

- Unexplained hypotension (resulting from hemorrhage or a compensatory vasovagal response mechanism)
- Unexplained syncope (as the aneurysm ruptures, blood pressure drops transiently to zero, producing sudden cerebral hypoperfusion and syncope)
- Sudden onset of abdominal or back pain (described as "tearing" or "ripping") from the physical trauma itself or from inflammation
- Low back or flank pain (radiating to the thigh, groin, testicle, or perineum) that is unrelieved by rest or changes in position
- Signs of peritoneal irritation
- Urge to defecate (caused by retroperitoneal leakage of blood)
- Pulsatile, tender mass (may be palpated when greater than 5 cm), usually located above the umbilicus, left of the midline
- Presence or absence of distal pulses (femoral artery and below), depending on the patient's blood pressure, the occurrence of a dissection, and the degree of peripheral vascular disease
- Possible presentation as bleeding in the gastrointestinal tract if the aneurysm erodes into it

made by auscultation. This may reveal a sound similar to that of a systolic murmur or bruit.

The management of hypotension varies and depends on whether the aneurysm is leaking or ruptured. A patient suspected of having a leaking aneurysm can be maintained with mildly hypotensive blood pressure to try to prevent rupture during transport. (The hypotension associated with small leaks is thought to result from a compensatory vasovagal mechanism.) In these patients, fluid resuscitation should be minimal and less aggressive than in patients who have a ruptured aneurysm.

If rupture has occurred, hypotension, tachycardia, and loss of the pulsating mass may develop suddenly. The patient also may become unresponsive. This often is followed by full cardiac and respiratory arrest. These patients require rapid and aggressive resuscitation (intubation, ventilation, fluid replacement) and rapid transport for surgery.

ACUTE DISSECTING AORTIC ANEURYSM

Acute dissecting aortic aneurysm (separation of the arterial wall) is the most common aortic catastrophe. It affects 5 to 10 people per 1 million population each year (three times as many as a ruptured abdominal aortic aneurysm).[24] Factors that can lead to the development of dissecting aneurysm are systemic hypertension, atherosclerosis, congenital abnormalities that affect connective tissue *(Marfan*

syndrome), degenerative changes in the connective tissue of the aortic media *(cystic medial necrosis),* trauma, and pregnancy. The syndrome affects men twice as often as women. It also is more common in African Americans.

A dissecting aneurysm of the aorta results from a small tear in the intimal layer of the vessel wall (Figure 22-119). After the tear, the process of dissection begins. The tear in the inner wall allows blood to move between the inner and outer layers. This creates a false passage between the layers of the vessel wall. Blood that enters the false passage results in the formation of a hematoma. As a result, this can rupture through the outer wall (adventitia) at any time, usually into the pericardial or pleural cavity.

Any area of the aorta may be involved. However, in most cases the dissecting aneurysm occurs in the ascending aorta. Once begun, the aneurysm may extend distally or proximally to involve all of the thoracic and abdominal aorta and tributaries, the coronary arteries, the aortic valve, and the carotid and subclavian vessels. Blood flow is reduced in any vessels bypassed by the dissection, including the carotid and other aortic arch vessels. As a result, aortic dissection may cause the following:

- Syncope
- Stroke
- Absent or reduced pulses
- Unequal blood pressure readings (right side compared to left side)
- Heart failure resulting from sudden aortic valve regurgitation
- Pericardial tamponade
- Acute myocardial infarction

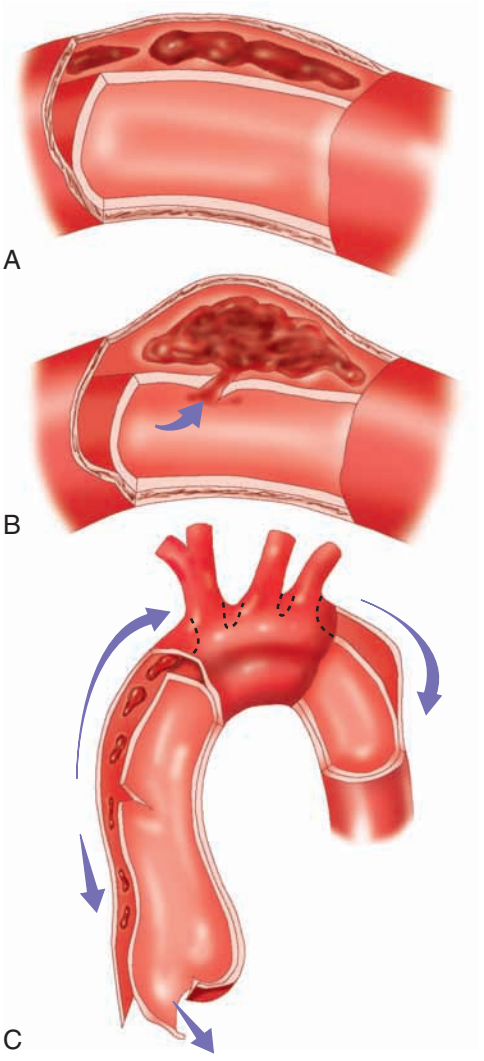

FIGURE 22-119 Pathogenesis of a dissecting aneurysm. **A,** Medial and intimal degeneration of the aortic wall sets the stage. **B,** Hemodynamic forces acting on the aortic wall produce an intimal tear, directing the bloodstream into the middle layer of the wall of the aorta. **C,** The resulting dissecting hematoma is propagated in both directions by a pulse wave produced by each myocardial contraction.

Signs and Symptoms. The signs and symptoms of a dissecting aortic aneurysm depend on the site of the intimal tear (ascending or descending aorta). They also depend on the extent of dissection. More than 70% of patients with acute dissecting aneurysm of the aorta complain of severe pain in the back, epigastrium, abdomen, or extremities. They often describe this pain as the most intense pain they have ever experienced. The pain usually is sudden in onset. It may be characterized by the patient as "ripping," "tearing," or "sharp and cutting, like a knife." Pain often originates in the back (between the scapulae). The pain possibly extends down into the legs. A patient with acute dissection may appear "shocky" and have pallor, sweating, and peripheral cyanosis (from impaired perfusion), even when the blood pressure is normal or elevated. If the patient is hypotensive, the paramedic should suspect cardiac tamponade or aortic rupture.

CRITICAL THINKING

What condition has signs and symptoms similar to those of an abdominal aortic aneurysm?

Differentiating the pain of aortic dissection from that of myocardial infarction or pulmonary embolism can be difficult in the prehospital setting. The following distinctive features may help:

1. The severity of the pain is maximal from the onset (compared with the crescendo pain characteristic of acute myocardial infarction).
2. The pain may migrate from the anterior portion of the chest or interscapular area downward as dissection progresses.
3. Significant differences in blood pressure occur between the left and right arm or between the arms and the legs.
4. The peripheral pulses are unequal.
5. Neurological deficits result from occlusion of a cerebral vessel.

NOTE
Blood pressure may differ significantly in the two arms if the dissection occludes either subclavian artery, leading to a decreased blood pressure in the affected upper extremity.

Management. The goals of managing suspected aortic dissection in the prehospital setting are relieving pain and rapid transport to a medical facility. (Transport should not be delayed; analgesics should be administered en route to the hospital.) The EMS crew should be ready to initiate intubation. They also should be ready to assist ventilation in case the patient begins to decompensate. Other prehospital care measures include the following:

- Handling the patient gently
- Reducing anxiety
- Administering high-concentration oxygen
- Beginning a large-bore IV line of crystalloid solution (fluids should be kept to a minimum unless severe hypotension is present)
- Giving analgesia (e.g., ***morphine*** or ***fentanyl***) per medical direction if the diagnosis is strongly suspected

Definitive in-hospital care generally includes reducing the myocardial contractile force to stop progressive dissection (with antihypertensives and beta blockers), monitoring of intraarterial pressure, and possibly surgical repair.

Acute Arterial Occlusion

Acute arterial occlusion is a sudden blockage of arterial flow. It most commonly is caused by trauma, embolus, or thrombosis. The severity of the ischemic episode depends on the site of occlusion and the extent of collateral circulation around the blockage. Vascular occlusion caused by thrombosis is a complication of atherosclerosis. Occlusions caused by emboli may indicate an abnormal cardiac rhythm, particularly atrial fibrillation.

CRITICAL THINKING
Why does atrial fibrillation put the patient at increased risk for emboli?

Arterial occlusion may follow blunt or penetrating trauma; it often is associated with long-bone fractures. These injuries vary from injuries to the lining of a vessel to complete severing of a vessel. The occlusion usually is evident because no signs of circulation are seen in the tissue or limb.

An embolism occurs when a blood clot breaks away and enters the arterial system. The clot travels until it reaches a narrow point in a vessel. This often is at a branching site of an artery. Ninety percent of peripheral emboli originate in the heart. Therefore, a history of cardiac disease (e.g., dysrhythmia, myocardial infarction, or valvular heart disease) favors a diagnosis of embolic occlusion, particularly if the patient has an asymptomatic opposite extremity with normal pulses. The most common sites of embolic occlusion are the abdominal aorta, common femoral artery, popliteal artery, carotid artery, brachial artery, and mesenteric artery (Figure 22-120).

Thrombosis usually results from atherosclerotic disease and usually occurs at a site of severe narrowing of a vessel. Unlike an embolus, a thrombus usually develops over time. As the thrombus enlarges, the collateral blood supply also can become occluded, causing progressive ischemia. The location of the ischemic pain often is related to the site of occlusion:

- Terminal portion of the abdominal aorta: Pain in both hips or lower limbs
- Iliac artery: Pain in the buttocks or hip on the involved side
- Femoral artery: Claudication (cramplike pain) in the calf of the involved leg
- Mesenteric artery: Severe abdominal pain

If severe ischemia persists, muscle necrosis occurs. Thrombotic occlusion is seen most often in men, smokers, and those over 60 years of age. Common sites of atherosclerotic (thrombotic) occlusion are depicted in Figure 22-121.

SIGNS AND SYMPTOMS

Regardless of the origin of the occlusion, the signs and symptoms of ischemia are the same and include the following:

- Pain in the extremity that may be severe and sudden in onset or absent as a result of paresthesia
- Pallor (the skin also may be mottled or cyanotic)
- Lowered skin temperature distal to the occlusion
- Changes in sensory and motor function
- Diminished or absent pulse distal to the injury
- Bruit over the affected vessel
- Slow capillary filling
- Sometimes shock (particularly with mesenteric occlusion)

NOTE
Some patients with vascular occlusion have unequal blood pressure readings in the arms. Systolic readings in the arms that differ by 15 mm Hg or more suggest vascular disease. (Normally, the difference between the arms is 5 to 10 mm Hg.)

MANAGEMENT

Acute arterial occlusion in an extremity is serious and painful. The occlusion may be limb-threatening if blood flow is not reestablished within 4 to 8 hours. The affected limb should be immobilized and protected. In addition, the patient should be transported for evaluation by a physician. Patients with mesenteric occlusion should be managed for

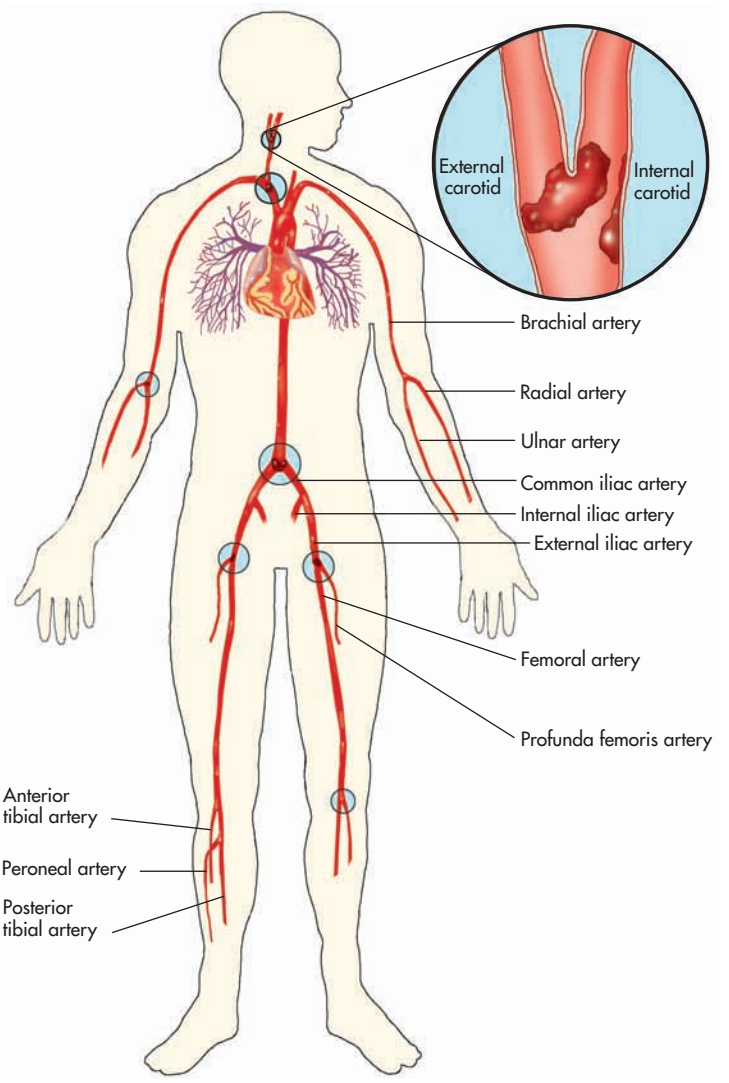

FIGURE 22-120 Common sites of embolic arterial occlusion.

shock with oxygen and IV fluids. Analgesics also may be prescribed by medical direction to relieve pain. In-hospital, definitive care may include anticoagulant or fibrinolytic therapy, transluminal arterial dilation using a balloon catheter, embolectomy, or vascular reconstruction.

Noncritical Peripheral Vascular Conditions

Noncritical peripheral vascular conditions include varicose veins, superficial thrombophlebitis (described in Chapter 11), and acute deep vein thrombosis. Of these conditions, deep vein thrombosis is the only one that can cause life-threatening pulmonary embolus. Predisposing factors to venous thrombosis include the following:

- Birth control pills
- Coagulopathies
- History of trauma
- Malignancy
- Obesity
- Pregnancy
- Recent immobilization (e.g., leg fracture)
- Sepsis
- Smoking
- Stasis or inactivity (e.g., bedridden patient or long air flights)
- Varicose veins (usually a benign condition)

ACUTE DEEP VEIN THROMBOSIS

Acute deep vein thrombosis (DVT) is a serious, common problem. Occlusion may involve any portion of the deep venous system. However, occlusion is much more common in the lower extremities. Risk factors for deep vein thrombosis include recent lower extremity trauma, recent surgery, advanced age, recent myocardial infarction, inactivity, confinement to bed, congestive heart failure, cancer, previous thrombosis, oral contraceptive therapy, sickle cell disease, and obesity. Signs and symptoms of acute deep vein thrombosis include the following:

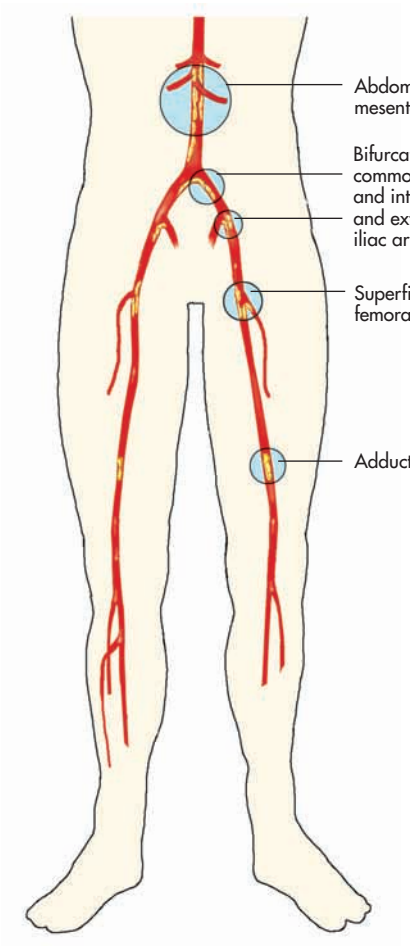

FIGURE 22-121 Common sites of atherosclerotic occlusive disease.

- Pain
- Edema
- Warmth
- Erythema or bluish discoloration
- Tenderness

MANAGEMENT

Patients with acute deep vein thrombosis require hospitalization. Prehospital care usually is limited to immobilization and elevation of the extremity and transport for evaluation by a physician. Deep vein thrombosis in the calf of the leg usually is much less serious than deep vein thrombosis of the thigh. The latter has a higher incidence of associated pulmonary embolus. Definitive care includes bed rest, administration of anticoagulants or, occasionally, fibrinolytic agents, and in rare cases, thrombectomy.

Hypertension

Hypertension is a common disorder. It afflicts about 23% of the U.S. population and is directly responsible for about 23,000 deaths a year.[25] Hypertension often is defined by a resting blood pressure consistently greater than 140/90 mm Hg (stage 1 hypertension).[26] The several categories of hypertension are based on the level of blood pressure, symptomatology, and urgency of need for intervention (Table 22-10 and Box 22-21). For the purpose of this textbook, two general categories are presented: chronic hypertension and hypertensive emergencies. (These emergencies include **hypertensive encephalopathy**.) A common cause of hypertension is discontinuing medication or other therapy prescribed by the physician.

TABLE 22-10 Blood Pressure Categories for Adults (18 Years or Older)*

	BLOOD PRESSURE (mm Hg)		
Category	**Systolic**		**Diastolic**
Normal	<120	and	<80
Prehypertension	120-139	or	80-89
Hypertension			
Stage 1	140-159	or	90-99
Stage 2	>160		>100

*For those not taking medicine for high blood pressure and not having a short-term serious illness.
From National High Blood Pressure Education Program, JNC 7 Express, The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, U.S. Department of Health and Human Services, National Institutes of Health, National Heart, Lung and Blood Institute, NIH Publication No. 03-5233, December 2003.

BOX 22-21 Signs and Symptoms of Hypertensive Emergencies

- Altered mental status
- Changes in visual acuity
- ECG changes
- Epistaxis
- Headache
- Nausea and vomiting
- Paroxysmal nocturnal dyspnea
- Seizures
- Shortness of breath
- Tinnitus
- Vertigo

CRITICAL THINKING
Why do patients fail to take medicines prescribed for hypertension?

CHRONIC HYPERTENSION

Chronic hypertension has an adverse effect on the function of the heart and blood vessels. It requires the heart to perform more work than normal. This leads to hypertrophy of the

cardiac muscle and left ventricular failure. Chronic hypertension increases the rate at which atherosclerosis develops. This in turn increases the probability of cardiovascular, cerebrovascular, and peripheral vascular disease and the risk of aneurysm formation. Along with congestive heart failure (CHF), conditions commonly associated with chronic, uncontrolled hypertension are cerebral hemorrhage and stroke, myocardial infarction, renal failure (caused by vascular changes in the kidney), and development of thoracic or abdominal aortic aneurysm.

Many people with established hypertension have elevated peripheral resistance and elevated cardiac output (a function of Starling's law), the result of an increase in the heart rate and stroke volume.[22] The heart responds to the increased workload that results from high peripheral resistance by becoming enlarged. An enlarged heart may be able to work fine for many years. In time, though, it is no longer able to maintain adequate blood flow. The patient then develops symptoms of pump failure.

Any hypertension-related illness, such as pulmonary edema, dissecting aortic aneurysm, toxemia of pregnancy (described in Chapter 46), or stroke, requires stabilization and prompt, appropriate management. The hypertension associated with these situations often is a result of a primary problem. Managing the primary problem (e.g., toxemia) often makes controlling the patient's blood pressure easier. However, the primary cause may not be easily correctable. In situations such as dissecting aortic aneurysm, controlling the blood pressure also is a key to managing the primary problem. A life-threatening condition that develops from unmanaged or partially managed hypertension may lead to a hypertensive emergency.

HYPERTENSIVE EMERGENCIES

Hypertensive emergencies are conditions in which an increase in blood pressure leads to significant, irreversible damage to organs. This damage can occur within hours if the hypertension is not treated. The organs most likely to be at risk are the brain, heart, and kidneys. This now uncommon condition is experienced by 1% of all hypertensive patients whose illness is poorly controlled or unmanaged. As a rule, the diagnosis is based on loss of organ function. The diagnosis also is based on the rate of the rise in blood pressure, not the level of blood pressure (although the diastolic blood pressure usually is greater than 100 mm Hg). All hypertensive emergencies (except hypertension in ischemic stroke) require a 5% to 20% reduction in blood pressure within a few hours of discovery to prevent permanent organ damage. In hypertensive emergencies, blood pressure readings ranging from 220/120 mm Hg to 240/140 mm Hg are not uncommon.

Hypertensive emergencies include the following clinical conditions: (1) myocardial ischemia with hypertension, (2) aortic dissection with hypertension, (3) pulmonary edema with hypertension, (4) hypertensive intracranial hemorrhage, (5) toxemia, and (6) hypertensive encephalopathy. Hypertension per se may not be the cause of the first five conditions. However, they all can be worsened by untreated hypertension. Hypertensive encephalopathy results solely from elevated blood pressure and a concurrently elevated intracranial pressure.

Persistent hypertension causes brain damage (hypertensive encephalopathy). It results in a decrease in blood and oxygen to the brain (cerebral hypoperfusion). It also damages the tissues that make up the blood-brain barrier. This results in fluid exudation into the brain tissue. Hypertensive encephalopathy may progress over several hours from initial symptoms of severe headache, nausea, vomiting, aphasia, and transient blindness to seizures, stupor, coma, and death. The condition is a true emergency. It requires immediate transport to a medical facility for definitive care. The goal of therapy is controlled but rapid lowering of the blood pressure to normalize cerebral blood flow. If the blood pressure is lowered too quickly, infarction of end organs (heart, kidney, brain) may occur.

NOTE

Lateralizing neurologic signs, such as hemiparesis or hemiplegia, are uncommon in hypertensive emergencies. Their presence is suggestive of stroke.[27]

CRITICAL THINKING

How does fluid leakage into the brain affect the intracranial pressure and cerebral perfusion pressure?

Prehospital management of patients with a hypertensive emergency includes the following:

- Supportive care
- Calming the patient
- Oxygen therapy
- IV line to keep the vein open
- ECG monitoring
- Rapid transport

In most cases, drug therapy for hypertensive emergencies is not initiated in the prehospital setting. However, in severe cases of hypertensive encephalopathy or if transport is delayed, medical direction may recommend the administration of antihypertensives such as ***nitroglycerin*** or ***labetalol***. These drugs induce arteriolar vasodilation and may lower the blood pressure.

SPECIFIC HEART DISEASES

In addition to atherosclerosis that results in coronary artery disease, numerous other diseases affect the heart. These include valvular heart disease, infectious heart disease, and congenital heart disease (see Chapter 47).

Valvular Heart Disease

Valvular heart disease refers to any disease process that affects one or more valves of the heart: the mitral, aortic, tricuspid, or pulmonary valves. To review, the mitral and

tricuspid valves control the flow of blood between the atria and the ventricles (the upper and lower chambers of the heart). The pulmonary valve controls the flow of blood from the heart to the lungs, and the aortic valve governs blood flow between the heart and the aorta and thereby the blood vessels to the rest of the body. (The mitral and aortic valves are the valves most frequently affected by valvular heart disease.) When one or more of these valves become narrowed, hardened, or thickened (stenotic), the valves do not open or close completely. As a result, blood does not flow with proper force or direction. A stenotic valve forces blood back up into the adjacent chamber of the heart. A valve that is unable to close properly allows blood to "leak" back (regurgitate) into the previous chamber (Figure 22-122). The defects in the pumping action of the valves can cause the heart to enlarge and thicken. This can result in a loss of elasticity and an increased risk of pulmonary embolism or stroke.

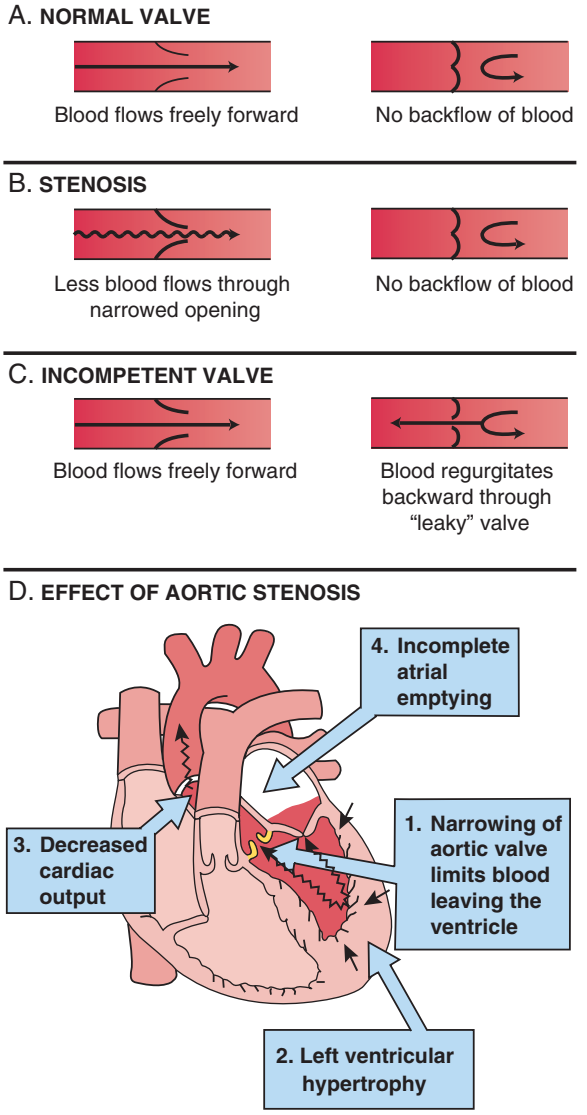

FIGURE 22-122 Effects of heart valve defects. (Gould BE, Dyer R: *Pathophysiology for health professions,* ed 4, St Louis, 2010, Saunders.)

NOTE
Valve leaflets normally are very thin and flexible. However, they can become thickened, rigid, or dysfunctional in response to a disease process, such as coronary artery disease or cardiac hypertrophy. Stenosis often is accompanied by calcification and atherosclerosis-type lesions (valvular lesion).

Valvular heart disease can be congenital (described later in this chapter). It also can develop slowly, or it may be acute. Depending on the course of the disease, signs and symptoms may be similar to those seen in congestive heart failure. These may include palpitations with or without chest pain, fatigue, dizziness or syncope, and weight gain. If the cause of the valvular heart disease is a bacterial infection (e.g., endocarditis, described later), fever may be present. After evaluation by a physician, treatment may include antibiotics to manage infection, anticoagulants to prevent clot formation, balloon dilation to widen a stenotic valve, clip insertion (MitraClip, not yet approved in the United States), and sometimes surgical valve replacement. Prehospital care is primarily supportive and may include oxygen administration, ECG monitoring, IV fluids, and transport for evaluation by a physician.

Infectious Heart Disease

Infectious heart disease is caused by intravascular contamination by pathogens. The infections can damage the muscles and valves of the heart. Infections also may lead to the formation of emboli, which can travel to the brain, kidneys, lungs, or abdomen. Three common forms of infectious heart disease are endocarditis, pericarditis, and myocarditis. Most patients with infectious heart disease also have underlying heart disease or problems with the heart valves. Prehospital care for infectious heart disease is primarily supportive.

NOTE
Rheumatic fever can lead to inflammation of the heart (carditis) and damage to the heart valves (rheumatic heart disease). Rheumatic fever follows infection by group A *Streptococcus* (GAS) bacteria, such as strep throat or scarlet fever. Proper diagnosis and adequate antibiotic treatment of GAS infections can prevent acute rheumatic fever in most cases. Most patients with a GAS infection respond well to antibiotic therapy.[28]

ENDOCARDITIS

Endocarditis is an infection of the endocardium (inner layer of the heart). Endocarditis usually results from a bacterium that enters the bloodstream (bacterial or infective

endocarditis). Risk factors for developing endocarditis include injection drug use, permanent central venous access lines, previous valve surgery, recent dental surgery, and weakened heart valves. Patients with a history of valvular heart disease or rheumatic fever also are at higher risk for endocarditis. Complications of the disease include atrial fibrillation, blood clots, brain abscess, CNS changes, congestive heart failure, glomerulonephritis, jaundice, severe heart valve damage, and stroke.

NOTE

Streptococcus viridans, a bacterium commonly found in the mouth, is responsible for about 50% of all cases of bacterial endocarditis.[29] For this reason, prophylactic antibiotics often are prescribed for high-risk patients undergoing dental procedures or surgery involving the respiratory, urinary, or intestinal tract.

Endocarditis may develop slowly or may be sudden in onset. Signs and symptoms include:

- Abnormal urine color
- Chills (common)
- Excessive sweating (common)
- Fatigue
- Fever (common)
- Joint pain
- Muscle aches and pains
- Night sweats
- Nail abnormalities (splinter hemorrhages under the nails)
- Paleness
- Red, painless skin spots on the palms and soles *(Janeway lesions)*
- Red, painful nodes in the pads of the fingers and toes *(Osler's nodes)*
- Shortness of breath with activity
- Swelling of the feet, legs, abdomen
- Weakness
- Weight loss

Treatment consists of blood cultures to identify the bacterium causing the disease, short-term IV antibiotics, and several weeks of oral antibiotic therapy. Valve replacement surgery may be indicated in some cases.

PERICARDITIS

Pericarditis is inflammation of the pericardium (the fibrous sac surrounding the heart). It usually is a complication of viral infection, most commonly echovirus, adenovirus, or Coxsackie virus. Less frequently, it is caused by the influenza virus or infection with the human immunodeficiency virus (HIV). Pericarditis is most common in men 20 to 50 years of age and in children after a respiratory infection. Pericarditis can be associated with diseases such as autoimmune disorders, cancer (including leukemia), acquired immunodeficiency syndrome (AIDS), hypothyroidism, kidney failure, rheumatic fever, and tuberculosis. Although the cause of the pericarditis often is unknown *(idiopathic pericarditis),* possible causes include myocardial infarction *(post-MI pericarditis);* injury, including surgery or trauma to the chest, esophagus, or heart; medications that suppress the immune system; myocarditis; and radiation therapy to the chest.[30] Signs and symptoms include the following:

- Swelling of the ankles, feet, and legs (occasionally)
- Anxiety
- Difficulty breathing when lying down
  - Crackles
  - Decreased breath sounds
- Chest pain caused by the inflamed pericardium rubbing against the heart
  - May radiate to the neck, shoulder, back, or abdomen
  - Often increases with deep breathing and lying flat; may increase with coughing and swallowing
  - Pleuritic chest pain (often relieved by sitting up and leaning forward)
- Pericardial friction rub
- Dry cough
- Fatigue
- Fever
- 12-lead ECG changes
  - Diffuse ST elevation
  - PR segment depression
  - Notched J point

NOTE

These 12-lead ECG changes are one of the "MI imposters." Pericarditis often can be distinguished from AMI in the prehospital setting by obtaining a good patient history and by noting ST elevation in all leads.[31]

Pericarditis is assessed with diagnostic imaging (chest radiograph, magnetic resonance imaging [MRI], computed tomography [CT]), blood and fluid cultures, and other laboratory tests. An ECG and echocardiogram also may be useful for ruling out mycoardial infarction and enlargement of the heart. Pericarditis is managed with analgesics, antibiotics, nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, and diuretics. With decreased cardiac function or cardiac tamponade, pericardiocentesis may be needed. Most patients recover completely within 2 to 3 months. However, the condition may recur.

MYOCARDITIS

Myocarditis is inflammation of the heart muscle. It is an uncommon disorder caused by a viral, bacterial, or fungal infection that reaches the heart. (Myocarditis also can be caused by chemical exposure, allergic reactions, or an inflammatory disease, such as rheumatoid arthritis or sarcoidosis.) The immune response associated with

myocarditis can damage the heart muscle. This can cause the heart to become thick, swollen, and weak, leading to symptoms of heart failure. Some patients with myocarditis are asymptomatic. In other patients, signs and symptoms that may occur with the disease include the following:

- Abnormal heartbeat, sometimes leading to syncope
- Chest pain that may be severe
- Fever and other signs of infection (headache, muscle aches, sore throat, diarrhea, rashes)
- Joint pain or swelling
- Leg swelling
- Shortness of breath
- Decreased urine output

Myocarditis is diagnosed and managed similarly to pericarditis (described previously). If the heart muscle has been damaged, the patient may need to be treated for heart failure. Dysrhythmias may need to be managed with antidysrhythmics and insertion of a pacemaker or an implantable cardioverter-defibrillator. If a blood clot has formed in the heart chamber, anticoagulants may be prescribed. Depending on the severity of the damage to the heart, the patient may recover completely or may have permanent heart failure.

CARDIOMYOPATHY

Cardiomyopathy is a weakening of the heart muscle or a change in heart muscle structure. It often is associated with inadequate heart pumping or other heart function problems. Common causes of the disease are alcoholism and cocaine use, chemotherapy drugs, pregnancy, genetic defects, amyloidosis, end-stage kidney disease, viral infection, long-term hypertension, nutritional deficiencies, and lupus. Cardiomyopathy can be classified into three main types[32]:

- *Dilated cardiomyopathy* (the most common type) is a condition in which the heart becomes weakened and enlarged. It cannot pump blood efficiently. Many different medical problems can cause this type of cardiomyopathy, including coronary artery disease, rheumatoid arthritis, muscular dystrophy, and HIV infection.
- *Restrictive cardiomyopathy* refers to a group of disorders in which the heart chambers are unable to properly fill with blood because of stiffness of the heart. The most common causes of restrictive cardiomyopathy are **amyloidosis** (deposits of abnormal protein in heart tissue) and scarring of the heart muscle. This type of cardiomyopathy frequently occurs after a heart transplant.
- *Hypertrophic cardiomyopathy (HCM)* is a condition in which parts of the heart muscle become thicker than other parts. This thickening makes it more difficult for blood to leave the heart and forces the heart to work harder to pump blood. This type of cardiomyopathy is inherited. The first symptom of the disease among many young patients is sudden collapse, and possibly death, caused by dysrhythmias.

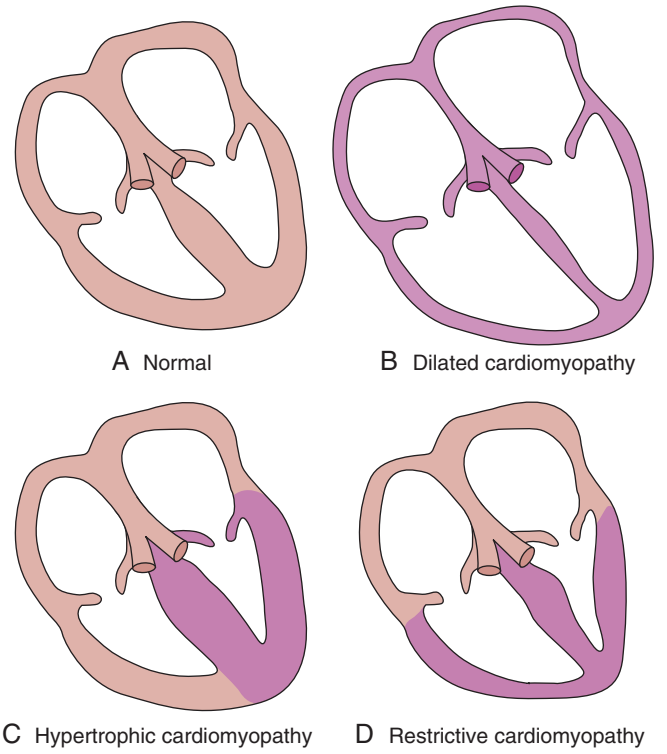

FIGURE 22-123 The three types of cardiomyopathy. **A,** Normal heart. **B,** Dilated cardiomyopathy demonstrating enlargement of all four chambers. **C,** Hypertrophic cardiomyopathy showing a thickened left ventricle. **D,** Restrictive cardiomyopathy characterized by a small left ventricular volume. (Copstead-Kirkhorn LE, Banasik JL: *Pathophysiology,* ed 4, St Louis, 2010, Saunders.)

Hypertrophic cardiomyopathy is a major cause of death in young athletes who seem completely healthy but who die during heavy exercise (Figure 22-123).[33]

Signs and Symptoms

Some patients with cardiomyopathy have no signs and symptoms in the early stage of the disease. However, as the disease progresses, signs and symptoms usually appear. These may include:

- Breathlessness with exertion or even at rest
- Swelling of the legs, ankles, and feet
- Bloating (distention) of the abdomen with fluid
- Fatigue
- Irregular heartbeats that feel rapid, pounding, or fluttering
- Dizziness, lightheadedness, and fainting

The treatment of cardiomyopathy is based on the patient's age and general health and the specific type and severity of the disease. Drugs often are prescribed to improve heart function and to prevent clot formation and fluid retention. These drugs include vasodilators, digitalis, angiotensin-converting enzyme (ACE) inhibitors, anticoagulants, and diuretics. Dilated cardiomyopathies usually respond well to medication, at least initially. Treatment of some cardiomyopathies that result from viral infections may not be effective. Therapy for those with restrictive

cardiomyopathy may be particularly limited. If end-stage heart failure develops, a heart transplant may be necessary.

SECTION NINE
Techniques for Managing Cardiac Emergencies

This section addresses the various procedures, techniques, and types of equipment used to manage cardiac emergencies. These include basic life support, mechanical cardiopulmonary resuscitation devices, monitor-defibrillators (manual, fully automated, and semiautomated), defibrillation, automatic implantable cardioverter-defibrillators, synchronized cardioversion, and transcutaneous cardiac pacing. This section also offers an overview of the management of a cardiac arrest as it applies to working within an advanced cardiac life support system. The reader is encouraged to review the dysrhythmias and drug therapy presented previously in this text.

BASIC CARDIAC LIFE SUPPORT

Basic cardiac life support (BCLS) provides circulation and respiration for a victim of cardiac arrest until advanced cardiac life support (ACLS) is available. The American Heart Association has stated:

> The highest hospital discharge rate—a measure of resuscitation success—is achieved in patients for whom CPR is initiated within 4 minutes of the time of the arrest and who, in addition, are provided with ACLS management within 8 minutes of their arrest. The victim whose heart and breathing have stopped for less than 4 minutes has an excellent chance for recovery if CPR is administered immediately. After 4 to 6 minutes without circulation, brain damage may occur; after 6 minutes brain damage will almost always occur.[34]

Cardiac arrest most often is associated with cardiovascular disease and is precipitated by ventricular fibrillation or ventricular asystole. Cardiac arrest also may result from noncardiac causes, such as poisoning, drug overdose, toxic inhalation, trauma, and foreign body airway obstruction.

Physiology of Circulation Provided by External Chest Compression

Two mechanisms are thought to be responsible for blood flow during cardiopulmonary resuscitation (CPR). The first is direct compression of the heart between the sternum and the spine. This increases pressure within the ventricles enough to provide blood flow to the lungs and other organs. The second mechanism (which is thought to play a more important role than direct compression of the heart) is the generalized increase in intrathoracic pressure that occurs during CPR. This increase in intrathoracic pressure allows the left heart to act as a conduit for the passage of blood. Other mechanisms not currently known may be involved as well. Artificial circulation generates only about 20% to 30% of the normal output of the heart.[31]

Research has been conducted for many years on ways to improve cardiopulmonary resuscitation. These methods include simultaneous chest compressions and ventilation, abdominal compression with synchronized ventilation, cardiopulmonary resuscitation augmented by pneumatic antishock garments, interposed abdominal compression, continuous abdominal binding, and plunger mechanisms for chest compression that cause active compression and active expansion. However, no alternative method has been shown to improve survival or circulation unequivocally.[1] Figure 22-124 presents the standards of cardiopulmonary resuscitation as recommended by the American Heart Association.

Mechanical Cardiopulmonary Resuscitation Devices

A number of mechanical devices (e.g., vest-type devices, plunger devices) have been designed to produce external chest compressions. Most operate to reduce intrathoracic pressure during decompression of the chest, thereby improving venous return to the heart (Box 22-22). Some devices provide chest compression and synchronized ventilation in the patient with cardiac arrest (Figure 22-125). These devices may help standardize the CPR technique, minimize the need to interrupt chest compressions, eliminate rescuer fatigue, free other rescuers to participate in advanced cardiac life support procedures, and ensure adequate compression during patient transport. In addition, they allow acceptable ECG recordings during compressions and defibrillation without interruption of CPR. There is currently no strong evidence for or against the use of these devices.[1] If used, the devices should be limited to adult patients. The use of mechanical cardiopulmonary resuscitation devices requires special training and authorization from medical direction. EMS personnel should follow the directions supplied with the equipment.

Monitor-Defibrillators

Cardiac monitor-defibrillators are classified as manual or automated external defibrillators. The latter may be semiautomated or fully automated. The paramedic should be familiar with the monitor-defibrillators used in the local EMS system or community settings.

MANUAL MONITOR-DEFIBRILLATORS

Monitor-defibrillators are available from a number of equipment manufacturers in a variety of designs and capabilities. All consist of the following:

- Patch electrodes
- Defibrillator controls
- Synchronizer switch
- Oscilloscope
- Patient cable and lead wires
- Controls for monitoring

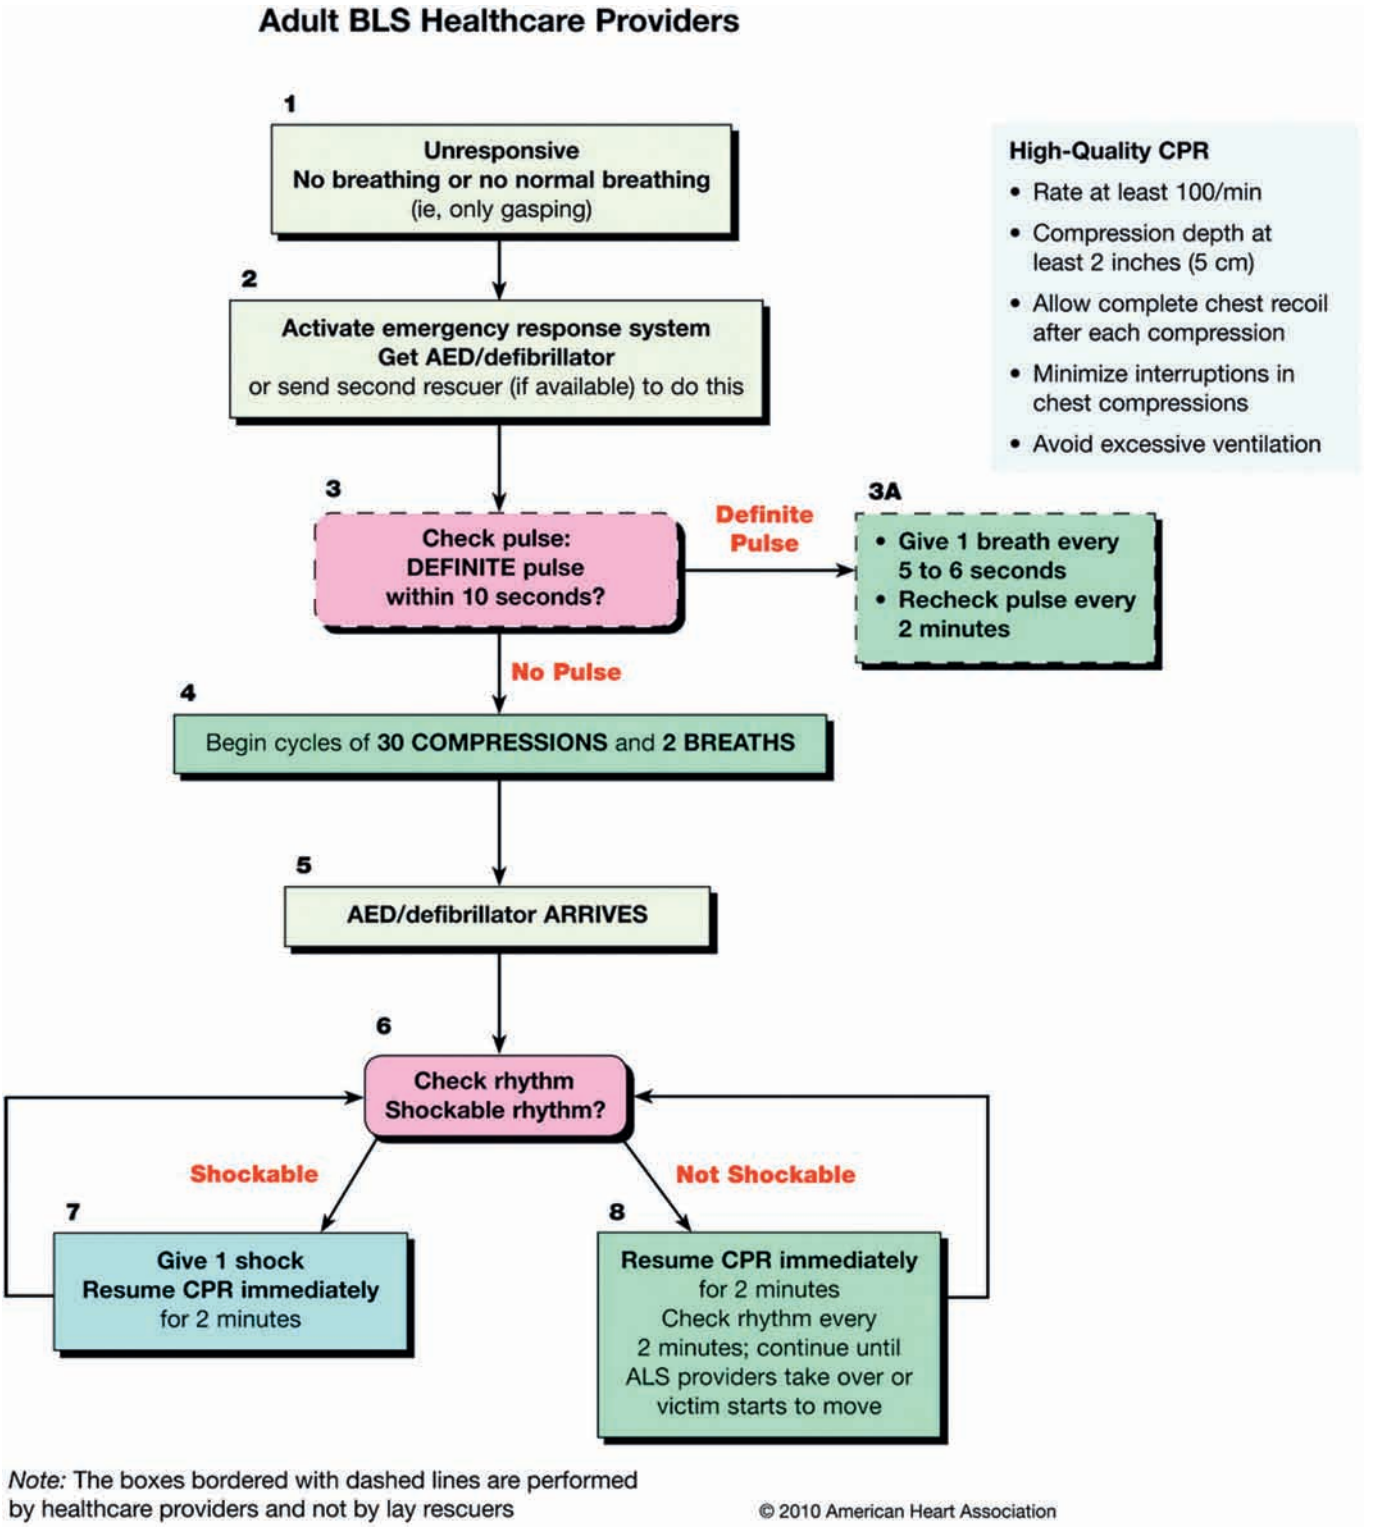

FIGURE 22-124 Health care provider algorithm for adult basic life support. (Reprinted with permission, American Heart Association Guidelines For CPR and ECC, *Circulation 122* [suppl 3]:S685-S919, American Heart Association, Inc, 2010.)

BOX 22-22 Impedance Threshold Device

Impedance threshold devices (ITDs) have a valve that limits the amount of air that enters the chest during the upstroke (recoil) during chest compressions. This enhances negative pressure inside the chest. The net effects of an ITD are:

- Blood flow to the heart is increased.
- Blood flow to the brain is enhanced.
- Systolic blood pressure doubles.
- Survival to the hospital may be increased.
- Chance of successful defibrillation may be increased.

The American Heart Association has classified ITDs as a class IIb intervention

FIGURE 22-125 Mechanical cardiopulmonary resuscitation devices. Vest type.

In addition, some manual monitor-defibrillators have special features, such as data recorders, transcutaneous cardiac pacing capabilities, and 12-lead monitoring and transmission.

AUTOMATED EXTERNAL DEFIBRILLATORS

Automated external defibrillators (Figure 22-126) analyze the ECG signal. They evaluate the frequency, amplitude, and shape of the ECG waves. They are designed to be used by people with little training. They increase the number of individuals who are able to use a defibrillator in a cardiac arrest emergency. Automated external defibrillators are available for adult and pediatric patients (see Chapter 48).

NOTE

There are many community-based first-responder defibrillation programs using automated external defibrillators. These programs and others (e.g., automated external defibrillators located in airports, businesses, schools, and on public airlines) are supported by the American Heart Association and other groups. The Food and Drug Administration (FDA) approved nonprescription sales of some automated external defibrillators for home use.

FIGURE 22-126 Automated external defibrillator.

All automated external defibrillators are attached to the patient by two adhesive monitor-defibrillator pads (electrodes) and connecting cables. Automated external defibrillators are available from a number of manufacturers. They have a variety of features and controls. Most units provide programmable modules, data recorders, and voice messages to the operator. All users should become familiar with the automated external defibrillator device used in their system. Moreover, they should follow the recommendations of the manufacturer.

A fully automated defibrillator requires only that the operator attach the defibrillation pads and turn on the device. The rhythm is analyzed in the internal circuitry of the automated external defibrillator. If a shockable rhythm is detected, the automated external defibrillator charges capacitors and delivers a shock.

A semiautomated defibrillator requires the operator to press an "analyze" button to interpret the rhythm and a "shock" button to deliver the shock. The operator presses the shock control only when the automated external defibrillator identifies a shockable rhythm and "advises" the operator to press the shock button.

CRITICAL THINKING

What safety measure is still the duty of the person who operates the automated external defibrillator?

Automated external defibrillators have four safety features:

1. They can analyze ECG waves.
2. They have built-in filters that check for QRS-like signals, radio transmission waves, 60-cycle interference, and loose or poor electrode contact.
3. Most are programmed to detect spontaneous patient movements, continued heartbeat and blood flow, and movement of the patient by others.
4. They make multiple evaluations of the rhythm before making a shock advisory or delivering a shock.

BIPHASIC TECHNOLOGY

In the past, defibrillation has used monophasic waveforms, in which the current travels in only one direction, from the positive pad to the negative pad. These defibrillators require high energy to defibrillate a patient effectively. In fact, they may deliver more energy than is needed for some patients. These machines also require large batteries, energy storage capacitors, inductors, and large, high-voltage mechanical devices.

Most newer automated external defibrillators and implantable defibrillators use biphasic waveform technology. This technology predicts a patient's energy requirements by determining chest wall impedance. The shock then is delivered by a current that travels in one direction, is stopped, and then is reversed to travel in the opposite direction. This technology allows for effective defibrillation to occur with lower energy for most patients.[35] (Biphasic defibrillation of 115 and 130 J appears to be as effective as 200 and 360 J delivered with monophasic shocks.[36]) Biphasic waveforms are more effective at lower energy than monophasic waveforms. As a result, automated external defibrillators (using smaller batteries) have become smaller, lighter, more durable. They also have become less expensive to manufacture.

DEFIBRILLATION

Defibrillation is the delivery of electrical current through the chest wall. The purpose is to terminate ventricular fibrillation and pulseless ventricular tachycardia. The shock depolarizes a large mass of myocardial cells at once. If about 75% of these cells are in the resting state (depolarized) after the shock is delivered, a normal pacemaker may resume discharging. Early defibrillation is supported by the following rationales[1]:

- The most frequent initial rhythm in sudden cardiac arrest is ventricular fibrillation.
- The most effective management for ventricular fibrillation is electrical defibrillation.
- The probability of successful defibrillation decreases rapidly over time.
- Ventricular fibrillation tends to convert to asystole within a few minutes.

The modern defibrillator is designed to deliver an electrical shock via patches or pads to the patient's chest. The defibrillator accepts the electrical charge from the battery source. It stores the charge in the capacitor and then releases the current into the patient in a short, controlled burst (within 5 to 30 msec).

NOTE

Older defibrillators used "quick look" paddles instead of the modern pads or patches. If paddles are used, they should be coated with electrode paste or gel to reduce resistance and should be held firmly on the patient's chest with about 20 to 25 pounds of pressure.

SHOW ME THE EVIDENCE

Menegazzi and coworkers combined existing cardiac arrest data from four cities and analyzed it to determine which factors predicted failure of the first defibrillation. They found that first defibrillation failure increased in cases of unwitnessed arrest, if the response time was longer than 6 minutes, and if no bystander-provided CPR was performed. Menegazzi J, Hsieh M, Niemann J: Derivation of clinical predictors of failed rescue shock during out-of-hospital ventricular fibrillation, *Prehosp Emerg Care* 12:347-351, 2008.

Patch Electrodes

The electrode patches of the defibrillator (Figure 22-127) should be placed so that the heart (mainly the ventricles) is in the path of the current and the distance between the electrodes and the heart is minimized. This helps ensure adequate delivery of current through the heart. Bone is not a good conductor. For that reason, the patches should not be placed over the sternum. As recommended by the American Heart Association, one patch should be placed to the right of the upper sternum below the right clavicle and the other patch should be placed to the left of the nipple in the midaxillary line.[1] (The anterior-posterior anterolateral, anterior-left infrascapular, and anterior-right infrascapular positions also are acceptable.) Most manufacturers have adult and pediatric patches available. Adult patches usually are 8 to 12 cm in diameter. Pediatric patches are 4.5 cm in diameter. They are used for children under 1 year of age.

The resistance to current by the chest wall is called *impedance.* Impedance is determined by body size, bone structure, skin properties, underlying health conditions, and other variables. The greater the resistance, the less current delivered. Dry, unprepared skin has high impedance. To reduce resistance, the electrode patches are gelled. Care must be taken to prevent contact (bridging) between the two conductive areas on the chest wall. If contact between the two areas is made, superficial burns of the skin may result. The effective current also may bypass the heart. Even with proper technique and equipment, minor skin damage may still occur.

Stored and Delivered Energy

Electrical energy is commonly measured in **joules** (watt seconds). One joule of electrical energy is the product of 1 V (potential) multiplied by 1 A (current) multiplied by 1 second. Delivered energy is about 80% of stored energy because of losses within the circuitry of the defibrillator and resistance to the flow of current across the chest wall. As a rule, 80% of stored energy approximates the number of joules delivered to the patient. The American Heart Association currently recommends that one initial defibrillation be attempted at 120 to 200 J biphasic (follow manufacturer's instructions) or 360 J monophasic. (Box 22-23).[1] Second and subsequent shocks may be the same or higher. Initial defibrillation in pediatric patients generally is 2 J/kg. This is followed by 4 J/kg if needed.

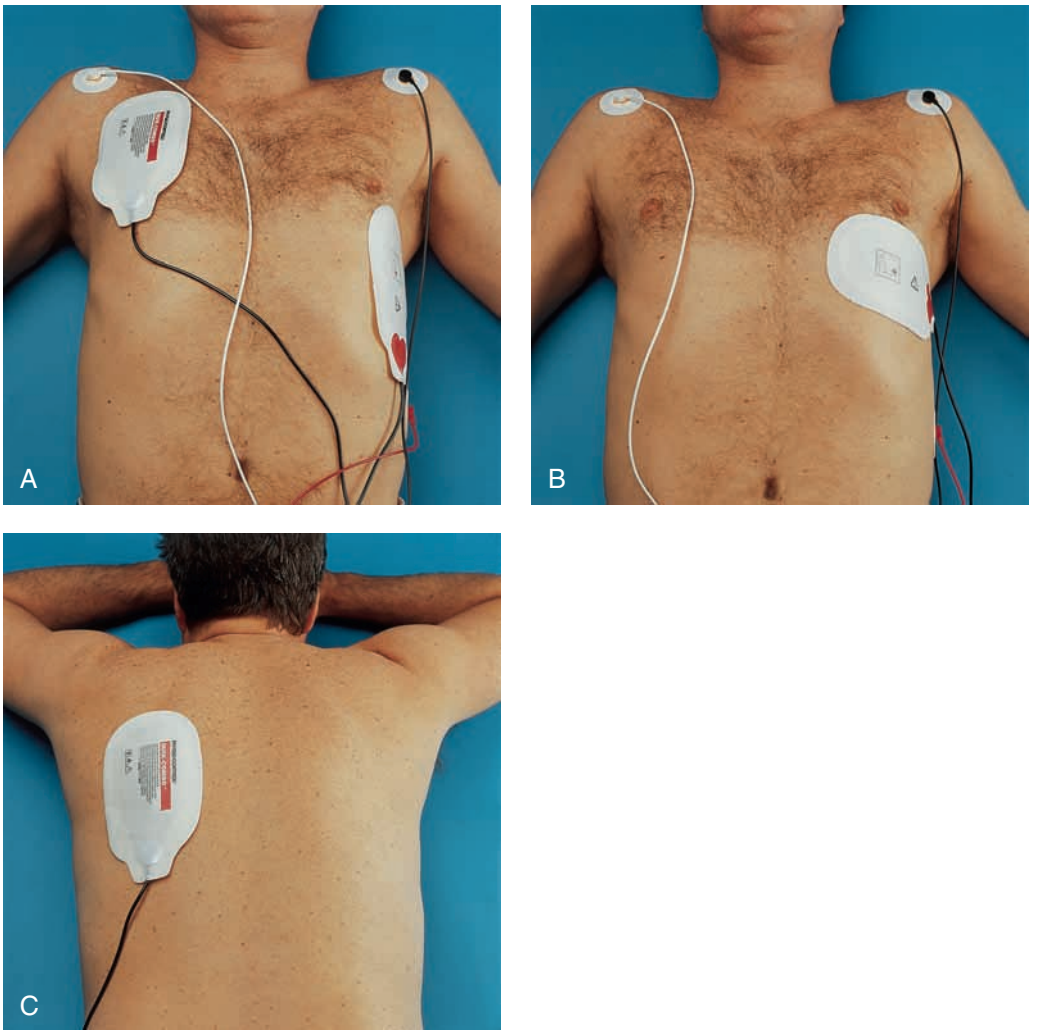

FIGURE 22-127 Proper electrode placement for defibrillation.

BOX 22-23 Current-Based Defibrillation

Current-based defibrillation has been studied as an alternative to traditional defibrillation. With current-based defibrillation, the defibrillator operator selects electrical current (amperes) versus energy (joules). This method avoids the problem of low-energy selection in the presence of high impedance (resulting in a current flow that is too low and thus failure to defibrillate). It also avoids the problem of high-energy selection in the presence of low impedance (resulting in excessive current flow, myocardial damage, and failure to defibrillate). The optimum current for ventricular defibrillation appears to be 30 to 40 A.[4]

Procedure for Defibrillation

The following is the procedure for defibrillation recommended by the American Heart Association.

1. Turn on the defibrillator.
2. Select the energy level at 120 to 200 J biphasic (based on manufacturer's recommendation) or 360 J for monophasic defibrillators.
3. Set lead I, II, or III if monitor leads are used.
4. Position electrode patches on the patient's chest (sternum-apex).
5. Visually check the monitor display and assess the rhythm. (Subsequent steps assume that ventricular tachycardia/ventricular fibrillation is present.)
6. Announce to the team members, "Charging the defibrillator."
7. Press the "charge" button on the defibrillator controls.
8. Continue CPR while the defibrillator is charging.
9. When the defibrillator is fully charged, state quickly, in a forceful voice, the following chant (or some suitable equivalent) before each shock.
   - *"I am going to shock on three. One, I'm clear."* (Check to make sure you are clear of contact with the patient, the stretcher, and the equipment.)
   - *"Two, you're clear."* (Make a visual check to ensure that no one continues to touch the patient or stretcher. In particular, do not forget about the person providing ventilations. That person's

hands should not be touching the ventilatory adjuncts, including the tracheal tube. Turn off oxygen or direct the flow away from the patient's chest.)
- *"Three, everybody's clear."* (Check yourself one more time before pressing the "shock" button.)

10. Perform five cycles of CPR.
11. Check the monitor. If ventricular fibrillation/ventricular tachycardia remains, recharge the defibrillator at once.
12. Shock at the same or higher biphasic energy (per manufacturer) or 360 J for monophasic defibrillators, repeating the verbal statements in step 9.

Operator and Personnel Safety

The following six guidelines are designed to ensure safe use of a defibrillator.[37]

1. Make sure all personnel are clear of the patient, the bed, and the defibrillator before making a defibrillation attempt.
2. Do not make contact with the patient during discharge.
3. Do not discharge current over a pacemaker or implantable cardioverter-defibrillator generator or ***nitroglycerin*** paste. Remove ***nitroglycerin*** patches before defibrillation.
4. Do not "open air" discharge the defibrillator to cancel an unwanted charge. Turn the defibrillator off to "dump" the charge. (In most models, changing the energy setting dumps the charge.)
5. Treat equipment with respect. It is safe when used properly.
6. Routinely check the defibrillator (including the batteries) to make sure the equipment is functioning properly. Follow the manufacturer's recommendations.

Defibrillator Use in Special Environments

On occasion a patient requires defibrillation in a special environment (e.g., inclement weather). The guidelines in operator and personnel safety always apply. However, additional precautions are taken in special situations.

A patient can be defibrillated in wet conditions, such as near water, in rain, or in snowy weather. The patient's chest should be kept dry between the defibrillator electrode sites. The operator's hands should be kept as dry as possible. In a rainstorm, the safest course is to find shelter.

Depending on the defibrillator and its equipment specifications, the device may not be guaranteed to work properly in nonpressurized aircraft. In addition, some electrical interference may occur between the radio equipment in the aircraft and the monitor-defibrillator or vice versa. This is affected by the distance and angle between the defibrillator and the radio equipment. Studies have demonstrated that defibrillation with current equipment would be expected to be safe in all types of rotary aircraft used for emergency medical transport.[38] Nonetheless, the medical crew should always inform the pilot when electrical therapy is being used. In addition, the paramedic should consult with the pilot to make sure the flight instruments are well shielded from electromagnetic interference.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

Implantable cardioverter-defibrillators (ICDs) commonly are used in patients at risk for recurrent, sustained ventricular tachycardia or fibrillation (Figure 22-128). During implantation, the various leads of the ICD are fed through a vessel (usually the subclavian vein) into the right ventricle or placed on the epicardium. The leads are tunneled to a pulse generator in the biphasic defibrillator device. The device is placed surgically in the left upper quadrant of the abdomen. (An outline of the generator usually can be felt or seen under the patient's skin.) The leads are used to deliver shocks, monitor cardiac rhythm, and sometimes pace the heart as needed if bradycardia occurs.

CRITICAL THINKING
These devices are used by what type of patients?

The implantable cardioverter-defibrillator works by monitoring the patient's cardiac rhythm, rate, and QRS complex morphology. When a monitored ventricular rate exceeds the preprogrammed rate, the implantable

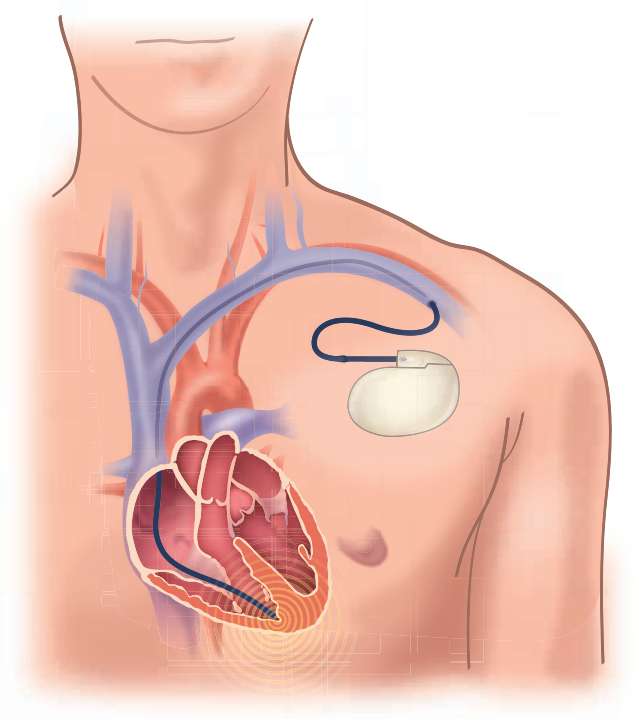

FIGURE 22-128 Implantable cardioverter-defibrillator.

cardioverter-defibrillator delivers a shock of about 6 to 30 J through the patches to restore a normal sinus rhythm. The device requires 10 to 30 seconds to sense ventricular tachycardia or ventricular fibrillation and to charge the capacitor before delivering the shock. If defibrillation does not restore a normal sinus rhythm, the implantable cardioverter-defibrillator charges again. It then delivers up to four shocks. A complete sequence of five shocks, if required, may take up to 2 minutes. If the tachycardia or fibrillation persists after five shocks, no further shocks are delivered. Once a slower rhythm (i.e., sinus or idioventricular rhythm) has been restored for at least 35 seconds, the device can deliver another series of up to five shocks if ventricular tachycardia or ventricular fibrillation recurs.

CRITICAL THINKING

A conscious patient has a device that is firing repeatedly in response to the presence of a ventricular rhythm. How can you lessen the patient's discomfort and anxiety?

The paramedic must manage patients with implantable cardioverter-defibrillators as if they did not have a device. The paramedic should follow standard ACLS protocols if the patient is in cardiac arrest or in any other way medically unstable. The American Heart Association recommends the following four guidelines for caring for a patient with an implantable cardioverter-defibrillator[1]:

1. If the implantable cardioverter-defibrillator discharges while the rescuer is touching the victim, the rescuer may feel the shock. However, the shock will not be dangerous. Personnel shocked by implantable cardioverter-defibrillators report sensations similar to contact with an electrical current.
2. Implantable cardioverter-defibrillators are protected against damage from traditional transchest defibrillation shocks. However, they require an implantable cardioverter-defibrillator readiness check after external defibrillation.
3. If ventricular fibrillation or ventricular tachycardia is present despite an implantable cardioverter-defibrillator, an external shock should be given immediately, because the implantable cardioverter-defibrillator likely has failed to defibrillate the heart. After an initial series of shocks, the implantable cardioverter-defibrillator becomes operative again only if a period of nonfibrillatory rhythm occurs to reset the unit.
4. Older implantable cardioverter-defibrillator units use patch electrodes instead of leads. These electrodes cover a portion of the epicardial surface. They may reduce the amount of current delivered to the heart from transthoracic shocks. Therefore, if transthoracic shocks of up to 360 J fail to defibrillate a patient with an implantable cardioverter-defibrillator, the chest electrode positions should be changed immediately (e.g., anterior-apex to anteroposterior). The transthoracic shocks should be repeated. The different electrode positions could increase transthoracic current flow. This in turn may facilitate defibrillation.

Because the implantable cardioverter-defibrillator can be deactivated and activated with a magnet, patients with implantable cardioverter-defibrillators should be kept away from strong magnets. This prevents accidental deactivation or reactivation of the device. The ability to use a magnet to deactivate and reactivate many of these devices can be useful when the unit is not working properly. However, use of a handheld magnet to turn the unit off or back on should be considered only with the advice and under the direction of a physician.

LEFT VENTRICULAR ASSIST DEVICE

A **left ventricular assist device** (LVAD) is a battery-operated pump that sometimes is implanted during heart surgery in a person waiting for a heart transplant ("bridge to transplant"). (The devices also are used in some patients to allow a weakened heart to recover.) The common LVAD is implanted in the patient's abdomen. A catheter in the pump pulls blood from the weakened left ventricle and then directs the blood into the aorta. (This takes stress off the left ventricle.) A second catheter is brought out of the abdominal wall to the outside of the body, where it can be attached to the pump's battery and control system.

Modern LVADs are portable, and they often are used for weeks to months while the patient waits for a donor heart to become available (Figure 22-129). LVADs also are prescribed for patients who are terminally ill and ineligible for a heart transplant. In these patients, the LVAD can improve the quality of life ("destination therapy"). Possible complications from the device include infection, internal bleeding, heart failure, and mechanical malfunction (see Chapter 52).

Special Care Considerations

Because the LVAD assumes the pumping function of the left ventricle, the patient may have no palpable pulse or measurable blood pressure. (This depends on the pulsatility of the specific device. A Doppler probe may be required for blood pressure readings.) The patient and family usually are quite knowledgeable about the LVAD and often are a valuable resource. In addition, many patients with LVADs advise emergency service agencies so that personnel can be made aware of their special equipment needs.

Because of the location of the LVAD and the tubing connecting it to the heart, the device can be dislodged during CPR, causing severe bleeding. Therefore, chest compressions to manage cardiac arrest are contraindicated in some of these patients. In addition, the procedure for defibrillation and cardioversion is specific to the LVAD and the manufacturer's recommendations.

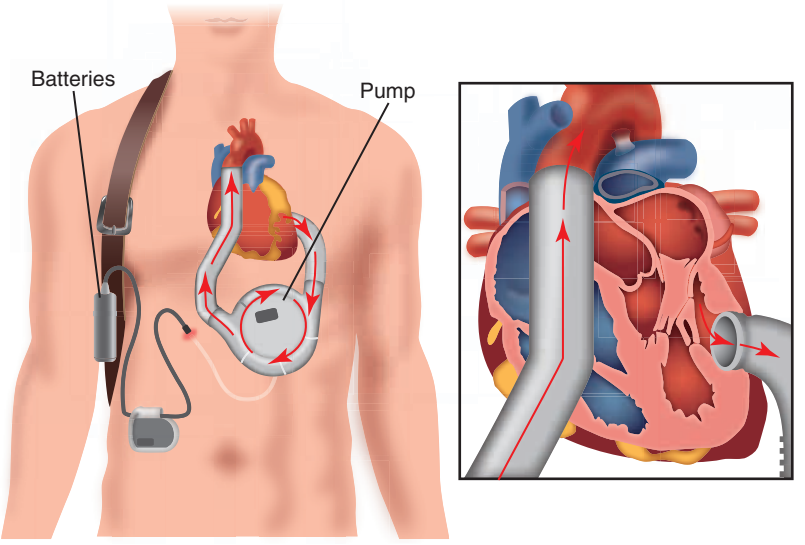

FIGURE 22-129 Left ventricular assist device.

SYNCHRONIZED CARDIOVERSION

Synchronized cardioversion (or countershock) is used to terminate dysrhythmias other than ventricular fibrillation and pulseless ventricular tachycardia. Defibrillation **(unsynchronized cardioversion)** delivers the shock on the operator's command and with no regard to where the shock occurs in the cardiac cycle. In contrast, synchronized cardioversion is designed to deliver the shock about 10 msec after the peak of the R wave of the cardiac cycle. This avoids the vulnerable relative refractory period of the ventricles. Synchronization may reduce the energy required to end the dysrhythmia. It also may decrease the chance of causing ventricular fibrillation.

When the defibrillator is placed in the synchronized mode, the ECG displayed on the oscilloscope shows a marker denoting where in the cardiac cycle the energy will be discharged. This marker should appear on the R wave; if it does not, the paramedic should select another lead. Adjustment of the ECG size may be needed if the marker does not appear. The procedure for synchronized cardioversion is as follows:

1. Consider sedation.
2. Turn on the defibrillator (monophasic or biphasic).
3. Attach monitor leads to the patient ("white to right, red to ribs, what's left over to the left shoulder") and ensure proper display of the patient's rhythm.
4. Engage the synchronization mode by pressing the "sync" control button.
5. Look for markers on R waves indicating the sync mode.
6. If necessary, adjust the monitor gain until the sync markers occur with each R wave.
7. Select the appropriate energy level.
8. Position the electrode patches on the patient (sternum-apex).
9. Announce to the team members: "Charging defibrillator."
10. Press the "charge" button on defibrillator.
11. When the defibrillator is charged, begin the final clearing chant. State firmly, in a forceful voice, the following chant before each shock:
    - *"I am going to shock on three. One, I'm clear."* (Check to make sure you are clear of contact with the patient, the stretcher, and the equipment.)
    - *"Two, you're clear."* (Make a visual check to ensure that no one continues to touch the patient or stretcher. In particular, do not forget about the person providing ventilations. That person's hands should not be touching the ventilatory adjuncts, including the tracheal tube. Turn off oxygen or direct the flow away from the patient's chest.)
    - *"Three, everybody's clear."* (Check yourself one more time before pressing the "shock" button.)
12. Press the "discharge" button.
13. Check the monitor. If tachycardia persists, increase the joules according to the electrical cardioversion algorithm.
14. Reset the sync mode after each synchronized cardioversion, because most defibrillators default back to the unsynchronized mode. This default allows an immediate shock if the cardioversion produces ventricular fibrillation.

TRANSCUTANEOUS CARDIAC PACING

Transcutaneous cardiac pacing (TCP), also known as *external cardiac pacing,* is an effective emergency therapy for bradycardia, complete heart block, and suppression of

some malignant ventricular tachydysrhythmias. TCP devices have been recognized by the American Heart Association. They are used to treat bradycardia.

Artificial Pacing

Artificial pacemakers deliver repetitive electrical currents to the heart (Figure 22-130). They can act as a substitute for a natural pacemaker. The natural pacemaker may have become blocked or dysfunctional. A patient with severe sinus bradycardia, heart block, or idioventricular rhythm who can generate a pulse with cardiac contractions may respond to an external pacing device and produce a perfusing pulse. Sinus bradycardia also may be paced. Generally, though, sinus bradycardia responds well to ***atropine.***

The two modes of TCP are nondemand (asynchronous) pacing and demand pacing. Most devices provide both modes. An asynchronous pacemaker delivers timed electrical stimuli at a selected rate. This occurs regardless of the patient's own cardiac activity. These pacing devices are used less often than demand pacers. This is because they may discharge during the vulnerable period of the cardiac cycle (producing the R-on-T phenomenon). The asynchronous mode generally is used only as a last resort, usually in asystole. This mode also can be used when artifact on the ECG interferes with the machine's ability to sense the patient's own heartbeat. Asynchronous pacing also can be used to override the high heart rates of tachydysrhythmias (e.g., torsades de pointes). This should be attempted only if other means of controlling the dysrhythmia have failed; it may be limited by the design of the machine.

Demand pacing senses the patient's QRS complex. The pacemaker delivers electrical stimuli only when needed. Demand pacing is much safer to apply than the nondemand mode. When the pacemaker senses an intrinsic beat, it is inhibited. If no beats are sensed, the pacemaker delivers pacing stimuli at a selected rate. The device usually is set to discharge at a rate of 70 to 80 beats/minute beginning with 50 mA. The charge then is increased in increments, beginning at 0 mA of electricity, until electrical and mechanical capture is achieved. Generally, the patient's clinical condition (blood pressure, level of consciousness, skin color, and temperature) improves at this point.

FIGURE 22-130 LifePak 15 defibrillator monitor pacer. (Courtesy Physio-Control, Redmond, Wash.)

NOTE

Electrical capture means that every pacer stimulus is followed by a large QRS complex, which indicates ventricular contraction. **Mechanical capture** occurs when an associated pulse is generated with the electrical capture.

The paramedic should make sure each pacemaker spike on the oscilloscope is followed by a QRS complex. If not, the current should be increased gradually until consistent capture is achieved. Unfortunately, motion artifact often makes ECG confirmation of electrical capture difficult. The only accurate method of monitoring mechanical function of the heart produced by the pacing device is the presence of a pulse with each QRS complex. Therefore, the paramedic must monitor the patient's pulse constantly. The paramedic should assess the patient's pulse rate and blood pressure on the patient's right side. This helps minimize interference from muscle artifact.

Procedure for Transcutaneous Pacing

The procedure for transcutaneous pacing is as follows:

1. Consider sedation.
2. Gather the required equipment.
3. Explain the procedure to the patient.
4. Connect the patient to a cardiac monitor and obtain a rhythm strip.
5. Obtain baseline vital signs.
6. Attach the limb leads and apply the pacing electrodes. Often the defibrillation position is used when the same pads can be used for defibrillation and pacing. The pads can also be placed in the anterior-posterior position (left of the lower sternum and just below the left scapula).
7. Select the pacing mode.
8. Select the pacing rate (usually 80 beats/minute); set the current (begin with 0 mA and then increase the current until ventricular capture is obtained).
9. Activate the pacemaker, observing the patient and the ECG.
10. Obtain rhythm strips as appropriate.
11. Continue monitoring the patient and anticipate further therapy.

NOTE

As with synchronized cardioversion, selecting the "pacing mode" should result in the appearance of light markers on intrinsic beats. Paramedics should make sure this happens so that they know the demand mode is activated and working properly.

Indications and Contraindications

The primary indications for transcutaneous cardiac pacing in the prehospital setting are symptomatic bradycardia, heart block associated with reduced cardiac output that is unresponsive to ***atropine,*** and pacemaker failure. As stated previously, cardiac pacing rarely is effective in cardiac arrest. It also is ineffective in pulseless electrical activity unless the underlying cause of the pulseless electrical activity is corrected. Cardiac pacing is not advised for patients with open wounds or chest burns or for patients in a wet environment.

CRITICAL THINKING

Why should patient movement be minimized during transcutaneous cardiac pacing?

Electrode Placement

Proper placement of the electrodes is one of the keys to effective external pacing. As stated previously, the defibrillation position often is used when the same pads can be used for defibrillation and pacing. Alternatively, the paramedic can apply the negative (anterior) electrode to the left of the sternum. The electrode should be centered as close as possible to the point of maximum cardiac impulse. The positive (posterior) electrode is placed directly behind the anterior electrode, just below the left scapula. In rare cases posterior placement cannot be used. In such cases the positive electrode can be placed in line with the patient's left nipple at the midaxillary line. (Anterior-anterior placement may produce pronounced chest muscle twitching.) The electrodes should be applied to clean, dry skin free of localized trauma or infection.

A conscious patient most likely will experience some pain and discomfort during transcutaneous cardiac pacing. This is related directly to the intensity of muscle contractions and the amount of applied current. Ideally, analgesia or sedation of the patient should be provided.

CARDIAC ARREST AND SUDDEN DEATH

It is becoming increasingly evident that patients who cannot be resuscitated in the prehospital setting rarely survive. This is the case even if the patient is resuscitated temporarily in the ED (Box 22-24). The patient's best chance for survival is rapid recognition and, appropriate treatment in the field. The priorities in cardiac arrest are effective CPR and rapid defibrillation (if indicated). Vascular access and advanced airway management are of secondary importance to the initial priorities and should never delay them. Prolonged field resuscitation in the face of difficulties with IV/IO access and intubation almost always is destined to fail.

BOX 22-24 Resuscitation Terminology

Resuscitation: The technique of providing efforts to return spontaneous pulse and breathing to a patient in full cardiac arrest.

Survival: Resuscitation of a patient who survives to hospital discharge.

Return of spontaneous circulation: Restoration of spontaneous circulation that provides evidence of more than an occasional gasp, occasional fleeting palpable pulse, or arterial waveform; the patient may or may not survive.

Adapted from the Utstein registry template.

Much research is under way in the area of emergency cardiac care. Some of the research deals with various drugs to improve cardiac and neurological outcomes after resuscitation. A fairly large number of patients regain cardiac function but never regain consciousness. Therefore, a good deal of interest has arisen in how to improve cerebral perfusion after cardiac arrest. This research may lead to a variety of new drugs that paramedics may use during resuscitation in the future.

Care of the Patient after Return of Spontaneous Circulation

Some patients survive cardiac arrest and have a return of spontaneous circulation (ROSC). In these situations, the principal objective of postresuscitation care is reestablishment of effective perfusion of organs and tissues.[6] Ideally, the patient is alert and awake. Patients also may be comatose, yet still have full potential for recovery with a good neurological outcome. Research is under way to improve the survival rate of patients with ROSC who remain comatose after resuscitation. Some of these methods include therapeutic hypothermia, hemodynamic and ventilation optimization, immediate coronary reperfusion with PCI, glycemic control, and neurological care and prognostication.[1]

THERAPEUTIC HYPOTHERMIA

The 2010 American Heart Association guidelines recommend inducing mild hypothermia in comatose survivors of cardiac arrest When a patient is resuscitated, reperfusion sets off a series of chemical reactions that can continue for up to 24 hours, possibly causing significant inflammation in the brain. Inducing mild hypothermia reduces the intracranial pressure, the cerebral metabolic rate, and the brain's demand for oxygen consumption. In addition, it is thought to suppress many of the chemical reactions associated with reperfusion injury, including free radical production, excitatory amino acid release, and calcium shifts.[39]

Some EMS agencies induce hypothermia in an unconscious patient after ROSC from ventricular fibrillation.[40]

(For example, cooling to induce mild hypothermia can be initiated in the prehospital setting by the application of iced IV bags or through the infusion of cold saline.) In the ED it is initiated by means of internal and external cooling methods. When a core body temperature of 91° to 92° F (28° to 32° C) has been established, the patient is transferred to intensive care. After 12 to 24 hours, the patient is slowly rewarmed to normal core body temperature.

Therapeutic hypothermia should be induced in a comatose patient within 30 to 60 minutes after resuscitation from cardiac arrest if the initial rhythm was ventricular fibrillation or out-of-hospital cardiac arrest with an initial rhythm of PEA or asystole. Therapeutic hypothermia is associated with an improved functional recovery and a better neurological outcome.[41] The technique is under study in other types of patients who may benefit from induced hypothermia, such as victims of severe stroke and adults with head injuries.[42]

HEMODYNAMIC AND VENTILATION OPTIMIZATION

The administration of 100% oxygen should be given during initial resuscitation measures. Following the return of spontaneous circulation, however, inspired oxygen should be titrated during the post-cardiac arrest phase to the lowest level required to achieve and maintain an arterial oxygen saturation of ≥94%. Doing so helps to avoid any complications associated with oxygen toxicity. In addition, excessive ventilation should be avoided. As described in Chapter 15, excessive ventilation can cause adverse hemodynamic effects from an increase in intrathoracic pressures and a potential decrease in cerebral blood flow. The American Heart Association recommends that ventilations begin at 10 to 12 breaths per minute, titrated to achieve a $PETCO_2$ of 35 to 40 mm Hg or a $PaCO_2$ of 40 to 45 mm Hg.

IV fluids and vasoactive and inotropic drugs should be titrated to optimize blood pressure, cardiac output, and systemic perfusion. Although an optimal post-cardiac arrest blood pressure remains unknown, a mean arterial pressure ≥65 mm Hg is suggested as a reasonable goal.

IMMEDIATE CORONARY REPERFUSION WITH PCI

As described earlier, all patients with ROSC should be transported to an appropriate facility that can provide effective postresuscitation care. These therapies include immediate coronary reperfusion (e.g., PCI), therapeutic hypothermia, and other treatment modalities to improve post-cardiac arrest survival.

GLYCEMIC CONTROL

The American Heart Association recommends that serum glucose levels be maintained at 144 to 180 mg/dL in adult patients with ROSC following cardiac arrest. This range prevents any increased risk for hypoglycemia. Attempts to alter serum glucose concentrations below this level should be avoided.

NEUROLOGICAL CARE AND PROGNOSTICIAN

Neurological recovery is an important component of postresuscitation care. The goal is to restore a level of functioning that the patient had before the cardiac arrest. An accurate prognosis of neurological recovery helps in making decisions to limit or withdraw life-sustaining care.

TERMINATION OF RESUSCITATION

As described in Chapter 6, health care professionals are expected to provide basic life support and advanced cardiac life support as part of their professional duty to respond, with the following exceptions:

- When a person lies dead and has obvious clinical signs of irreversible death
- When attempts to perform CPR would place the rescuer at risk of physical injury
- When the patient or surrogate has indicated that resuscitation is not desired

The termination of resuscitative efforts in the prehospital setting should follow rules established by the local EMS system and medical direction. The rules should include consideration for advance directives and orders specifying no CPR. If at any time paramedics are presented with an advance directive (e.g., a written directive, living will, or durable power of attorney) that indicates a patient should not be resuscitated, they should follow established protocol or immediately consult with medical direction (see Chapter 6).

In some adult cases resuscitation can be appropriately terminated in the prehospital setting. For example, the National Association of EMS Physicians (NAEMSP) suggests that resuscitation can be terminated in patients who do not respond to at least 20 minutes of ALS care.[43]

The American Heart Association recommends considering terminating resuscitation when ALL of the following criteria apply[1]:

1. Arrest was not witnessed
2. No bystander CPR was provided
3. No ROSC after full ALS care in the field
4. No AED shocks were delivered

Finally, unusual clinical features (e.g., drowning, profound hypothermia, young age, toxins, electrolyte abnormalities, drug overdose) may be indicators that continued resuscitation is appropriate. Termination of resuscitation in the prehospital setting should be guided by medical direction.

SHOW ME THE EVIDENCE

Using focus groups, Grudzen and colleagues[41] interviewed EMTs and paramedics about their attitude toward a policy change that permitted cessation of resuscitation in the field for nontraumatic cardiac arrest. Overall the groups had a very positive response; they believed that except in select circumstances, this approach was beneficial to patients, families, EMS agencies, and the public. Grudzen C, et al: Paramedic and emergency medical technicians views on opportunities and challenges when forgoing and halting resuscitation in the field, *Acad Emerg Med* 16:532-538, 2009.

Procedure for Termination of Resuscitation

The process for terminating resuscitation in the field varies by protocol. The paramedic must follow the guidelines set by medical direction. When termination is considered appropriate, the paramedic should contact medical direction to convey the following information:

- Patient's medical condition
- Known causes of the arrest
- Any treatment provided
- Family's appraisal of the situation and any resistance or uncertainty

While gathering and giving this information to medical direction, the paramedic should maintain ongoing documentation of the event. (This should include continuous ECG monitoring.) Documentation aids the review of the call. The review usually is performed for quality assurance in most EMS systems.

CRITICAL THINKING

You have just terminated resuscitation in the home. What resources can you contact to help the family?

Special Considerations

In addition to attending to the needs of the patient, paramedics must consider grief support for the family.

DID YOU KNOW?

Helping a Grieving Person

Conveying the news of a death to family members, friends, and loved ones at the scene is difficult. In addition to ensuring the family's privacy, the following guidelines may be helpful in this situation.

What to Say

- Acknowledge the situation (e.g., "I'm sorry to say that [patient's name] has died").
- Express your concern (e.g., "I'm sorry this has happened to you").
- Offer your support (e.g., "Tell me what I can do to help you").

What Not to Say

"I know how you feel."
"Look at what you have to be thankful for."
"It's part of God's plan."
"He's in a better place now."
"It's over, and it's all behind you now."

Listen with Compassion

- Accept and acknowledge the feelings of the bereaved.
- Be willing to sit in silence.
- Let the bereaved talk about how their loved one died.
- Offer comfort without minimizing the loss.

Offer Practical Assistance

- Contact a neighbor or other family member.
- Make sure the bereaved has a means of transportation if needed.

Modified from *Supporting a grieving person: helping others through grief, loss, and bereavement.* http://helpguide.org/mental/helping_grieving.htm. Accessed May 26, 2010.

Support services vary by agency. Often a paramedic (or other EMS personnel) is assigned to stay with the family for a time. At times a community agency referral is arranged.

Law enforcement officers may have additional duties at the scene as part of their professional role. These duties may include an on-scene determination that the patient be assigned to a medical examiner. This may occur when the death or event is suspicious or when a patient's private physician refuses or hesitates to sign the death certificate. The paramedic must be familiar with local and state laws regarding reporting an out-of-hospital death and the disposition of the patient's remains under such circumstances.

SUMMARY

- Individuals at high risk for cardiovascular disease include males, older adults, and those with diabetes, hypertension, a family history of premature cardiovascular disease, and prior myocardial infarction. Prevention strategies include community educational programs in nutrition, cessation of smoking (smoking prevention for children), and screening for hypertension and high cholesterol.
- The left coronary artery carries about 85% of the blood supply to the myocardium. The right coronary artery carries the rest. The pumping action of the heart is a product of rhythmic, alternate contraction and relaxation of the atria and ventricles. The stroke volume is the amount of blood ejected from each ventricle with one contraction. The stroke volume depends on the preload, afterload, and myocardial contractility. Cardiac output is the amount of blood pumped by each ventricle per minute.
- In addition to the intrinsic control of the body in regulating the heart, extrinsic control by the parasympathetic and sympathetic nerves of the autonomic nervous system is a major factor influencing the heart rate, conductivity, and contractility. Sympathetic impulses cause the adrenal medulla to secrete epinephrine and norepinephrine into the blood.
- The major electrolytes that influence cardiac function are calcium, potassium, sodium, and magnesium. The electrical charge (potential difference) between the

inside and outside of cells is expressed in millivolts. When the cell is in a resting state, the electrical charge difference is referred to as a *resting membrane potential*. The specialized sodium-potassium exchange pump actively pumps sodium ions out of the cell. It also pumps potassium ions into the cell. The cell membrane appears to have individual protein-lined channels. These channels allow for passage of a specific ion or group of ions.

- Nerve and muscle cells are capable of producing action potentials. This property is known as *excitability*. An action potential at any point on the cell membrane stimulates an excitation process. This process is spread down the length of the cell and is conducted across synapses from cell to cell.
- The contraction of cardiac and skeletal muscle is believed to be activated by calcium ions. This results in binding between myosin and actin myofilaments.
- The conduction system of the heart is composed of two nodes and a conducting bundle. One of the nodes is the sinoatrial node. The other is the atrioventricular node.
- Parasympathetic stimulation by the vagus nerve affects primarily the SA node and the AV node, causing the heart to slow. Sympathetic stimulation increases the heart rate and contractility.
- The ECG represents the electrical activity of the heart. It is generated by depolarization and repolarization of the atria and ventricles.
- Routine monitoring of cardiac rhythm in the prehospital setting usually is obtained in lead II or V_1. These are the best leads to monitor for dysrhythmias, because they allow visualization of P waves. The paper used to record ECGs is standardized. This allows comparative analysis of an ECG wave.
- A normal ECG consists of a P wave, QRS complex, and T wave. The P wave is the first positive deflection on the ECG. The P wave represents atrial depolarization. The P-R interval is the time required for an electrical impulse to be conducted through the atria and the AV node up to the instant of ventricular depolarization. The QRS complex represents ventricular depolarization. The ST segment represents the early part of repolarization of the right and left ventricles. The T wave represents repolarization of the ventricular myocardial cells. Repolarization occurs during the last part of ventricular systole. The Q-T interval is the period from the beginning of ventricular depolarization (onset of the QRS complex) until the end of ventricular repolarization or the end of the T wave.
- The steps in ECG analysis include analyzing the QRS complex, P waves, rate, rhythm, and P-R interval.
- Dysrhythmias originating in the SA node include sinus bradycardia, sinus tachycardia, sinus dysrhythmia, and sinus arrest. Most sinus dysrhythmias are the result of increases or decreases in vagal tone.
- Dysrhythmias originating in the atria include wandering pacemaker, premature atrial complexes, paroxysmal supraventricular tachycardia, atrial flutter, and atrial fibrillation. Common causes of atrial dysrhythmias are ischemia, hypoxia, and atrial dilation caused by congestive heart failure or mitral valve abnormalities.
- When the SA node and the atria cannot generate the electrical impulses needed to begin depolarization because of factors such as hypoxia, ischemia, myocardial infarction, and drug toxicity, the AV node or the area surrounding it may assume the role of the secondary pacemaker. Dysrhythmias originating in the atrioventricular junction include premature junctional complexes, junctional escape complexes or rhythms, and accelerated junctional rhythm.
- Ventricular dysrhythmias pose a threat to life. Ventricular rhythm disturbances generally result from failure of the atria, atrioventricular junction, or both to initiate an electrical impulse. They also may result from enhanced automaticity or reentry phenomena in the ventricles. Dysrhythmias originating in the ventricles include ventricular escape complexes or rhythms, premature ventricular complexes, ventricular tachycardia, ventricular fibrillation, asystole, and artificial pacemaker rhythm.
- A 12-lead ECG can be used to help identify changes relative to myocardial ischemia, injury, and infarction; distinguish ventricular tachycardia from supraventricular tachycardia; determine the electrical axis and the presence of fascicular blocks; and determine the presence of bundle branch blocks.
- Partial delays or full interruptions in cardiac electrical conduction are called *heart blocks*. Causes of heart blocks include atrioventricular junctional ischemia, atrioventricular junctional necrosis, degenerative disease of the conduction system, and drug toxicity. Dysrhythmias that are disorders of conduction are first-degree atrioventricular block, second-degree atrioventricular block type I (Wenckebach), second-degree atrioventricular block type II, third-degree atrioventricular block, disturbances of ventricular conduction, pulseless electrical activity, and preexcitation (Wolff-Parkinson-White syndrome).
- Common chief complaints of the patient with cardiovascular disease include chest pain or discomfort, including shoulder, arm, neck, or jaw pain or discomfort; dyspnea; syncope; and abnormal heartbeat or palpitations. Paramedics should ask patients suspected of having a cardiovascular disorder whether they take prescription medications, especially cardiac drugs. Paramedics also should ask whether patients are being treated for any serious illness. They should ask whether patients have a history of myocardial infarction, angina, heart failure, hypertension, diabetes, or chronic lung disease. In addition, paramedics should ask whether patients have any allergies or other risk factors for heart disease.

Continued

- After performing the initial assessment of the patient with cardiovascular disease, the paramedic should look for skin color, jugular venous distention, and the presence of edema or other signs of heart disease. The paramedic should listen for lung sounds, heart sounds, and carotid artery bruit. The paramedic should feel for edema, pulses, skin temperature, and moisture.
- Atherosclerosis is a disease process characterized by progressive narrowing of the lumen of medium and large arteries. It has two major effects on blood vessels. First, it disrupts the intimal surface. This causes a loss of vessel elasticity and an increase in thrombogenesis. Second, the atheroma reduces the diameter of the vessel lumen. This reduces the blood supply to tissues.
- Angina pectoris is a symptom of myocardial ischemia. Angina is caused by an imbalance between myocardial oxygen supply and demand. Prehospital management includes placing the patient at rest, administering oxygen if SaO_2 <94%, initiating IV therapy, administering nitroglycerin and possibly morphine, monitoring the patient for dysrhythmias, and transporting the patient for evaluation by a physician.
- Acute myocardial infarction occurs when a coronary artery is blocked and blood does not reach an area of heart muscle. This results in ischemia, injury, and necrosis to the area of myocardium supplied by the affected artery. Death caused by myocardial infarction usually results from lethal dysrhythmias (ventricular tachycardia, ventricular fibrillation, and cardiac standstill), pump failure (cardiogenic shock and congestive heart failure), or myocardial tissue rupture (rupture of the ventricle, septum, or papillary muscle). Some patients with acute myocardial infarction, particularly those in the older age groups, have only symptoms of dyspnea, syncope, or confusion. However, substernal chest pain is usually present in patients with acute myocardial infarction (70% to 90% of patients). ST-segment elevation greater than or equal to 1 mV in at least two side-by-side ECG leads indicates an acute myocardial infarction. However, some patients infarct without ST-segment elevation. Other conditions also can produce ST-segment elevation. Prehospital management of the patient with a suspected myocardial infarction should include placing the patient at rest; administering oxygen if SaO_2 <94%; frequently assessing vital signs and breath sounds; initiating an IV line with normal saline or lactated Ringer solution to keep the vein open; monitoring for dysrhythmias; administering medications such as nitroglycerin, morphine, and aspirin; and screening for risk factors for fibrinolytic therapy; transport to an appropriate hospital.
- Left ventricular failure occurs when the left ventricle fails to function as an effective forward pump. This causes a back pressure of blood into the pulmonary circulation. This in turn may lead to pulmonary edema. Emergency management is directed at reducing the venous return to the heart, improving myocardial contractility, decreasing myocardial oxygen demand, improving ventilation and oxygenation, and rapidly transporting the patient to a medical facility.
- Right ventricular failure occurs when the right ventricle fails as a pump. This causes back pressure of blood into the systemic venous circulation. Right ventricular failure is not usually a medical emergency in itself unless it is associated with pulmonary edema or hypotension.
- Cardiogenic shock is the most extreme form of pump failure. It usually is caused by extensive myocardial infarction. Even with aggressive therapy, cardiogenic shock has a mortality rate of 70% or higher. Patients in cardiogenic shock require rapid transport to a medical facility.
- Cardiac tamponade is defined as impaired filling of the heart caused by increased pressure in the pericardial sac.
- Abdominal aortic aneurysms usually are asymptomatic. However, signs and symptoms signal impending or active rupture. If the vessel tears, bleeding initially may be stopped by the retroperitoneal tissues. The patient may be normotensive on the arrival of EMS. If the rupture opens into the peritoneal cavity, however, massive fatal hemorrhage may follow.
- Acute dissection is the most common aortic catastrophe. Any area of the aorta may be involved. However, in 60% to 70% of cases, the site of a dissecting aneurysm is in the ascending aorta, just beyond the takeoff of the left subclavian artery. The signs and symptoms depend on the site of the intimal tear. They also depend on the extent of dissection. The goals of managing suspected aortic dissection in the prehospital setting are relief of pain and immediate transport to a medical facility.
- Acute arterial occlusion is a sudden blockage of arterial flow. Occlusion most commonly is caused by trauma, an embolus, or thrombosis. The most common sites of embolic occlusion are the abdominal aorta, common femoral artery, popliteal artery, carotid artery, brachial artery, and mesenteric artery. The location of ischemic pain is related to the site of occlusion.
- Noncritical peripheral vascular conditions include varicose veins, superficial thrombophlebitis, and acute deep vein thrombosis. Of these conditions, deep vein thrombosis is the only one that can cause a life-threatening problem: pulmonary embolus.
- Hypertension often is defined by a resting blood pressure that is consistently greater than 140/90 mm Hg. Chronic hypertension has an adverse effect on the heart and blood vessels. It requires the heart to perform more work than normal. This leads to hypertrophy of the cardiac muscle and left ventricular failure. Conditions associated with chronic, uncontrolled hypertension are cerebral hemorrhage and stroke, myocardial infarction, and renal failure.

- Hypertensive emergencies are conditions in which a blood pressure increase leads to significant, irreversible end-organ damage within hours if not treated. The organs most likely to be at risk are the brain, heart, and kidneys. As a rule, the diagnosis is based on altered end-organ function and the rate of the rise in blood pressure, not the blood pressure level.
- Valvular heart disease may occur as a result of infection, or it may be related to heart disease. When one or more of these valves become narrowed, hardened, or thickened (stenotic), the valves do not open or close completely. As a result, blood does not flow with proper force or direction.
- Infectious heart disease includes endocarditis, pericarditis, and myocarditis. Complications can be severe and may include heart failure.
- Cardiomyopathy is an alteration in or weakness of the heart muscle. It can cause heart failure or sudden death. Basic cardiac life support helps maintain the circulation and respiration of a victim of cardiac arrest. Basic life support is continued until advanced cardiac life support is available. Two mechanisms are thought to be responsible for blood flow during cardiopulmonary resuscitation. One is direct compression of the heart between the sternum and the spine. This increases pressure within the ventricles to provide a small but critical amount of blood flow to the lungs and body organs. The second mechanism is increased intrathoracic pressure transmitted to all intrathoracic vascular structures. This creates an intrathoracic-to-extrathoracic pressure gradient. This gradient causes blood to flow out of the thorax. A number of mechanical devices provide external chest compression. Others provide chest compression with ventilation in a cardiac arrest patient.
- Cardiac monitor-defibrillators are classified as manual or automated external defibrillators. Defibrillation is the delivery of electrical current through the chest wall. Its purpose is to terminate ventricular fibrillation and certain other nonperfusing rhythms.
- Implantable cardioverter-defibrillators monitor the patient's cardiac rhythm. When a monitored ventricular rate exceeds the preprogrammed rate, the implantable cardioverter-defibrillator delivers a shock of about 6 to 30 J through patches. This is an attempt to restore a normal sinus rhythm.
- Synchronized cardioversion is designed to deliver a shock about 10 msec after the peak of the R wave of the cardiac cycle. (Therefore. the device avoids the relative refractory period.) Synchronization may reduce the amount of energy needed to end the dysrhythmia. It also may decrease the chances of causing another dysrhythmia.
- Transcutaneous cardiac pacing is an effective emergency therapy for bradycardia, complete heart block, and suppression of some malignant ventricular dysrhythmias. Proper electrode placement is important for effective external pacing.
- It is becoming increasingly evident that patients who cannot be resuscitated in the prehospital setting rarely survive. This is the case even if they are resuscitated temporarily in the emergency department. Cessation of resuscitative efforts in the prehospital setting should follow system-specific criteria established by medical direction.

CHAPTER

23 Diseases of the Eyes, Ears, Nose, and Throat

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Label a diagram of the eye.
2. Describe the pathophysiology, signs and symptoms, and specific management techniques for each of the following disorders of the eye: conjunctivitis, corneal abrasion, foreign body, inflammation (chalazion and hordeolum), glaucoma, iritis, papilledema, retinal detachment, central retinal artery occlusion, and orbital cellulitis.
3. Label a diagram of the ear.
4. Describe the pathophysiology, signs and symptoms, and specific management techniques for each of the following conditions that affect the ear: foreign body, impacted cerumen, labyrinthitis, Meniere's disease, otitis media, perforated tympanic membrane.
5. Label a diagram of the nose.
6. Describe the pathophysiology, signs and symptoms, and specific management techniques for each of the following conditions that affect the nose: epistaxis, foreign body, rhinitis, and sinusitis.
7. Label a diagram of the oropharynx.
8. Describe the pathophysiology, signs and symptoms, and specific management techniques for each of the following conditions that affect the oropharynx and throat: toothache and dental abscess, Ludwig's angina, epiglottitis, laryngitis, tracheitis, oral candidiasis, peritonsillar abscess, pharyngitis/tonsillitis, and temporomandibular joint disorders.

KEY TERMS

angle-closure glaucoma A form of glaucoma associated with a physically obstructed anterior chamber angle; may be chronic or, rarely, acute.

central retinal artery occlusion The blockage of blood supply to the arteries of the retina.

cerumen A yellowish or brownish waxy secretion produced in the external ear canal; also known as earwax.

chalazion A small bump in the eyelid, caused by the blockage of a tiny oil gland in the upper or lower eyelid.

conjunctivitis Inflammation of the conjunctiva, caused by bacterial or viral infection, allergy, or environmental factors.

corneal abrasion The rubbing off of the outer layers of the cornea.

dental abscess A bacterial infection in the center of the tooth.

dentalgia The medical term for toothache.

epiglottitis Inflammation of the epiglottis; a severe form of the condition that affects primarily children is characterized by fever, sore throat, stridor, croupy cough, and an erythematous epiglottis.

epistaxis Bleeding from the nose.

glaucoma A condition in which intraocular pressure increases and causes damage to the optic nerve.

hordeolum An acute infection of the oil gland; commonly known as a stye.

iritis Inflammation of the iris of the eye.

labyrinthitis An ear disorder that involves irritation and swelling of the inner ear structure called the labyrinth.

laryngitis Inflammation of the larynx.

Ludwig's angina A type of cellulitis that involves inflammation of the tissues of the floor of the mouth, under the tongue.

Meniere's disease An abnormality of the inner ear that causes vertigo and tinnitus; associated with fluctuations in hearing loss and a sensation of pressure or pain in the affected ear.

mononucleosis A viral infection causing fever, sore throat, and swollen lymph glands, especially in the neck.

open-angle glaucoma The most common type of glaucoma; structures of the eye appear normal but fluid in the eye does not flow properly through the trabecular meshwork; also called wide-angle glaucoma.

oral candidiasis An infection of yeast fungi of the genus *Candida* on the mucous membranes of the mouth; also known as thrush.

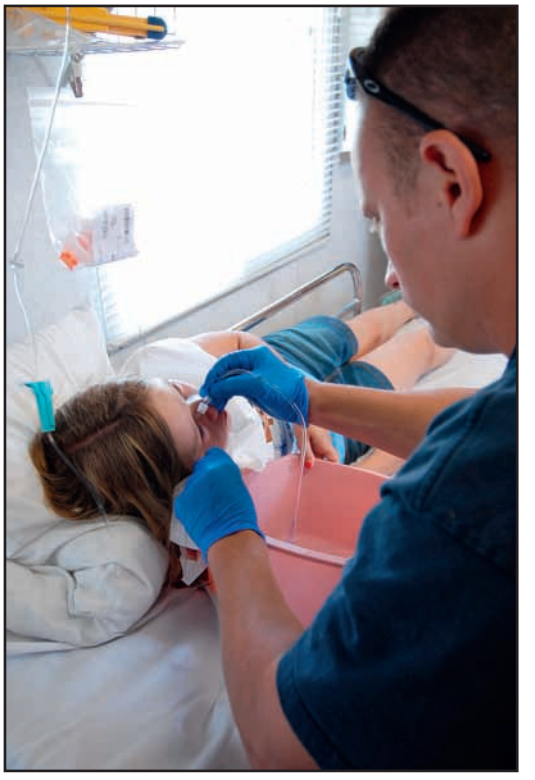
orbital cellulitis An acute inflammation in the tissues immediately surrounding the eye, including the eyelids, eyebrow, and cheek.

otitis media Infection or inflammation of the middle ear.

papilledema Swelling of the head of the optic disc, caused by a rise in intracranial pressure (ICP).

perforated tympanic membrane A hole or rupture in the eardrum, usually from trauma or infection.
peritonsillar abscess A collection of pus in and around one or both tonsils; often caused by tonsillitis.
pharyngitis Inflammation or infection of the pharynx.
retinal detachment A separation of the light-sensitive retina from its supporting layers.
rhinitis Inflammation of the mucous membranes of the nose.
sinusitis Inflammation of one or more paranasal sinuses.
strep throat An infection of the throat caused by streptococcal bacteria.
temporomandibular joint dysfunction Acute or chronic inflammation in the temporomandibular joint.
tinnitus A ringing sound in the ears.
tonsillitis Inflammation of the tonsils.
tracheitis A bacterial infection of the upper airway and subglottic trachea.
trismus Muscle spasms of the jaw.
vertigo A sensation of faintness or an inability to maintain normal balance in a standing or seated position.

Medical conditions that affect the ears, eyes, nose, and throat are a common occurrence in the prehospital setting.[1] This chapter will review the anatomy of these structures and discuss the specific findings, symptoms, and management considerations for common diseases.



CONDITIONS OF THE EYE

As described in Chapter 10, the eye is composed of three layers: the fibrous tunic, consisting of the sclera and cornea; the vascular tunic, consisting of the choroid, ciliary body, and the iris; and the nervous tunic, consisting of the retina (Figure 23-1). In addition, there are accessory structures that protect, lubricate, move, and aid in the function of the eye. These structures include the eyebrows, eyelids, conjunctiva, and lacrimal gland. Box 23-1 lists conditions of the eyes described in this chapter.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 206-208.

BOX 23-1 Medical Conditions That Affect the Eye

Conjunctivitis
Corneal abrasion
Foreign body
Inflammation (chalazion and hordeolum)
Glaucoma
Iritis
Papilledema
Retinal detachment
Central retinal artery occlusion
Orbital cellulitis

NOTE
As described in Chapter 20: Secondary Assessment, eye movement is controlled by cranial nerves III, IV, and VI. The paramedic should remember that visual disturbances of the eyes may be an early indication of stroke, tumor, or other nervous system disease. These possibilities must always be considered when caring for a patient with an eye movement disorder.

CRITICAL THINKING
Which assessment will you perform on an unconscious patient to determine if there is pressure on cranial nerve III?

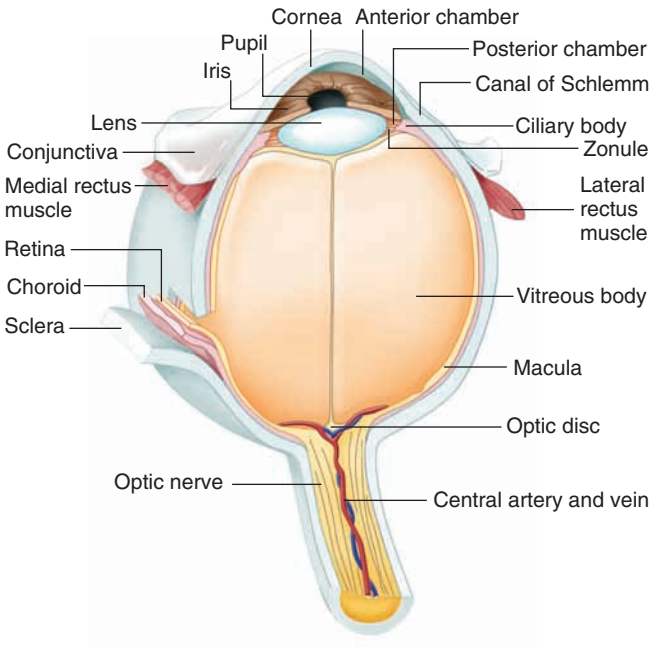


FIGURE 23-1 Anatomy of the eye. (From Goldman L: *Cecil medicine,* ed 23, Philadelphia, 2008, Saunders.)

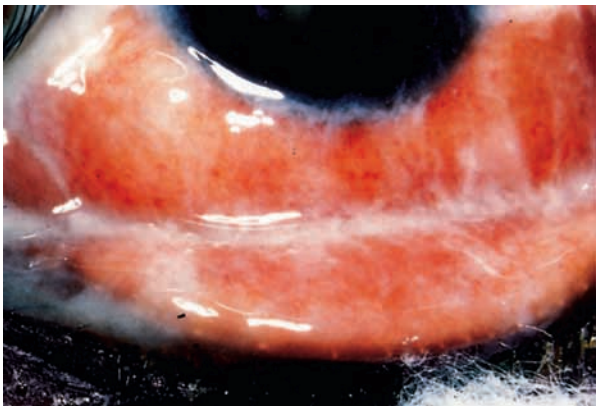

FIGURE 23-2 Gonococcal conjunctivitis showing redness and copious discharge in the eye caused by *Neisseria gonorrhoeae*. (From Mahon CR, Manuselis G: *Textbook of diagnostic microbiology,* ed 2, Philadelphia, 2000, Saunders.)

Conjunctivitis

Conjunctivitis refers to inflammation or infection of the conjunctiva (the membrane lining of the eyes). The condition is commonly called "pink eye," or "Madras eye." Two common causes of conjunctivitis are bacterial or viral infection and an allergic reaction (Figure 23-2). In newborns, conjunctivitis can result from an incompletely opened tear duct.

NOTE
Conjunctivitis can also be caused by agents that irritate the eye. Examples include an accidental exposure to chemicals and a foreign body in the eye (see Chapter 39 and Chapter 40).

Conjunctivitis caused by viral or bacterial infection is very contagious. Therefore, early diagnosis and treatment can prevent spread of the disease. This type of conjunctivitis can affect both eyes and is often associated with a cold. If the cause is viral, there may be a watery, mucous discharge. If the cause is bacterial, the discharge may be thick and yellow-green. Most bacterial infections are associated with a respiratory tract infection or sore throat. Bacterial conjunctivitis is more common in children than adults. To help prevent the spread of infectious conjunctivitis, patients who have the disease should be cautioned not to touch their eyes with their hands and to practice the following precautions:

- Wash hands thoroughly and frequently.
- Change towels and washcloths daily, and do not share them with others.
- Change pillowcase often.
- Discard eye cosmetics, particularly mascara.
- Avoid using another person's eye cosmetics or personal eyecare items.
- Follow instructions from eye physician about proper contact lens care.

Conjunctivitis can be caused by allergies. An example is exposure to an allergen such as pollen (see Chapter 27). This type of inflammation is often associated with eyes that water and itch, and sometimes with sneezing and a nasal discharge ("runny nose").

MANAGEMENT CONSIDERATIONS

Although conjunctivitis is irritating to the eye, it rarely affects vision. Bacterial causes of the condition are usually managed with antibiotic eye drops or eye ointment.[2] Symptoms generally improve within 1 to 2 days. Viral and allergic forms of conjunctivitis are usually managed with over-the-counter medicines (e.g., antihistamines and decongestants) to relieve symptoms. If severe, drugs such as steroids and antiinflammatories may be prescribed. The symptoms of viral and allergic conjunctivitis may take several days to a week or more to subside.

Corneal Abrasion

As the name implies, a **corneal abrasion** is a painful scrape or scratch on the cornea of the eye. It most often occurs from trauma, such as being struck in the eye by a tree branch or limb. It is also frequently caused by foreign bodies in the eye that lodge under the upper lid (e.g., dust, paint chips, wind debris). Corneal abrasions can also be caused by wearing contact lenses longer than recommended,

or by allowing the contact lens, fingers, or nails to scratch the eye during insertion or removal of contact lenses. Signs and symptoms of a corneal abrasion include:[3]

- Pain (which can be severe)
- A sensation of a foreign body in the eye
- Tearing and redness
- Blurred vision
- Spasms of the muscles around the eye, causing the patient to squint

MANAGEMENT CONSIDERATIONS

Prehospital care for a patient with a corneal abrasion is usually limited to supportive measures to relieve pain and prevent further injury. Care may include applying a topical ophthalmic anesthetic, such as ***tetracaine,*** and covering the affected eye. Patients with corneal abrasion should be seen by a physician.

NOTE

Patients who are given ***tetracaine*** should be cautioned not to rub or manipulate the eye or eyelid. Doing so to an eye that has been anesthetized can worsen the injury.

Foreign Body

As stated earlier in this chapter, small foreign bodies in the eye are not uncommon. They are often irritating to the patient, but seldom affect vision. Common complaints are pain, tearing, and a sensation of fullness in the eye.

MANAGEMENT CONSIDERATIONS

Small foreign bodies can be washed or irrigated from the eye using eye cups or saline solution attached to intravenous (IV) tubing. The patient should be instructed not to rub the lid of the affected eye, which could lead to a corneal abrasion. Large or penetrating foreign bodies in the eye are serious in nature and should be managed as described in Chapter 40.

Inflammation of the Eyelid

Inflammation of the eyelid usually results from blockage of a gland or from bacterial infection. Two common conditions are chalazion and hordeolum.

Chalazion is a small bump in the eyelid, caused by the blockage of a tiny oil gland in the upper or lower eyelid. These oil glands normally secrete oil into tears (Figure 23-3). The lump appears as localized and hard, and may increase in size over days to weeks. Symptoms include tenderness, tearing, painful swelling, and sensitivity to light (*photophobia*).[4]

DID YOU KNOW?

There are about 40 oil glands (*meibomian glands*) within each upper and lower eyelid. The glands secret oil into tears, through a tiny opening located just behind the eyelashes.

FIGURE 23-3 Bilateral chalazion in the upper eyelids. (From Goldman L: *Cecil medicine,* ed 23, Philadelphia, 2008, Saunders.)

FIGURE 23-4 Acute hordeolum of upper eyelid. (From Krachmer JH, Palay DA: *Cornea color atlas*, St. Louis, 1997, Mosby.)

A **hordeolum** is commonly known as a **stye.** It represents an acute infection of the oil gland. A stye is usually more painful than a chalazion caused by inflammation, and may look infected (Figure 23-4). The pain of a stye can cause redness around the eye, the eyelid, and cheek tissue. A stye can be limited to one eyelid or can occur on both eyelids simultaneously.

MANAGEMENT CONSIDERATIONS

Inflammation of the eyelids from either of these conditions usually subsides without treatment within 5 to 7 days.[5] Home care may include applying warm compresses 3 to 4 times a day, and gentle scrubbing of the affected eyelid with warm water and a mild soap or shampoo. Patients should be advised not to squeeze or puncture the inflamed area because it can result in serious infection. Eye makeup and eye lotions and creams should be avoided until the inflammation clears. If fever or headache develops, the patient should seek physician evaluation.

Glaucoma

Glaucoma refers to a group of diseases that affect the optic nerve (Box 23-2). It develops when too much aqueous humor accumulates in the anterior chamber of the eye, between the cornea and the iris. This fluid normally flows

BOX 23-2 Two Common Types of Glaucoma

Open-angle glaucoma (also called *wide-angle glaucoma*) is the most common type of glaucoma. The structures of the eye appear normal, but fluid in the eye does not flow properly through the trabecular meshwork.

Angle-closure glaucoma (also called *acute* or *chronic angle-closure* or *narrow-angle glaucoma*) is a less common type of glaucoma. Drainage may be poor because the angle between the iris and the cornea (where the trabecular meshwork is located) is too narrow. Another cause is a pupil that opens too wide, narrowing the angle and blocking the flow of the fluid through that channel (Figure 23-6).

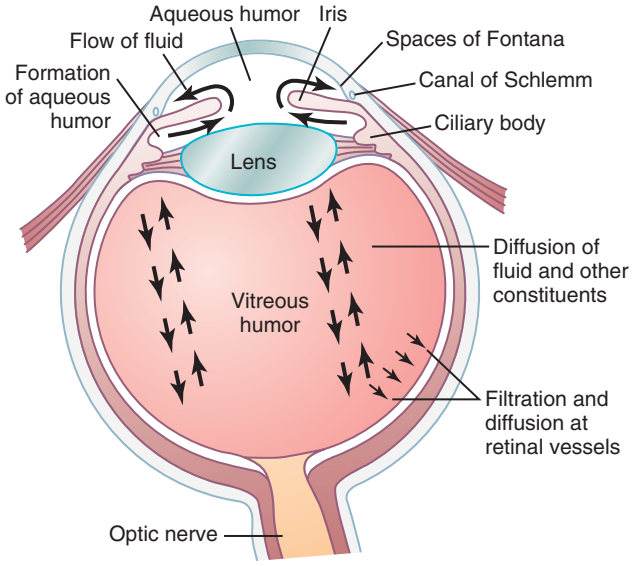

FIGURE 23-5 Formation and flow of fluid in the eye. (From Hall J: *Guyton and Hall textbook of medical physiology,* ed 12, Philadelphia, 2011, Saunders.)

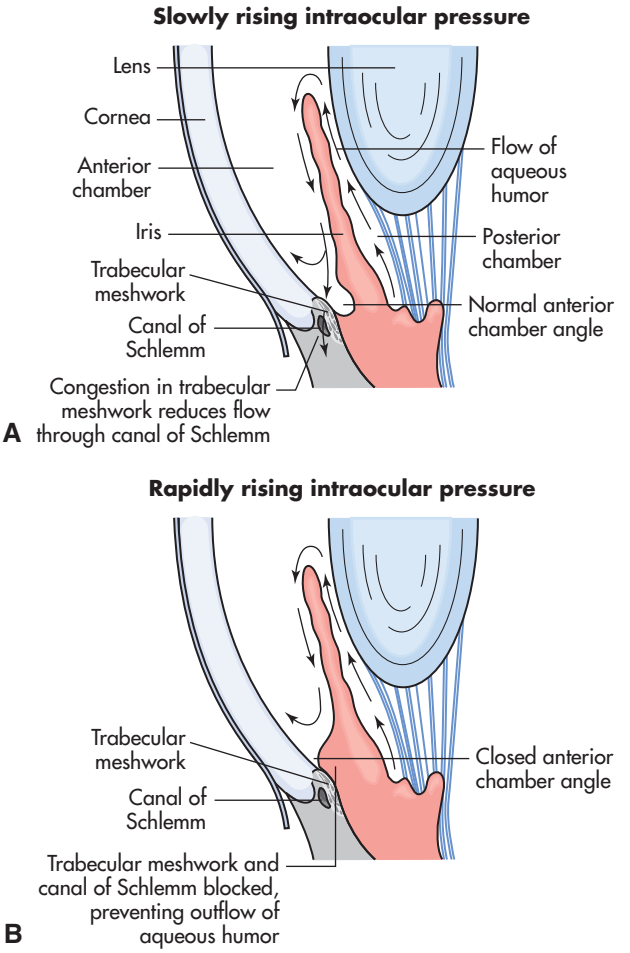

FIGURE 23-6 **A,** Primary open-angle glaucoma. Congestion in the trabecular meshwork reduces the outflow of aqueous humor. **B,** Primary closed-angle glaucoma (acute). The angle between the iris and the anterior chamber narrows, obstructing the outflow of aqueous humor. (From Christensen BL, et al: *Adult health nursing,* ed 6, St Louis, 2010, Mosby.)

out of the eye through a mesh-like channel (trabecular channel) (Figure 23-5). If this channel becomes blocked, the increase in intraocular pressure damages the optic nerve and can lead to a loss of vision. Without treatment, the condition can lead to permanent blindness. The disease usually occurs in both eyes, but affects one more than the other. The direct cause of the blockage is unknown, but seems to have a heritable **component.**[6] Other risk factors for developing the disease include:

- African-American, Hispanic, Inuit, Irish, Japanese, Russian, or Scandinavian heritage
- More than 40 years old
- Poor vision
- Diabetes
- Use of systemic corticosteroid drugs (e.g., prednisone)

Glaucoma can occur at any age (including children and infants), but occurs most often after age 40 (see Chapter 49). There may be no symptoms of the disease (early screening every 1 to 2 years is important). The first sign of glaucoma is usually a loss of peripheral vision, which can remain unnoticed until the disease has progressed. If the rise in intraocular pressure is severe, the patient may have sudden eye pain, headache, vomiting, and blurred vision. The patient may also complain of seeing halos around lights caused by swelling of the cornea.

CRITICAL THINKING

If a patient presents with these signs and symptoms, what other conditions should you consider in your differential diagnosis?

MANAGEMENT CONSIDERATIONS

Prehospital care for patients with glaucoma is primarily supportive. If symptoms are sudden in onset, rapid transport for physician evaluation is indicated. Physician care to treat glaucoma may include eye drops to reduce the formation of fluid in the eye, laser surgery to increase the

outflow of fluid in the eye, or microsurgery to create a new channel to drain the fluid from the eye. In some cases, a combination of these therapies will be needed to prevent blindness.

Iritis

Iritis (*anterior uveitis*) is inflammation of the iris of the eye. It is a serious disease that can cause blindness if not treated (Figure 23-7). Causes of iritis include eye trauma, inflammatory and autoimmune disorders, infection, and cancer. Examples of medical causes of the inflammation include rheumatoid arthritis, lupus, Crohn's disease, Lyme disease, herpes, syphilis, tuberculosis, and **leukemia.**[7] Iritis can be classified as acute or chronic. The acute form of the disease develops suddenly and usually heals within a few weeks with treatment. Chronic iritis can exist for months or years, and is associated with a higher risk of vision impairment or blindness. Iritis can affect one or both eyes. Signs and symptoms of iritis include a reddened eye, ocular or periorbital pain, photophobia, and blurred or cloudy vision.

MANAGEMENT CONSIDERATIONS

Prehospital care is primarily supportive. Physician care may include a variety of steroidal antiinflammatory eye drops, pressure-reducing eye drops, and oral and injectable steroids to reduce inflammation.

Papilledema

Papilledema is swelling of the head of the optic disc, caused by a rise in intracranial pressure (ICP). There are numerous causes of elevated ICP, including cerebral edema, bleeding within the skull, tumors, encephalitis, and increased production of cerebral spinal fluid (CSF), among others (see Chapter 25 and Chapter 40). The swelling of the optic disc is usually bilateral and may be more severe in one eye than the other. The condition is diagnosed using an ophthalmoscope (described in Chapter 20), where visible signs may include (Figure 23-8):

- Venous engorgement (usually the first sign)
- Loss of venous pulsation
- Hemorrhages over and/or adjacent to the optic disc
- Blurring of optic margins
- Elevation of optic disc
- *Paton's lines* (radial retinal lines cascading from the optic disc)

Patient complaints may include a headache that is usually worse on awakening and made worse by coughing, holding the breath, or straining. Other complaints may include nausea and vomiting and vision disturbances (double vision and vision that temporarily flickers or grays).

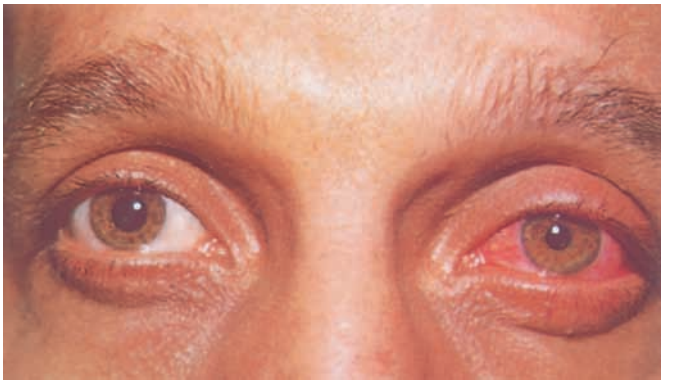

FIGURE 23-7 Iritis. (From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2008, Saunders.)

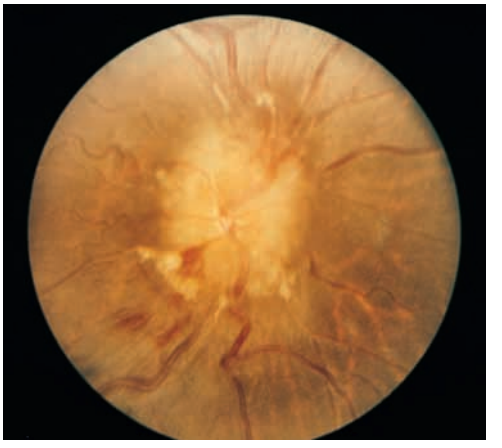

FIGURE 23-8 Severe papilledema. (Courtesy John W. Payne, MD, The Wilmer Ophthalmological Institute, The Johns Hopkins University and Hospital, Baltimore, Md.)

MANAGEMENT CONSIDERATIONS

Prehospital care is primarily supportive. Physician care will depend on the cause of the disease. After the underlying cause is determined and treated, medical care may include diuretics to reduce increased CSF and corticosteroids to reduce inflammation. If papilledema is diagnosed and managed early, permanent vision damage can often be prevented.

Retinal Detachment

As described in Chapter 10, the retina is the light-sensitive tissue that lines the inside of the eye. It also sends visual messages from the optic nerve to the brain. If the retina detaches, it is lifted or pulled from its normal position. Small areas of the retina can also be torn. These retinal *tears, breaks,* or *defects* can lead to retinal detachment. Box 23-3 describes the three different types of retinal detachment.

NOTE

Infants who are victims of *shaken baby syndrome* may be unconscious with papilledema. Therefore, shaken baby syndrome should be suspected with this presentation. External signs of abuse may or may not be present (see Chapter 50).

BOX 23-3 Types of Retinal Detachment

Rhegmatogenous—A tear or break in the retina allows fluid to get under the retina and separate it from the retinal pigment epithelium (RPE), the pigmented cell layer that nourishes the retina. These types of retinal detachments are the most common.

Tractional—In this type of detachment, scar tissue on the retina's surface contracts and causes the retina to separate from the RPE. This type of detachment is less common.

Exudative—Frequently caused by retinal diseases, including inflammatory disorders and injury/trauma to the eye. In this type, fluid leaks into the area underneath the retina, but there are no tears or breaks in the retina.[8]

Retinal detachment is a true emergency and can lead to permanent vision loss. The condition can occur at any age, but is more likely to occur in people who[8]:

- Are extremely nearsighted
- Have had a retinal detachment in the other eye
- Have a family history of retinal detachment
- Have had cataract surgery
- Have other eye diseases or disorders
- Have had an eye injury
- Have diabetes
- Have sickle cell disease

Signs and symptoms of retinal detachment include a sudden or gradual increase in either the number of floaters, which are little "cobwebs" or specks that float in your field of vision, and/or the number of light flashes in the eye. Another symptom is the appearance of a curtain over the field of vision.

CRITICAL THINKING

How would your life change if you were to lose your sight next week?

MANAGEMENT CONSIDERATIONS

Like most eye conditions, prehospital care for a patient with retinal detachment is primarily supportive. Because the condition is a true emergency, rapid transport for physician evaluation is key. Small tears in the retina may be repaired with laser surgery or a freeze treatment (*cryopexy*) to reattach the retina. Full retinal detachment requires advanced surgery and usually hospitalization. About 90% of patients can be successfully treated if managed early, with varying degrees of visual outcome. Visual results are best if the retinal detachment is repaired before the macula (the center region of the retina responsible for fine, detailed vision) detaches.[9]

Central Retinal Artery Occlusion

Central retinal artery occlusion (CRO) is the blockage of blood supply to the arteries of the retina. CRO produces sudden, painless blindness and is usually limited to one eye. This is a true ocular emergency. Retinal circulation must be reestablished within 60 to 90 minutes to prevent permanent loss of vision. Occasionally, before total occlusion occurs, the patient may experience transient episodes of blindness called *amaurosis fugax*. This can be equated to a transient ischemia attack of the retinal artery. Patients usually describe the episode as a shade coming down over the eye. Causes of CRO include embolus (carotid and cardiac), thrombosis, hypertension, or simple angiospasm (rare) associated with a migraine or atrial fibrillation. Hence, the patient will need to be thoroughly evaluated to rule out other systemic problems.

MANAGEMENT CONSIDERATIONS

Prehospital care is primarily supportive. The patient requires rapid transport to an appropriate facility. To prevent permanent damage, retinal perfusion needs to be reestablished as rapidly as possible. In-hospital care may include vasodilation techniques, ocular massage, and administration of *intraocular pressure–lowering drugs,* none of which have been shown to be extremely beneficial.[10]

Orbital Cellulitis

Orbital cellulitis is an acute infection of the tissues that surround the eye. These areas include the eyelids, eyebrow, and cheek (Figure 23-9). Orbital cellulitis is a dangerous infection that can have serious consequences if not treated. It can quickly lead to blindness, especially in children. Other complications of the disease include hearing loss, septicemia, sinus thrombosis, and meningitis.

Orbital cellulitis can be caused from bacteria (often *Haemophilus influenzae*) from a sinus infection. (This form is especially common in children less than 6 years of age, but

FIGURE 23-9 Orbital cellulitis. (From Marx J, et al: *Rosen's emergency medicine: concepts and clinical practice,* ed 6, St Louis, 2006, Mosby.)

the rate has decreased steadily with the HiB vaccine.[11]) The bacteria *Staphylococcus aureus, Streptococcus pneumoniae,* and beta-hemolytic streptococci may also cause orbital cellulitis. Other causes of orbital cellulitis include stye and eyelid injury with inflammation. Signs and symptoms of the disease include:

- Fever, with temperature generally >102° F (38.9° C)
- Painful swelling of upper and lower eyelids
- Shiny, red or purple eyelid
- Eye pain
- Decreased vision
- Bulging eyes
- General malaise
- Painful or difficult eye movements

MANAGEMENT CONSIDERATIONS

Prehospital care is focused on recognition of the signs and symptoms and rapid transport for physician evaluation. Patients will usually be hospitalized for diagnostic tests. Physician care may include IV antibiotics and sometimes surgery to drain any abscess associated with the illness. With prompt treatment, most patients will make a full recovery.

CRITICAL THINKING

If a patient with orbital cellulitis has developed sepsis, what additional signs and symptoms should you anticipate?

CONDITIONS OF THE EAR

As described in Chapter 10, the ear can be divided into three portions: external, middle, and inner ear. The external ear and middle ear are involved in hearing only. The inner ear functions in both hearing and balance (Figure 23-10). Common medical conditions that affect the ear are listed in Box 23-4.

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 208-209.

Foreign Body

A foreign body in the ear is a fairly common occurrence, especially in toddlers. Most foreign bodies are lodged in the ear canal. Common objects found in the ears of young children include food material and toys that are usually

BOX 23-4 Medical Conditions That Affect the Ear

Foreign body
Impacted cerumen
Labyrinthitis
Meniere's disease
Otitis media
Perforated tympanic membrane

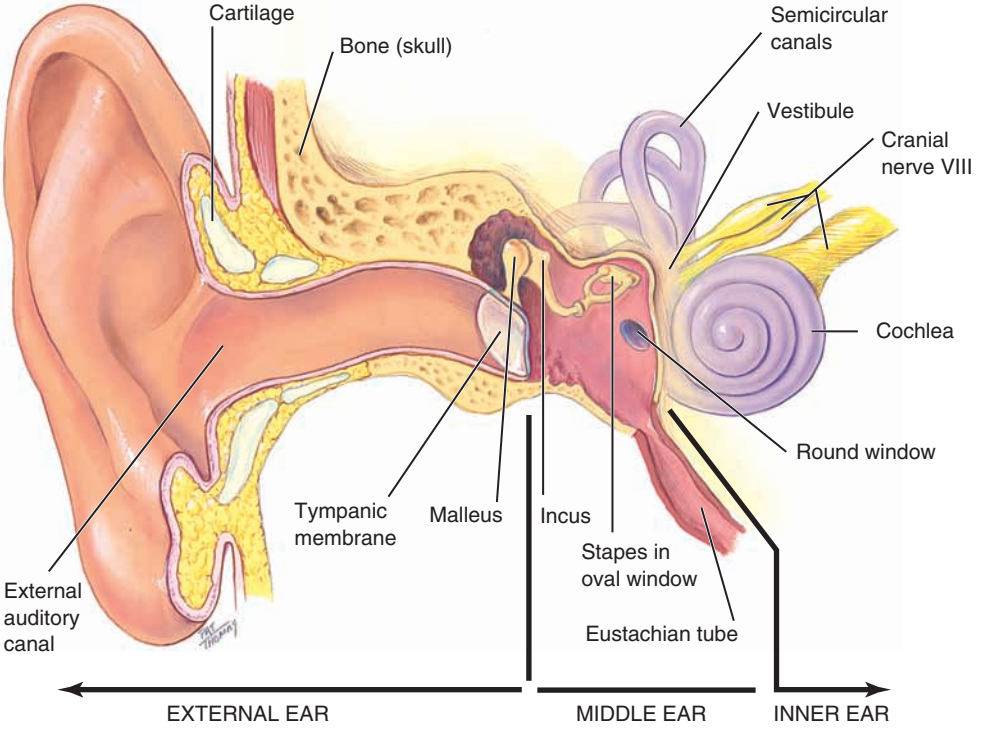

FIGURE 23-10 Anatomy of the ear. (From Jarvis C: *Physical examination and health assessment,* ed 5, St. Louis, 2008, Saunders.)

inserted voluntarily. Children and adults are also subject to insects that enter the ear canal during sleep. Foreign bodies in the ear are often easily detected by complaints of pressure, discomfort, and decreased hearing in the affected ear. (If the foreign body stays undetected, serious infection can result.) Bleeding from the ear can also occur if the foreign body is sharp or is manipulated during attempts to remove it.

NOTE
It is not uncommon for young children to have multiple foreign bodies inserted in both ears and the nose. The paramedic should be alert for this possibility. All children should be reminded not to put anything "smaller than an elbow" in the ear or nose.

Foreign bodies in the ear are seldom a serious medical condition that requires emergency care. Most objects can be easily removed at a physician's office or clinic. Some foreign bodies do require immediate removal in the emergency department. These include button-type batteries than can cause chemical burns, and food and plant material that can swell when moistened. If the patient complains of significant pain or discomfort, immediate evaluation by a physician is also indicated.

MANAGEMENT CONSIDERATIONS

Prehospital care for foreign bodies in the ear is limited to gentle examination of the external auditory canal. This can be done by gently pulling back on the ear's pinna (changing the shape of the ear canal), and viewing the canal with a penlight or ear speculum. Objects that are visible may sometimes be easily removed with alligator forceps. Care should be taken not to push the object deeper into the canal. This can make the object more difficult to retrieve and may also damage the eardrum. Patients who require physician evaluation should be advised not to eat or drink before their exam, because sedation may be needed to safely remove the foreign body. In-hospital care may include diagnostic imaging, irrigation of the ear canal, suction, surgical removal of the foreign body, and prescribed antibiotics.

CRITICAL THINKING
What additional signs and symptoms might your patient experience if there is a live insect in his or her ear?

Impacted Cerumen

As described in Chapter 10, **cerumen** (earwax) is produced normally by the ceruminous glands that are located in the external auditory canal. Cerumen protects and lubricates the skin of the ear canal. It also provides some protection from bacteria, fungi, insects, and water. Cerumen is a yellowish-waxy substance that has the consistency of toothpaste. Excess cerumen can become impacted, pressing up against the eardrum and creating a foreign body in the ear. Excessive cerumen can impede the passage of sound in the ear canal, causing hearing loss. Signs and symptoms of impacted cerumen include:

- Earache, fullness in the ear, or a sensation the ear is plugged
- Partial hearing loss, which may be progressive
- Tinnitus, ringing, or noises in the ear
- Itching, odor, or discharge
- Coughing

Many patients regularly clean their ears of excess cerumen with cotton-tipped swabs. This is a dangerous practice that can push the cerumen deeper into the ear. It is recommended that cerumen not be removed from the ear canal, unless the cerumen is impacted.[12] Most forms of ear blockage respond well to home treatments to soften the wax. These treatments include irrigation and syringing with warm water or saline and wax-dissolving drops (e.g., mineral oil, baby oil, glycerin, and other commercial drops).

NOTE
Ears should not be irrigated if a person has diabetes, a perforated eardrum, a tube in the eardrum, or a weakened immune system.[12]

MANAGEMENT CONSIDERATIONS

Prehospital care for a patient with impacted cerumen is primarily supportive. Patients should be encouraged to see a physician for wax removal. This is most often performed by an otolaryngologist using special equipment and techniques.

Labyrinthitis

Labyrinthitis is an ear disorder that involves irritation and swelling of the inner ear structure called the *labyrinth* (described in Chapter 10). Inflammation of this balance-control area in the ear can cause sudden **vertigo.** It may also cause a temporary hearing loss and a ringing sound in the ears **(tinnitus).** Labyrinthitis can result from a viral infection or, more rarely, a bacterial infection. Common triggers are an upper respiratory tract infection and middle ear infection.

NOTE
Vertigo (dizziness) is an uncomfortable feeling when there is no actual movement. It is commonly described as spinning or whirling. It may also include the sensations of falling or tilting. Vertigo may cause nausea and vomiting, and may impair the patient's ability to walk or stand. Vertigo and ataxia (failure of muscle coordination) also can signal stroke (see Chapter 26).

MANAGEMENT CONSIDERATIONS

Prehospital care for patients with labyrinthitis is primarily supportive. Patients should be advised to be careful of falling and to have assistance when walking. Most cases of labyrinthitis resolve without treatment. If infection is to blame, antibiotics may be prescribed. Antiemetics may also be prescribed for symptoms of nausea and vomiting.

Meniere's Disease

Meniere's disease is an abnormality of the inner ear. Like labyrinthitis, this disease causes vertigo and tinnitus. It is also associated with fluctuations in hearing loss and a sensation of pressure or pain in the affected ear. The symptoms of Meniere's disease are associated with a change in fluid volume in the labyrinth. Causes of the disease may include environmental factors, such as noise pollution, viral infection, and biological factors. It is estimated that about 615,000 Americans have been diagnosed with the disease and that 45,500 new cases are diagnosed each year.[13]

The classic presentation of Meniere's disease is a combination of vertigo, tinnitus, and hearing loss that lasts several hours. The symptoms occur suddenly. Episodes can be as frequent as once a day or as infrequent as once per year. The vertigo is often debilitating and can lead to severe nausea and vomiting. Other symptoms of the disease may include headache, abdominal discomfort, and diarrhea.

MANAGEMENT CONSIDERATIONS

Like most other conditions that affect the ear, prehospital care for a patient with Meniere's disease is primarily supportive. There is no cure for the illness. Physician care may include medications and diet restrictions to reduce fluid retention. Drug therapy to improve blood circulation in the inner ear may also be prescribed. Eliminating tobacco use and reducing stress may help with the severity of the symptoms.

CRITICAL THINKING
What other conditions in addition to labyrinthitis and Meniere's disease can cause vertigo?

Otitis Media

Otitis media is infection or inflammation of the middle ear. (*Otitis externa* is inflammation of the outer ear and ear canal. It is commonly known as "swimmer's ear.")

Otitis media occurs between the eardrum and inner ear and involves the eustachian tube (Figure 23-11). Otitis often begins with viral or bacterial infections that cause sore throats, colds, or other respiratory problems that spread to the middle ear. Otitis media can be acute or chronic. It most commonly affects infants and young children, but can also occur in adults. Signs and symptoms of otitis media include:

- Chills
- Diarrhea
- Drainage from the ear
- Earache
- Ear noise or buzzing
- Fever
- Hearing loss
- Discomfort in the ear or ear canal
- Irritability
- General malaise
- Nausea
- Vomiting

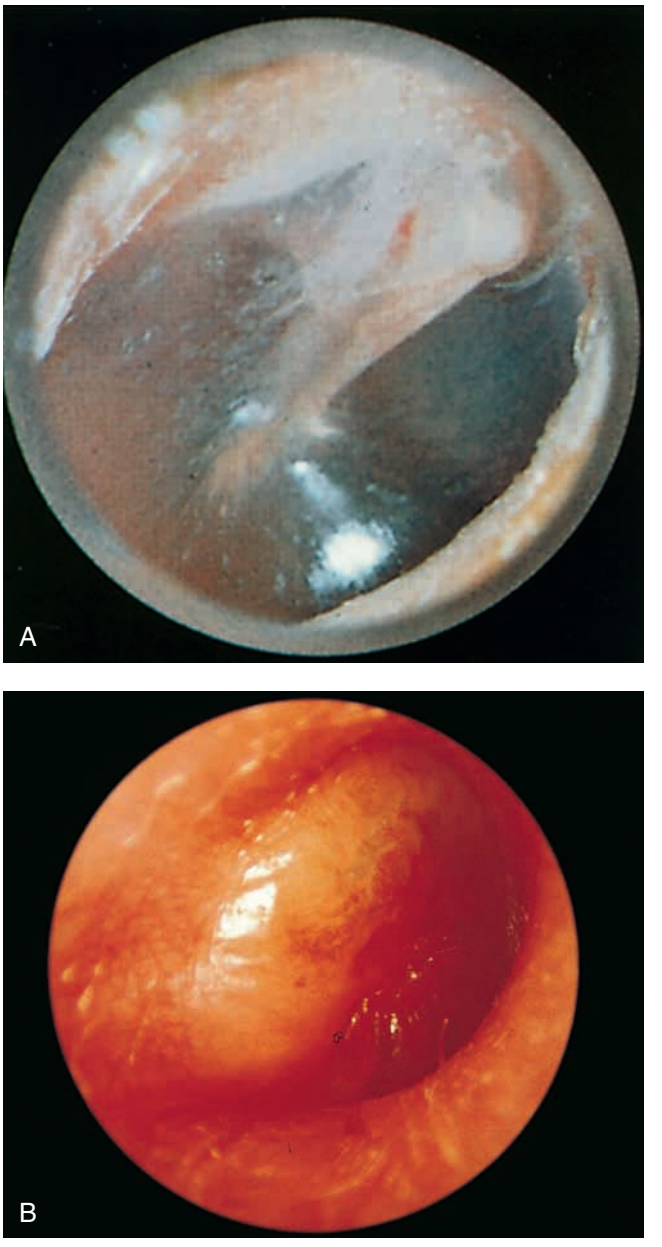

FIGURE 23-11 **A,** Normal tympanic membrane. **B,** Tympanic membrane with otitis media. (**A,** Courtesy Richard A. Buckingham, Clinical Professor, Otolaryngology, Abraham Lincoln School of Medicine, University of Illinois, Chicago, from Seidel HM, Ball JW, Dains JE, et al: *Mosby's guide to physical examination,* ed 5, St Louis, 2003, Mosby. **B,** Courtesy Michael Hawke, MD, from Zitelli BJ, Davis HD: *Atlas of pediatric physical diagnosis,* ed 4, St Louis, 2002, Mosby.)

NOTE

Infants and children have more ear infections than adults. This is due in part to the immature immune system of children. It is also related to the child's straighter and shorter eustachian tube that allows bacteria to reach the middle ear. One more factor is the larger adenoids in children that lie close to the eustachian tube. Enlarged adenoids can interfere with eustachian tube opening and, if infected, can spread the infection through the tube. It is estimated that 75% of children have at least one episode of otitis media by their third birthday. Half of these children will have three or more ear infections during their first 3 years.[14]

Otitis media causes severe pain and can have serious consequences. If untreated, the infection can travel from the middle ear to the brain and may lead to permanent hearing loss. Because the illness often strikes small children with limited speech and communications skills, the paramedic should be keen to subtle signs and symptoms such as irritability, tugging at the ear, fever, and drainage from the ear. Parents or other caregivers may notice a loss of balance, sleeplessness, and signs of hearing difficulty.

MANAGEMENT CONSIDERATIONS

Children with otitis media need to be evaluated by a physician. Until such time, the child should avoid contact with other children who are sick; the child should not be exposed to environmental smoke, which may aggravate the condition. Physician assessment will include an otoscope examination of the outer ear and eardrum. Various tests may also be used to assess middle ear fluid, eardrum movement, and hearing. Prescribed medications may include antibiotics for a bacterial infection, and agents to reduce pain and fever. Once the infection is eradicated, fluid may remain in the middle ear for several months. Follow-up with a physician is required. Other treatments may include surgical removal of the adenoids and the placement of tubes in the affected ears (myringotomy) to ventilate the middle ear. These procedures often are done at the same time.

Perforated Tympanic Membrane

Perforated tympanic membrane is a hole or rupture in the eardrum. Causes of perforation are usually from trauma or infection. Examples of traumatic causes of perforated tympanic membrane include blunt trauma to the ear, barotrauma, skull fracture, explosion or blast injury, and foreign bodies in the ear (see Part 9: Trauma). Otitis media is an example of an infection that can cause a perforated tympanic membrane (*otitis media with perforation*). Signs and symptoms of perforation caused by infection are those of middle ear infections (described previously), and include decreased hearing and an occasional bloody discharge. Pain is usually not persistent with perforation.

MANAGEMENT CONSIDERATIONS

Perforations of the tympanic membrane often cause a patient to be anxious, especially if it is related to trauma. However, prehospital care is primarily supportive. Most perforations of the eardrum heal without treatment within weeks of the rupture. Some perforations may take several months to heal. During the healing process, the affected ear should be protected from water and trauma. Perforations that do not heal on their own require advanced technologies and/or surgical intervention to close the tympanic membrane. These techniques often will restore or improve hearing.

The amount of hearing loss associated with perforations is related to the size and location of the hole in the tympanic membrane. A large hole that is close to inner ear structures will cause a greater hearing loss. The hearing loss may be severe. Chronic infection that results from perforation may also lead to progressive loss of hearing. Patients must be evaluated by a physician to determine the underlying cause.

CONDITIONS OF THE NOSE

As described in Chapter 10, the nose is the organ of smell (Figure 23-12). The nose is located in the middle of the face and is composed of several components:

- External meatus—the triangular-shaped projection in the center of the face
- External nostrils—two chambers divided by the septum
- Septum—composed primarily of cartilage and bone and covered by mucous membranes
- Nasal passages—passages that are lined with mucous membranes and cilia
- Sinuses—four pairs of air-filled cavities, also lined with mucous membranes

Common conditions that affect the nose are listed in Box 23-5.

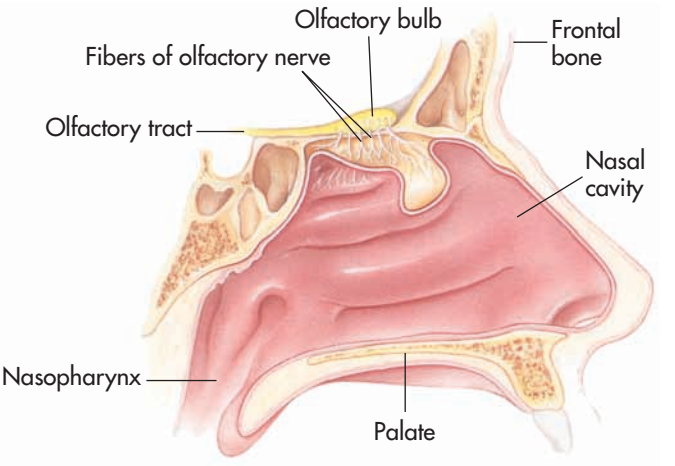

FIGURE 23-12 Anatomy of the nasal cavity. (From Shade BR: *Mosby's EMT-intermediate for the 1999 national standard curriculum,* ed 3, St Louis, 2007, Mosby.)

BOX 23-5 Conditions That Affect the Nose

Epistaxis
Foreign body
Rhinitis
Sinusitis

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 205-206.

Epistaxis

Epistaxis is acute hemorrhage from the nostril, nasal cavity, or nasopharynx. It is a fairly common occurrence and a frequent complaint in emergency departments. Bleeding from epistaxis is most commonly *anterior,* originating from the nasal septum. Less common is *posterior* bleeding, originating from the posterior nasal cavity or nasopharynx. Local trauma (nose picking) is the most common cause of epistaxis. This is followed by facial trauma, foreign bodies, nasal or sinus infection, and prolonged breathing of dry air. Other less common causes of epistaxis include:[15]

- Nasogastric and nasotracheal intubation
- Topical nasal drugs
- Upper respiratory tract infection (especially in children)
- Oral anticoagulants
- Medical conditions that affect coagulation, such as splenomegaly, thrombocytopenia, hemophilia, platelet disorders, liver disease, renal failure, chronic alcohol use, or acquired immunodeficiency syndrome (AIDS) related conditions
- Dry climates
- Vascular abnormalities (e.g., sclerosis, neoplasm, aneurysm, endometriosis)
- Use of cocaine or other drugs that are inhaled (Figure 23-13)

NOTE

Nosebleeds can occur at any age, but are most common in children ages 2 to 10 years and in adults ages 50 to 80 years. For unknown reasons, nosebleeds most commonly occur in the morning hours.

SHOW ME THE EVIDENCE

Researchers in the United Kingdom evaluated the relative risk of epistaxis in patients taking low-dose aspirin or clopidogrel compared to patients who took none of these drugs. There was an increased risk of epistaxis in both drug groups, but little difference in risk between groups taking clopidogrel versus those taking low-dose aspirin.

Rainsbury JW, Molony NC: Clopidogrel versus low-dose aspirin as risk factors for epistaxis, *Clin Otolaryngol* 34(3):232-235, 2009.

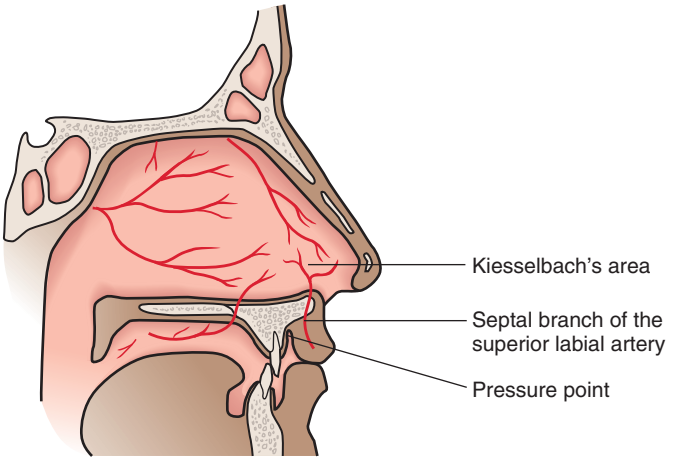

FIGURE 23-13 Epistaxis. (From Kulig K: Epistaxis. In Rosen P, et al: *Emergency medicine: concepts and clinical practice,* St Louis, 1983, Mosby.)

MANAGEMENT CONSIDERATIONS

Most nosebleeds can be visualized in the anterior portion of the nasal cavity. If not, the source of bleeding is likely posterior. This is especially true if the bleeding is coming from both nares, or if blood is draining into the posterior pharynx. If time permits, the patient should be questioned about previous nosebleeds, medication use that may cause or worsen epistaxis (e.g., aspirin, nonsteroidal antiinflammatory drugs [NSAIDs], Coumadin), hypertension, family history, and preexisting disease.

NOTE

Hypertension is rarely a direct cause of epistaxis. Patients with epistaxis usually have an elevated blood pressure because of their anxiety. However, nosebleeds in hypertensive patients are more often caused by long-standing disease and not the hypertension. Management should focus on controlling hemorrhage and reducing anxiety as the primary means of blood pressure reduction.

Prehospital care for epistaxis consists of controlling the hemorrhage and calming the patient. To control bleeding, the conscious patient should be positioned upright and leaning forward. (An unconscious patient should be positioned on the side, if not complicated by injury.) Direct pressure should be applied midway on the nose for about 5 minutes or until bleeding subsides. An emesis basin should be nearby to catch any blood or drainage. Packing the nose to control bleeding should not be attempted in the prehospital setting. If bleeding is severe or prolonged, the patient should be treated for shock and transported for physician evaluation (Figure 23-14).

FIGURE 23-14 Epistaxis. (From Henry MC, Stapleton ER: *EMT prehospital care,* ed 4, St Louis, 2009, Mosby.)

Foreign Body

As described previously, a foreign body placed in the ear or nose is a common occurrence. Beans or other foodstuffs, beads, paper wads, and eraser tips are frequently found in the noses of young children. The foreign bodies usually lodge on the floor of the anterior or middle third of the nasal cavity. Most cases are not serious, and most foreign bodies can be easily removed by a physician. Signs and symptoms of a foreign body in the nose include obstruction to airflow in the affected nostril, nasal discomfort, tearing, and unilateral nasal discharge (sometimes foul smelling).

NOTE
If a child has inserted a foreign body in the nose, suspect that more than one object has been placed. The ears of the child should also be inspected for foreign bodies.

MANAGEMENT CONSIDERATIONS

Prehospital care for foreign bodies in the nose is limited to gentle examination of the nares. A cooperative patient may be coached to blow his or her nose to try to expel the foreign body. Foreign bodies that are easily visible may be removed with alligator forceps. The patient must be cooperative, and special care must be taken not to push the object deeper into the nasal cavity. Most likely, the patient will require physician evaluation and topical anesthesia. Small children may need to be restrained or sedated for the examination. Methods to remove foreign bodies in the nose include removal by forceps and irrigation or by use of Foley catheters: after the catheter is passed beyond the foreign body, the balloon is inflated and the object is pulled out through the nose.

Rhinitis

Rhinitis is commonly known as a "runny nose." The term is used to describe irritation and inflammation of the mucous membranes of the nose, often caused by a virus, bacteria, or allergens (*allergic rhinitis*). A foreign body in the nose can also cause rhinitis. The hallmark feature of rhinitis is nasal drip, caused by an increase in histamine production. The increase in the amount of histamine increases the production of mucus. Other symptoms of rhinitis include nasal congestion and itchy eyes and nose.

MANAGEMENT CONSIDERATIONS

Prehospital care for a patient with rhinitis is primarily supportive. Emergency care or transport is seldom needed. Patients should be advised to follow up with their private physician if symptoms persist. Treatment for rhinitis usually consists of use of antihistamines, avoidance of exposure to suspected allergens or irritants, and sometimes administration of antibiotics if the cause is bacterial.

Sinusitis

Sinusitis (sinus infection) is inflammation of the sinuses and nasal passages. The condition can be caused by a viral, bacterial, or fungal infection. Symptoms of sinusitis include headache, and pressure in the eyes, nose, or cheek area. Often the discomfort is limited to one side of the head. Sinusitis may also be associated with a cough, fever, bad breath (halitosis), and nasal congestion. The nasal congestion can produce thick nasal secretions. Sinusitis affects 37 million people each year, making it a common health condition in the United States.[16]

As described in Chapter 10, the paranasal sinuses are four pairs of air-filled sacs that connect the space between the nostrils and the nasal passages. These include the frontal sinuses (in the forehead), the maxillary sinuses (behind the cheek bones), the ethmoid sinuses (between the eyes), and the sphenoid sinuses (behind the eyes). Normally, mucus that collects in the sinuses drains into the nasal passages and is eliminated from the body. When a patient has a cold or allergy, the sinuses can become inflamed and unable to drain, leading to congestion and infection. Sinusitis can be acute or chronic (lasting 3 months or more). Chronic sinusitis can damage the sinuses and cheekbones, and can sometimes require surgical intervention.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 191-193.

MANAGEMENT CONSIDERATIONS

Prehospital care for patients with sinusitis is primarily supportive. Because the signs and symptoms are easily confused with those of a cold or allergy, the chart in Box 23-6

BOX 23-6 Signs and Symptoms of Sinusitis, Allergy, and Cold

What are the symptoms of sinusitis versus a cold or allergy?

Sign/Symptom	Sinusitis	Allergy	Cold
Facial pressure/pain	Yes	Sometimes	Sometimes
Duration of illness	More than 10-14 days	Varies	Less than 10 days
Nasal discharge	Whitish or colored	Clear, thin, watery	Thick, whitish, or thin
Fever	Sometimes	No	Sometimes
Headache	Sometimes	Sometimes	Sometimes
Pain in upper teeth	Sometimes	No	No
Bad breath	Sometimes	No	No
Coughing	Sometimes	Sometimes	Yes
Nasal congestion	Yes	Sometimes	Yes
Sneezing	No	Sometimes	Yes

From Sinusitis, American Academy of Otolaryngology-Head and Neck Surgery, http://www.entnet.org/HealthInformation/Sinusitis.cfm, accessed 8-18-10.

can aid in a differential diagnosis. Patients should be encouraged to follow up with their private physician, where treatment may include antibiotics for bacterial infection, antihistamines, and decongestants.

CONDITIONS OF THE OROPHARYNX AND THROAT

As described in Chapter 10, the oropharynx begins at the level of the uvula and extends down to the level of the epiglottis. The oropharynx opens into the oral cavity. This cavity contains the lips, cheeks, teeth, tongue, the hard and soft palates, and the palantine tonsils. The throat is the anterior portion of the neck, located in front of the vertebral column. The throat consists of the pharynx and larynx. It also contains the epiglottis, which separates the esophagus from the trachea (Figure 23-15). Box 23-7 lists common conditions that affect these structures.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 191-192.

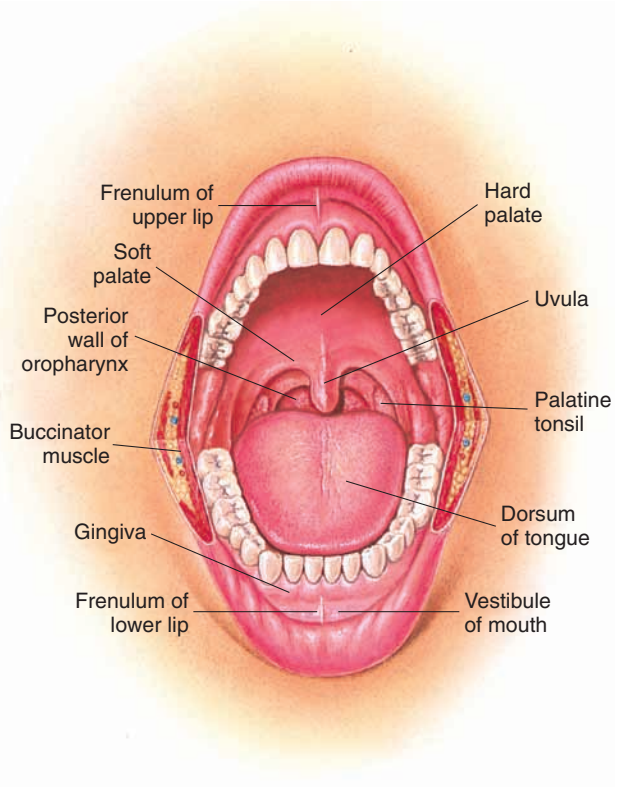

FIGURE 23-15 Anatomic structures of the oral cavity. (From Seidel H, et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

Toothache and Dental Abscess

The medical term for toothache is **dentalgia.** Toothache usually refers to pain around the teeth or jaws. Common causes of toothache include dental cavities, **dental abscess** (a bacterial infection in the center of the tooth), a cracked tooth, an exposed tooth root, and gum disease. The most common cause of toothache is a dental cavity; the second most common cause is gum disease.

The normal adult mouth has 32 teeth. Each tooth consists of two sections: the *crown* and the *root*. The crown projects above the oral mucosa around the tooth. The root fits into the bony socket of the maxilla or mandible. There are three layers that comprise the hard tissues of the teeth. They are the *enamel,* the *dentin* (ivory), and the *cementum*. The soft tissues of the teeth include the *pulp* and *periodontal membrane* (Figure 23-16). Symptoms of toothache include:

- Sharp, throbbing, or constant pain in the tooth
- Swelling around the tooth
- Fever or headache
- Foul-tasting drainage from infection of the tooth

MANAGEMENT CONSIDERATIONS

Prehospital care for a patient with a toothache is primarily supportive. Follow-up with a private dentist or oral surgeon should be recommended. Dental care will vary by nature of the problem and may include cavity fill, tooth extraction, root canal, x-ray, phototherapy to reduce pain, and antibiotics to treat bacterial infection. Proper identification and treatment of dental infections is important. Infection that is not treated can spread to other parts of the face and skull, and may even enter the bloodstream (sepsis). Prehospital care for the patient who has suffered dental trauma will be addressed in Chapter 40.

BOX 23-7 Conditions That Affect the Oropharynx and Throat

Toothache and dental abscess
Ludwig's angina
Foreign body*
Epiglottitis
Laryngitis
Tracheitis
Oral candidiasis
Peritonsillar abscess
Pharyngitis/tonsillitis
Temporomandibular joint disorders

*Foreign body airway obstruction was described in Chapter 15.

CRITICAL THINKING
What serious medical condition should be ruled out in high-risk patients who complain of tooth or jaw pain?

Ludwig's Angina

Ludwig's angina is a type of cellulitis that involves inflammation of the tissues of the floor of the mouth, under the tongue. It can occur following dental abscess or mouth injury. Ludwig's angina is most common in adults. The disease can cause swelling of the tissues that can occur rapidly. The swelling may block the airway or prevent

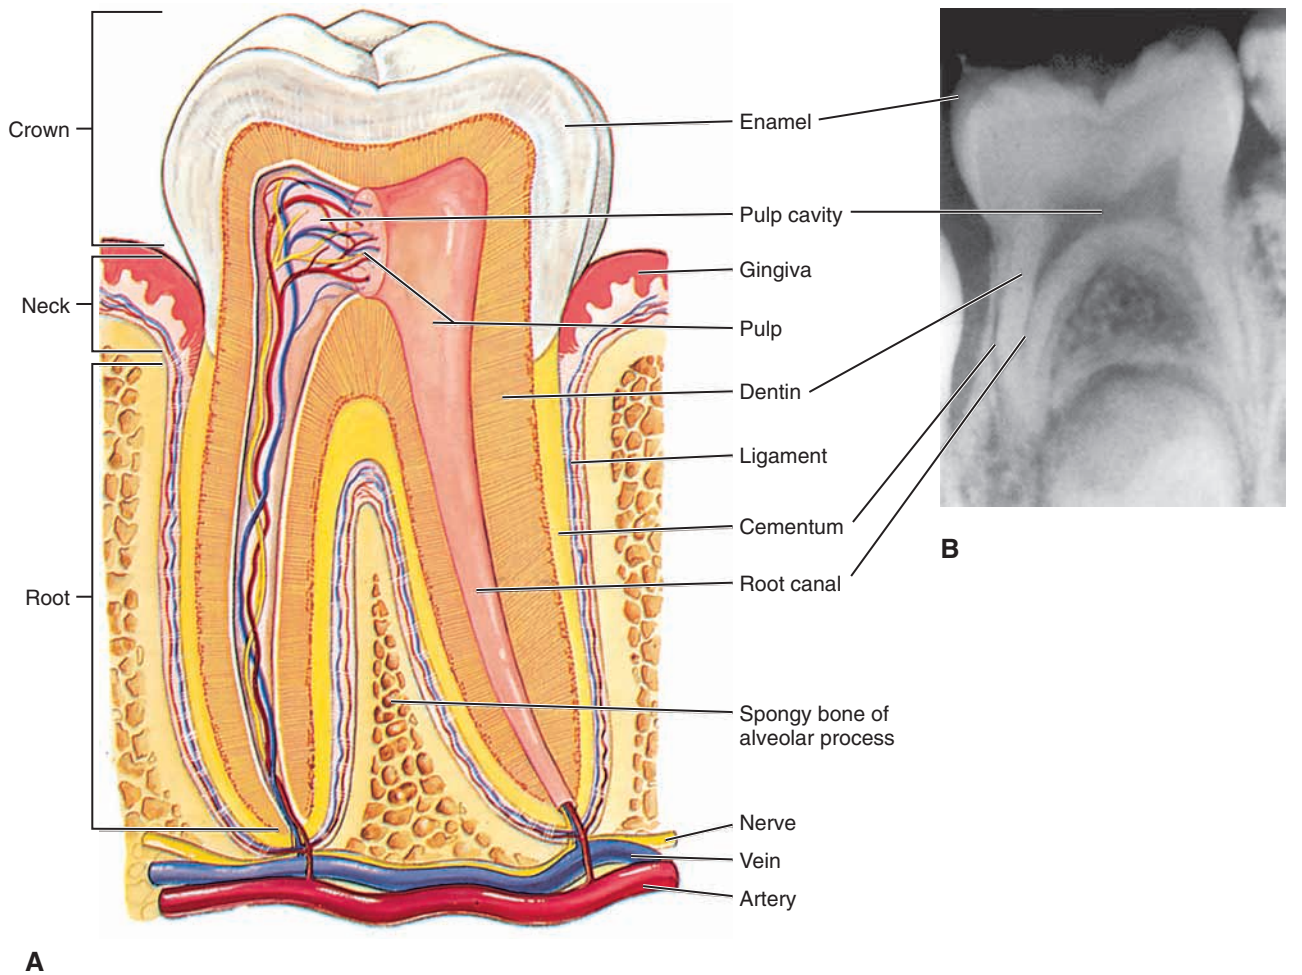

FIGURE 23-16 Tooth anatomy. **A,** Sagittal section of a lower molar. **B,** X-ray of a healthy tooth. (From Solomon EP: *Introduction to human anatomy and physiology,* Philadelphia, 2009, Saunders.)

swallowing of saliva. Signs and symptoms of Ludwig's angina may include:

- Breathing difficulty
- Confusion or other mental changes
- Fever
- Neck pain
- Neck swelling
- Redness of the neck
- Weakness, fatigue, excessive tiredness
- Drooling
- Earache

MANAGEMENT CONSIDERATIONS

Ludwig's angina is a medical emergency that can be life threatening. Prehospital care may include airway and ventilatory support. Rapid transport to an emergency department is indicated. Physician care may include airway maintenance, computed tomography (CT) scan, blood cultures to identify the bacteria, IV/oral antibiotics, and surgery to drain fluids that are causing the swelling. Although Ludwig's angina can be successfully treated, possible complications include complete airway obstruction, sepsis, and septic shock.

Epiglottitis

As the name implies, **epiglottitis** is inflammation of the epiglottis. The disease is caused by a bacterial infection that can lead to life-threatening airway obstruction. It can occur at any age. The bacterial infection causes edema and swelling of the epiglottis and supraglottic structures. The disease usually begins suddenly in children. It frequently occurs after a child goes to bed. Signs and symptoms include sore throat, pain on swallowing, drooling, fever, and a muffled voice. Classic signs of respiratory distress usually are present.

NOTE
The HiB vaccine has greatly reduced the number of cases of epiglottitis in children.[17]

MANAGEMENT CONSIDERATIONS

Epiglottitis is a true emergency that requires prompt recognition and immediate transport for definitive care (see Chapter 48). Airway occlusion can occur suddenly. This can be precipitated by minor irritation of the throat, aggravation, and anxiety. It is therefore important that these patients be handled gently. Patients with suspected epiglottitis should not lie down. They should be transported in a position of comfort that helps them breathe and facilitate drainage of oral fluids. IV access should not be attempted in the field to avoid creating anxiety and agitation in the child. High-concentration oxygen should be applied by mask, unless it provokes anxiety. If respiratory arrest occurs before emergency department (ED) arrival, the patient should be intubated by the most experienced paramedic (intubation will likely be difficult). In-hospital care may include airway and circulatory support, placement of a surgical airway, and IV antibiotic therapy.

Laryngitis

Laryngitis is swelling and irritation of the larynx that inflames the vocal cords. It is usually associated with hoarseness or loss of voice, and swollen glands and lymph nodes in the neck. The most common form of laryngitis is caused by a virus, and often occurs along with an upper respiratory tract infection. Other causes include allergies, bacterial infection, bronchitis, pneumonia, influenza, and exposure to irritants or chemicals.

MANAGEMENT CONSIDERATIONS

Laryngitis is usually not a serious condition and typically improves without treatment. (Only rarely does respiratory distress develop.) Prehospital care is primarily supportive. Patients should be encouraged to follow up with their private physician if symptoms persist. Recommendations may include resting the voice and humidifying the air at home. Drug therapy may include analgesics, decongestants, and antibiotics if the infection is bacterial. Young children with laryngitis may need to be seen by a specialist for further evaluation.

Tracheitis

Tracheitis is a bacterial infection of the upper airway and subglottic trachea. The major site of the disease is at the level of the cricoid cartilage, the narrowest part of the trachea. The disease generally occurs in infants and toddlers (1 to 5 years of age) but can also occur in older children. It frequently follows a viral upper respiratory tract infection (see Chapter 48). Signs and symptoms are those of respiratory distress or respiratory failure (depending on severity). These include agitation, high-grade fever, inspiratory and expiratory stridor, productive cough, hoarseness, and throat pain.

NOTE
Tracheitis is an uncommon infectious cause of upper airway obstruction, but is more prevalent than acute epiglottitis.[18]

MANAGEMENT CONSIDERATIONS

Emergency care is focused on providing airway, ventilatory, and circulatory support, and rapid transport to an appropriate medical facility. If respiratory failure or arrest develops in the field, tracheal intubation and tracheal suction are indicated. (High-pressure bag-mask ventilation may be needed because of airway swelling and accumulation of mucus or pus.) In-hospital care will include IV antibiotics after the child's airway has been stabilized.

Oral Candidiasis

Oral candidiasis (also known as *thrush*) is an infection of yeast fungi of the genus *Candida*. It affects the mucous membranes of the mouth. The infection usually appears as thick or white cream-colored deposits on the mucosal membranes (Figure 23-17). The area may appear inflamed and can be painful. Bleeding can occur from irritation of the area. Oral candidiasis most commonly affects infants and toddlers, and those with impaired immune function. The disease is contagious, but is seldom passed from person-to-person if immune systems are healthy. Persons at risk for oral candidiasis include:

- Newborns
- Those with diabetes
- Those taking antibiotics or inhaled corticosteroids
- Those with immune deficiencies (human immunodeficiency virus [HIV], AIDS, cancer)
- Those with oral piercings
- Denture wearers

MANAGEMENT CONSIDERATIONS

Emergency care is seldom required for patients with oral candidiasis. Physician care generally includes the use of topical or oral antifungal drugs. In severe cases, IV antifungal drugs may be needed.

Peritonsillar Abscess

Peritonsillar abscess (also called PTA or *quinsy*) is a collection of pus in and around one or both tonsils. The abscesses form in the area between the palatine tonsil and its capsule. It is a complication of **tonsillitis** (infection of the tonsils) and is the most common deep infection of the head and neck in adults. It is most common in persons 20 to 40 years of age who have chronic tonsillitis.[19] Presenting symptoms include fever, throat pain, and **trismus** (muscle spasms of the jaw).

MANAGEMENT CONSIDERATIONS

Prehospital care for the patient with peritonsillar abscess is primarily supportive. Physician care may include ultrasound, antibiotics, and procedures to remove the abscess material. These procedures may include needle aspiration or incision and drainage. Tonsillectomy also may be indicated.

FIGURE 23-17 White, curdlike plaques of thrush (oral candidiasis, oral moniliasis), a common fungal infection in infants. (From McKinney ES, et al: *Maternal-child nursing,* ed 3, St Louis, 2009, Saunders.)

Pharyngitis/Tonsillitis

Pharyngitis and tonsillitis are infections in the throat that cause inflammation. If the tonsils are primarily affected, it is called tonsillitis. If the throat is primarily affected, it is called pharyngitis. Inflammation of the throat usually is associated with an underlying illness. The most common cause of inflammation is a virus, but the inflammation may also be caused by bacteria (especially streptococci), resulting in **strep throat.** Signs and symptoms that accompany pharyngitis and tonsillitis depend on underlying illness, such as the common cold, influenza, and **mononucleosis:**[20]

Sore throat with common cold:

- Sneezing
- Cough
- Low-grade fever (temperature less than 102° F) (38.9° C)
- Mild headache

Sore throat with flu:

- Fatigue
- Body aches
- Chills
- Fever (temperature higher than 102° F) (38.9° C)

Sore throat with mononucleosis:

- Enlarged lymph nodes in neck and armpits
- Swollen tonsils
- Headache
- Loss of appetite
- Swollen spleen
- Liver inflammation

NOTE

Tonsillitis may be caused by a bacterial or a viral infection. The condition may be acute, recurrent, or chronic. Nearly all children in the United States have at least one episode of tonsillitis. Complications associated with the disease are rare. The herpes simplex virus, *Streptococcus pyogenes* (GABHS) and Epstein-Barr virus (EBV), cytomegalovirus, adenovirus, and the measles virus cause most cases of acute pharyngitis and acute tonsillitis.[21]

MANAGEMENT CONSIDERATIONS

Prehospital care for a patient with pharyngitis or tonsillitis is primarily supportive. Emergency care is seldom needed. Physician care may include antihistamines, cough suppressants, and antipyretics. Throat cultures and blood analyses may be needed if a bacterial infection requiring antibiotics or mononucleosis is suspected. Severe or recurrent tonsillitis may require tonsillectomy.

CRITICAL THINKING

What complications may occur if a patient's pharyngitis is related to strep throat and is not treated?

Temporomandibular Joint Disorders

The **temporomandibular joint** (TM joint; TMJ) is the joint on each side of the head in front of the ears where the mandible meets the temporal bones (Figure 23-18). TM joint disorders are a set of conditions that cause pain in the area of the joint. They may also involve associated muscles and can cause problems using the jaw. One or both of the TM joints may be affected. The disorders can influence a person's ability to speak, eat, chew, swallow, and make facial expressions. In severe cases, TM joint disorders can affect a person's ability to breathe. TM joint disorders affect about 35 million people in the United States. Most who seek treatment are women in their child-bearing years.[22]

Some of the causes of TM joint disorders are not clearly understood. Risk factors for developing the disorders include jaw injury, arthritis, dental procedures, infection, autoimmune disease, endotracheal intubation where the jaw is stretched to visualize the airway, and clenching or grinding of the teeth. TM joint disorders may also be a symptom of other diseases such as sinus or ear infection, periodontal disease, headaches, and facial neuralgia. Poor diet, stress, and lack of sleep may also contribute to the disease. Common complaints associated with TM joint disorders include:

- Pain in the neck and shoulders
- Headache
- Jaw muscle stiffness
- Limited movement or locking of the jaw
- Painful clicking, popping, or grating in the jaw joint when opening or closing the mouth
- A change in the way the upper and lower teeth fit together or a bite that feels "off"
- Ringing in the ears
- Ear pain
- Decreased hearing
- Dizziness and vision problems.

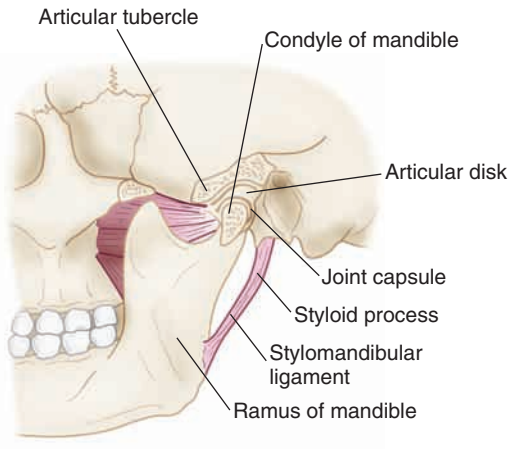

FIGURE 23-18 Structures of the temporomandibular joint. (From Seidel H, et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

MANAGEMENT CONSIDERATIONS

The symptoms of TM joint disorders are usually temporary, but may be painful. In addition, patients experiencing discomfort will often be anxious. Prehospital care should be focused on calming the patient and providing comfort measures. Physician care may include diagnostic tests of the head, neck, face, and jaw. A complete medical history will also be obtained to rule out other possible causes for the disorder. Health care professionals who may be involved in the patient's treatment and recovery include dentists; sleep specialists; ear, nose, and throat specialists; neurologists; endocrinologists; rheumatologists; and pain specialists.

SUMMARY

- The eye is composed of both primary vision structures and accessory structures, which protect, lubricate, move, and aid in the function of the visual structures. Cranial nerves control vision, pupil constriction, and movement of the eyes. Consider nervous system disease if these functions are impaired.
- Conjunctivitis is inflammation or infection of the eye and is sometimes called pink eye. Infectious conjunctivitis is contagious.
- A corneal abrasion is a scrape or scratch of the cornea. It is very painful and may cause tearing, redness, and blurred vision. Patch the eye and administer a topical ophthalmic anesthetic if permitted by protocol.
- Foreign bodies in the eye are very painful and cause pain and tearing. Irrigation of the eye may be indicated to remove small foreign bodies.
- Two types of eyelid inflammation are chalazion (obstructed oil gland) and hordeolum (stye).
- Glaucoma is caused by an increase in intraocular pressure related to excess aqueous humor. This results in pressure on the optic nerve and can lead to blindness if untreated. Signs and symptoms include loss of peripheral vision, pain, headache, vomiting, or blurred vision.
- Iritis is inflammation of the iris. It can cause blindness if untreated.
- Papilledema is swelling of the optic disc caused by an increase in intracranial pressure (ICP). The increased ICP may be related to illness or injury.
- The retina is the eye structure central to vision. Tears, breaks, or defects in the retina cause retinal detachment. Without treatment, retinal detachment leads to blindness. Signs and symptoms include an increase in

Continued

floaters, light flashes in the eye, or the appearance of a curtain over the field of vision.
- Central retinal artery occlusion occurs when blood supply to the retina is blocked. If circulation is not reestablished within 60 to 90 minutes permanent loss of vision occurs. Onset is marked by sudden, painless loss of vision or the sense that a shade has been pulled down over the eye.
- Orbital cellulitis is an infection of the tissue around the eye that can lead to serious complications that include blindness, sepsis, and meningitis. Signs and symptoms include fever, pain and swelling of the eyelids, eye pain, decreased vision, bulging eyes, malaise, and impaired eye movement. Immediate treatment with IV antibiotics is essential.
- When excess earwax (cerumen) accumulates in the ear it can cause earache, hearing loss, tinnitus, itching, odor, or discharge. Removal of the wax usually resolves the symptoms.
- Swelling of the inner ear causes labyrinthitis. This results in vertigo and tinnitus.
- Meniere's disease causes vertigo, tinnitus, and hearing loss. This can lead to nausea and vomiting. Stroke can cause similar symptoms and should be ruled out.
- Otitis media is an infection or inflammation of the middle ear. In addition to earache, it can produce a number of signs and symptoms.
- Infection or trauma can cause perforation of the tympanic membrane. This can result in brief pain, hearing loss, and drainage from the affected ear.
- Epistaxis is bleeding from the structures of the nose or nasopharynx. Attempt to control epistaxis by positioning the patient upright, leaning forward. Apply direct pressure on the nose until bleeding is controlled. Treat for shock if indicated.
- It is common for children to place foreign bodies in their nose. Transport for physician examination and removal.
- Rhinitis is a runny nose. Common causes are infection, allergy, or foreign body in the nose.
- Sinusitis is inflammation of sinuses and nasal passages. Signs and symptoms include cough, fever, halitosis, nasal congestion, headache, and pressure sensation over the eyes, nose or cheek.
- Toothache is frequently caused by tooth decay, abscess, cracked tooth, exposed root, or gum disease. Transport for definitive care and pain management.
- Ludwig's angina is cellulitis of the tissues under the tongue. It can cause rapid tissue swelling and airway obstruction. Signs and symptoms include dyspnea, confusion, fever, neck pain, redness or swelling, and weakness or drooling. Urgent transport is needed.
- Epiglottitis is inflammation of the epiglottis caused by bacterial infection. It can lead to airway obstruction. Signs and symptoms include sore throat, high fever, drooling, and muffled voice. Airway obstruction is possible. Perform minimal interventions unless airway obstruction occurs.
- Laryngitis is a hoarse voice and swollen lymph nodes associated with inflamed vocal cords.
- Tracheitis is a bacterial infection of the upper airway and subglottic trachea. It can cause respiratory failure and arrest. Be prepared to manage the airway and assist with ventilation if needed.
- Oral candidiasis is a yeast fungal infection of the mouth. It covers the tongue and mucous membranes with a thick cream-colored coating.

CHAPTER

24 Respiratory

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Distinguish the pathophysiology of respiratory emergencies related to ventilation, diffusion, and perfusion.
2. Outline the assessment process for the patient who has a respiratory emergency.
3. Describe the causes, complications, signs and symptoms, and prehospital management of patients diagnosed with obstructive airway disease, pneumonia, adult respiratory distress syndrome, pulmonary thromboembolism, upper respiratory tract infection, spontaneous pneumothorax, hyperventilation syndrome, and lung cancer.

KEY TERMS

acute respiratory distress syndrome A fulminant form of respiratory failure characterized by acute lung inflammation and diffuse alveolar-capillary injury.

aspiration pneumonia Inflammation of the lung tissue from foreign material entering the tracheobronchial tree.

asthma A respiratory disorder characterized by recurring episodes of paroxysmal dyspnea, wheezing on expiration caused by constriction of the bronchi, coughing, and viscous mucoid bronchial secretions.

bacterial pneumonia A type of pneumonia associated with a bacterial infection.

biphasic positive airway pressure Airway support that combines partial ventilatory support and continuous positive airway pressure; allows the pressure to vary during each breath cycle.

bleb An accumulation of fluid under the skin.

bronchiectasis An abnormal dilation of the bronchi caused by a pus-producing infection of the bronchial wall.

bullae Thin-walled blisters of the skin or mucous membranes that contain clear, serous fluid.

chronic bronchitis Obstructive airway disease of the trachea and bronchi.

continuous positive airway pressure Airway support that transmits positive pressure into the airways of a spontaneously breathing patient throughout the respiratory cycle.

deficient ambient oxygen An oxygen concentration that is less than 21%.

diffusion The process in which solid, particulate matter in a fluid moves from an area of higher concentration to an area of lower concentration, resulting in an even distribution of the particles in the fluid.

emphysema An abnormal condition of the pulmonary system characterized by overinflation and destructive changes in the alveolar walls, resulting in a loss of lung elasticity and a decrease in gases.

glottic opening The vocal cords and the space between them.

hemoptysis Coughing up of blood from the respiratory tract.

hyperventilation syndrome Abnormally deep or rapid breathing that leads to excessive loss of carbon dioxide, resulting in respiratory alkalosis.

lung cancer A disease of uncontrolled cell growth in tissues of the lung.

metastasis The movement or spreading of cancer cells from one organ or tissue to distant locations in the body.

mycoplasmal pneumonia A type of atypical pneumonia. It is caused by the bacterium *Mycoplasma pneumoniae*.

near-fatal asthma Acute asthma associated with respiratory arrest, a drop in blood pressure, and reduced cardiac output.

peak expiratory flow rate A measurement of how fast a person can exhale air.

perfusion The circulation of blood to the tissues.

pneumonia An acute inflammation of the lungs, usually caused by inhaled pneumococci of the species *Streptococcus pneumoniae*.

positive end-expiratory pressure Airway support that maintains a degree of positive pressure at the end of exhalation.

pulmonary embolism The blockage of a pulmonary artery by foreign matter such as fat, air, tumor tissue, or a thrombus that usually arises from a peripheral vein.

pulmonary respiration The exchange of gases between the cells of the body and the outside environment.

spontaneous pneumothorax A condition that results when a subpleural bleb ruptures, allowing air to enter the pleural space from within the lung.

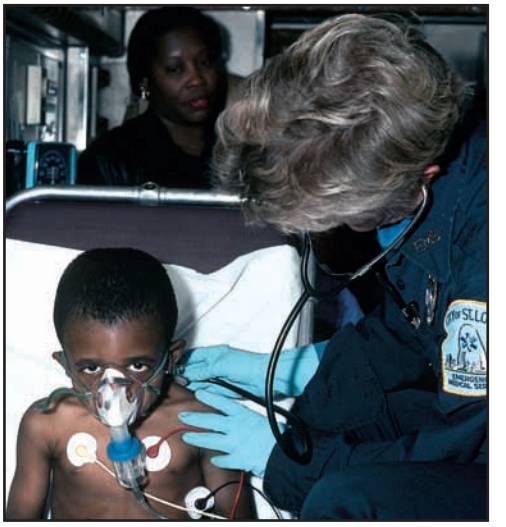
status asthmaticus A severe, prolonged asthma attack that has not been broken with repeated doses of bronchodilators.

upper respiratory tract infection Infection of the upper airway, affecting the nose, throat, sinuses, and larynx.

ventilation The mechanical movement of air into and out of the lungs; makes respiration possible.

viral pneumonia An inflammation of the lungs caused by viral infection.

Respiratory emergencies are common in the prehospital setting. They account for 28% of the chief complaints in all EMS calls.[1] Each year more than 400,000 people die as a result of respiratory emergencies in the United States.[2] Therefore, patients with respiratory emergencies require the highest priority of care. The paramedic must be able to quickly assess a patient with respiratory distress, identify the cause, initiate management, and provide appropriate care en route to the hospital.



(Courtesy Monroe Yancey, St. Louis, Mo.)

NOTE

Age-related variations in disease and methods of patient assessment are described throughout this textbook by subject matter. Respiratory diseases specific to children will be addressed in Chapter 48; those unique to older adults will be presented in Chapter 49; those associated with infectious disease (e.g., tuberculosis) will be presented in Chapter 28. Respiratory emergencies related to trauma will be presented in Part 9: Trauma.

ANATOMY AND PHYSIOLOGY REVIEW

As described in Chapter 10, the structures of the respiratory system are divided into upper and lower airways. Their location is assigned in relation to the **glottic opening** (the vocal cords and the space between them). For the purpose of this chapter, upper airway structures are those located above the glottis. Lower airway structures are those located below the glottis. The upper and lower airway structures include (Figure 24-1):

Upper Airway Structures
- Nasopharynx
- Oropharynx
- Laryngopharynx
- Larynx

Lower Airway Structures
- Trachea
- Bronchial tree
- Alveoli
- Lungs

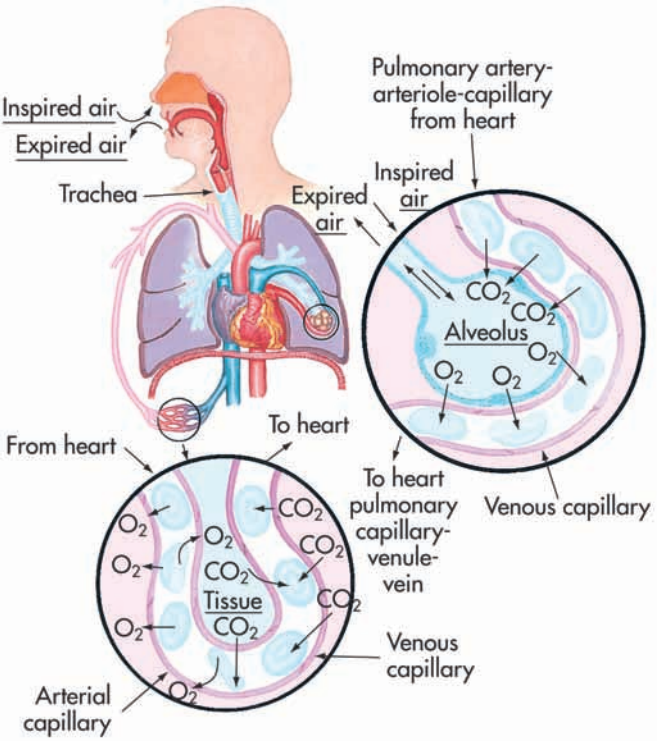


FIGURE 24-1 Structures of the pulmonary system. The circles denote the alveoli. (Modified from Wilson SF, Thompson JM: *Mosby's clinical nursing series: respiratory disorders,* St Louis, 1990, Mosby.)

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 191-196.

Physiology

The exchange of gases between the cells of the body and the outside environment is the essence of respiratory physiology. As described in Chapter 15, for gas exchange to occur, air must move freely in and out of the lungs. This process, known as pulmonary respiration, brings oxygen to the lungs and removes carbon dioxide. This is made possible by:

- *External respiration:* the transfer of oxygen and carbon dioxide between inspired air and pulmonary capillaries
- *Internal respiration:* the transfer of oxygen and carbon dioxide between the capillary red blood cells and the tissue cells

LOOK AGAIN

See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 391-411.

There are many other factors that are essential elements of pulmonary respiration. One of these factors is the structure and function of the chest wall (diaphragm, ribs, intercostal muscles, accessory muscles). Another factor is the control of respirations by the central nervous system (medulla, phrenic nerve innervation of the diaphragm, spinal nerves that innervate intercostal muscles, and reflexes that prevent overinflation). Acid-base balance mediated by the buffer systems also plays an important role in respiration (see Chapter 11).

LOOK AGAIN

See Chapter 11: General Principles of Pathophysiology, pp. 226-227.

PATHOPHYSIOLOGY

A variety of problems can affect the pulmonary system's ability to achieve gas exchange. Gas exchange must occur to provide for cellular needs and the excretion of wastes (see Chapter 10 and Chapter 15). Specific disorders responsible for respiratory emergencies include those related to ventilation, diffusion, and perfusion. Risk factors associated with the development of respiratory disease are listed in Box 24-1. The following discussion of pulmonary physiology serves as a review.

Ventilation

Ventilation is the process of air movement into and out of the lungs. For ventilation to occur, the following must be intact:

- Neurological control (to initiate ventilation)
- Nerves between the brainstem and the muscles of respiration
- Functional diaphragm and intercostal muscles
- Patent upper airway
- Functional lower airway
- Alveoli that are functional and have not collapsed

Specific pathophysiologies associated with ventilation include upper and lower airway obstruction, chest wall impairment, and problems in neurological control. Emergency treatments for ventilation problems include ensuring the upper and lower airways are open and clear and providing assisted ventilations (Box 24-2).

BOX 24-1 Risk Factors Associated With the Development of Respiratory Disease

Intrinsic Factors

Genetic predisposition may influence the development of these conditions:

- Asthma
- Obstructive lung disease
- Cancer

Cardiac or circulatory disorders may influence the development of these conditions:

- Pulmonary edema
- Pulmonary emboli

Stress may increase the following:

- Severity of respiratory complaints
- Frequency of attacks of asthma and chronic obstructive pulmonary disease (COPD)

Extrinsic Factors

Smoking increases the following:

- Prevalence of COPD and cancer
- Severity of virtually all respiratory disorders

Environmental pollutants increase the following:

- Prevalence of COPD
- Severity of all obstructive airway disorders

Diffusion

Diffusion is the process of gas exchange. This gas exchange occurs between the air-filled alveoli and the pulmonary capillary bed. Gas exchange is driven by simple diffusion in which gases move from areas of high concentration to areas of low concentration. (This occurs until the concentrations are equal.) For diffusion to occur, the following must be intact:

- Alveolar and capillary walls that are not thickened
- Interstitial space between the alveoli and capillary wall that is not enlarged or filled with fluid

Specific pathophysiologies associated with diffusion include inadequate oxygen concentration in ambient air, alveolar disorders, interstitial space disorders, and capillary bed disorders (Box 24-3). Emergency treatment for diffusion problems includes providing high-concentration oxygen. Treatment is also directed at reducing inflammation in the interstitial space.

BOX 24-2 Causes of Ventilation Problems

Upper Airway Obstruction
- Trauma
- Epiglottitis
- Laryngotracheobronchitis
- Abscess
- Foreign body obstruction
- Inflammation of the tonsils

Lower Airway Obstruction
- Trauma
- Obstructive/restrictive lung disease
- Emphysema
- Chronic bronchitis
- Mucus accumulation
- Reactive airway disease
- Smooth muscle spasm, including asthma
- Airway edema

Chest Wall Impairment
- Spontaneous pneumothorax
- Pleural inflammation
- Pleural effusion
- Neuromuscular diseases
- Muscular sclerosis
- Muscular dystrophy

BOX 24-3 Causes of Diffusion Problems

Inadequate oxygen concentration in ambient air
Alveolar pathology
Asbestosis; other environmental lung diseases
Blebs/bullae associated with COPD
Inhalation injuries
Interstitial space pathology
Pulmonary edema
Acute respiratory distress syndrome
Submersion/drowning
Acute lung syndrome (ALS)

Perfusion

Perfusion is the process of circulation of the blood through the lung tissues (capillary bed). For perfusion to occur, the following must be intact:
- Adequate blood volume
- Adequate hemoglobin in the blood
- Pulmonary capillaries that are not occluded
- Efficient pumping by the heart that provides a smooth flow of blood through the pulmonary capillary bed

Specific pathophysiologies associated with perfusion include inadequate blood volume, impaired circulatory blood flow, and capillary wall disorders (Box 24-4). Emergency treatment for perfusion problems includes ensuring an adequate circulating blood volume and hemoglobin levels. Treatment also may be needed to optimize left-sided heart function (see Chapter 22).

BOX 24-4 Causes of Perfusion Problems

Inadequate blood volume/hemoglobin levels
Hypovolemia
Anemia
Impaired circulatory blood flow
Pulmonary embolus

Unknown Pulmonary Diagnosis

If the patient's diagnosis is unknown, paramedics should try to determine whether it is primarily related to ventilation, diffusion, or perfusion, or to a combination of defects. Care for a patient with an unknown pulmonary diagnosis should be focused on the specific disorder responsible for the respiratory emergency. That is, is the problem a disorder of ventilation, diffusion, or perfusion? Ventilation disorders are managed by assisting the patient's airway using mechanical means (e.g., opening the airway, relieving airway obstructions, clearing the airway of secretions, the use of airway adjuncts). Diffusion disorders are treated to improve gas exchange between the alveoli and the pulmonary capillary bed (e.g., medications to improve breathing and reduce inflammation in the airways, continuous positive airway pressure [CPAP]). Perfusion disorders are managed by improving the circulation of blood through the lung tissues (e.g., intravenous [IV] fluids, medications to improve cardiac function). Regardless of the specific disorder, all patients with respiratory compromise should receive high-concentration oxygen and ventilatory support as needed.

NOTE

Pulmonary complaints may be associated with exposure to environments that have deficient ambient oxygen. Examples include scenes with poisonous or toxic gases. During the scene size-up, it is critical to ensure a safe environment for all EMS personnel before initiating patient contact. Rescue personnel with special training and equipment should be utilized as needed to ensure scene safety. **Deficient ambient oxygen** is defined as oxygen concentration that is less than 21%. (An oxygen concentration less than 16% is immediately dangerous.) Oxygen can be consumed or displaced by toxic or inert gas (e.g., carbon monoxide, methane gas), and is usually associated with confined or enclosed spaces. Poison gases are hazardous because they can harm lower airways, cause bronchospasm, or interfere with the blood's ability to carry oxygen or the cell's ability to use oxygen (e.g., exposure to hydrogen cyanide) (see Chapter 34).

ASSESSMENT FINDINGS

Primary Survey

A general impression of the patient can be made in the primary survey. As described in Chapter 19, the major focus of the primary survey is to detect and manage any life-threatening conditions that affect airway, breathing, and

circulation. This and initiating resuscitation measures take priority over a detailed assessment. Signs of life-threatening respiratory distress in adults include the following[3]:

- Alterations in mental status
- Severe cyanosis
- Audible stridor
- Inability to speak one or two words without dyspnea
- Tachycardia (>130 beats/min)
- Pallor and diaphoresis
- Retractions and/or the use of accessory muscles to assist breathing

A quick assessment of lung sounds may be indicated in the primary survey for a patient in respiratory distress. As described in Chapter 20, abnormal breath sounds include absent or diminished breath sounds, crackles, wheezes, and rhonchi.

LOOK AGAIN
see Chapter 20: Secondary Assessment, pp. 536-540.

Focused History

The paramedic should ascertain the patient's chief complaint. A chief complaint may include dyspnea, chest pain, productive or nonproductive cough, **hemoptysis** (coughing up blood from the respiratory tract), wheezing, and signs of respiratory tract infection (e.g., fever, increased sputum production). The history should focus on the patient's previous experiences with similar or identical symptoms. The patient's objective description of severity often is an accurate indicator of the severity of the current episode if the condition is chronic.

Asking the patient, "What happened the last time you had an attack this severe?" is very useful for predicting what will happen with this episode. The following is a sample of questions that might be asked in order to obtain a focused history for a patient with respiratory distress. This format uses the acronym OPQRST (onset, provocation, quality, region/radiation, severity, and time):

Onset: "What were you doing when the breathing difficulty began? Do you think anything might have triggered it? Did your breathing difficulty begin gradually or was it sudden in onset? Did you experience any pain when the breathing difficulty began?"

Provocation: "Does lying down or sitting up make your breathing better or worse? Do you have any pain when you breathe? If so, does the pain increase when you take a deep breath or does it stay the same?"

Quality: "Is it more difficult to breathe when you inhale or exhale? If you have pain when you breathe, would you describe it as sharp or dull?"

Region/radiation: "What area of the chest has the most discomfort? Can you point with your finger to the specific area that hurts? Does the pain move anywhere or does it stay in the same place?"

Severity: "On a scale of 0 to 10 (with 10 being the worst), how would you rate the difficulty of your breathing?"

Time: "What time did the breathing difficulty start? Has it been constant since it began? If you've had this type of difficulty before, how long did it last?"

NOTE
It is important to ask patients if intubation was ever required to manage their respiratory disease. A history of previous intubation indicates severe pulmonary disease. It also suggests that intubation may be required again.

After obtaining a history of the present illness, a medication history should be obtained. A medication history includes current medications, medication allergies, cardiac medications, and pulmonary medications (e.g., in-home oxygen therapy; inhaled, oral, or parenteral sympathomimetics; inhaled or oral corticosteroids; cromolyn sodium; methylxanthines; leukotriene inhibitors, antibiotics). Obtaining a medication history (as well as when and why the patient takes these medications) may help the paramedic determine the nature of the respiratory emergency.

Secondary Assessment

The secondary assessment should be guided by the paramedic's general impression of the patient and by the patient's chief complaint. As part of the secondary assessment, the paramedic should note the patient's position, mental status, ability to speak, respiratory effort, and skin color (see Chapter 20: Secondary Assessment). Vital signs should be assessed, with the following considerations[3]:

- *Pulse rate:* Tachycardia may be a sign of hypoxemia. Bradycardia caused by respiratory problems is a warning sign of severe hypoxemia and imminent cardiac arrest.
- *Blood pressure:* Hypertension may result from the use of medications the patient takes to manage cardiac and respiratory disorders. (Patients with congestive heart failure [CHF] often are hypertensive.) Hypertension also may result from the patient's fear and anxiety. Like hypertension, hypotension can be caused by medication therapy. It may also result from fluid loss and dehydration in some respiratory illnesses. (Patients with pneumonia often are dehydrated.)
- *Respiratory rate:* The respiratory rate is not an accurate sign of respiratory status unless it is very slow. Trends are essential in evaluating a patient with chronic respiratory disease. A slowing rate in a patient who is not improving suggests exhaustion and impending respiratory insufficiency. As described in Chapter 15, abnormal patterns that may be seen in patients with severe illness or injury include tachypnea, Cheyne-Stokes respirations,

central neurogenic hyperventilation, Kussmaul respirations, ataxic respirations, apneustic respirations, and apnea.

LOOK AGAIN
See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 417-419.

The patient's face and neck should be assessed for pursed-lip breathing, grunting, nasal flaring, and use of accessory muscles. (Visible head bobbing in infants indicates they are using accessory muscles to breathe.) Pursed-lip breathing and grunting helps maintain pressure in the airways (even during exhalation). This pressure helps to support bronchial walls internally that have lost their external support as a result of disease. The use of accessory muscles can quickly result in respiratory fatigue. The patient should be questioned about sputum production. An increasing amount of sputum suggests infection. Thick green or brown sputum may indicate pneumonia; yellow or pale gray sputum may be related to allergic or inflammatory causes; pink, frothy sputum is associated with severe and late stages of pulmonary edema (described in Chapter 22 and in Chapter 45). The patient's neck should be evaluated for jugular vein distention. Jugular vein distention may be a sign of right-sided heart failure resulting from severe pulmonary congestion.

The patient's chest should be inspected for injury, if indicated by history. It also should be inspected for any indicators of chronic disease. (An example is a barrel chest from long-standing chronic obstructive pulmonary disease.) Other components of the chest examination include noting accessory muscle use or retractions to facilitate breathing, evaluating chest wall symmetry, and auscultating the patient's lungs for normal and abnormal breath sounds.

The patient's extremities should be assessed for peripheral cyanosis, pitting edema, clubbing of the fingers, and carpopedal spasm. Peripheral cyanosis is caused when a large amount of the hemoglobin in the blood is not carrying oxygen. Pitting edema is an indication of heart failure. Clubbing is an abnormal enlargement of the ends of the fingers (Figure 24-2). It indicates long-standing chronic hypoxemia. Carpopedal spasms are spasms of the hands, thumbs, feet, or toes. They often are associated with hypocapnia that results from hyperventilation.

Physical findings in a patient with respiratory disease should be documented on the patient care report. They also should be communicated to medical direction.

DIAGNOSTIC TESTING

Diagnostic testing that may be appropriate for some patients with respiratory disease includes pulse oximetry, capnometry, and the use of peak flow meters. As described in Chapter 15, pulse oximeters measure oxygen saturation. Capnography monitors end-tidal carbon dioxide level. Peak flow meters provide a baseline assessment of airflow for patients with obstructive lung disease.

NOTE
New diagnostic devices are available and are in use by some EMS and fire service agencies. These devices (e.g., Rad57) measure levels of carboxyhemoglobin (SpCO), hemoglobin (SpHB), and methemoglobin (SpMet) as well as oxygen content (SpOC).

FIGURE 24-2 Severe finger clubbing in a patient with cyanotic congenital heart disease. (From Forbes CD, Jackson WD: *Color atlas and text of clinical medicine,* ed 3, London, 2003, Mosby, with permission.)

Pulse Oximetry

To review, pulse oximetry helps determine how well the patient is being oxygenated. The device does this by measuring the transmission of red and near-infrared light through arterial beds using a probe placed on a finger, toe, or earlobe. Hemoglobin that is bound with oxygen (oxyhemoglobin) absorbs more infrared than red light; reduced hemoglobin absorbs more red than infrared light. The pulse oximeter measures this difference and calculates the oxygen saturation of the blood (SaO_2). The low range of normal SaO_2 is 93% to 95%. The upper range is 99% to 100%. An SaO_2 reading below 90% indicates a PaO_2 (partial pressure of arterial oxygen) of 60 mm Hg or less. An SaO_2 of 75% indicates a PaO_2 of 40 mm Hg. An SaO_2 of 50% indicates a PaO_2 of 27 mm Hg.

See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 451-455.

Capnography

As described in Chapter 15, capnography is a noninvasive monitoring technique that is primarily used in the prehospital setting to confirm correct tracheal tube placement. When used in conjunction with pulse oximetry and electrocardiogram (ECG) monitoring, capnography also can provide insight into ventilation, circulation, and metabolism. It is a useful indicator of efficient cardiopulmonary resuscitation and also can help confirm the diagnosis of pulmonary embolism. In patients with hemorrhage, capnography can provide continuous hemodynamic monitoring, information about tissue perfusion, and fluid resuscitation strategies for patients in shock[4] (see Chapter 36).

NOTE

Although capnography is a direct measurement of ventilation in the lungs, it also indirectly measures metabolism and circulation. For example, an increased metabolism will increase the production of carbon dioxide. This leads to an increase in the $EtCO_2$. A decrease in cardiac output will reduce the delivery of carbon dioxide to the lungs. This decreases the $EtCO_2$.

USE OF CAPNOGRAPHY IN MEDICAL PATIENTS WITH SPONTANEOUS RESPIRATIONS

Capnography is the graphical representation of carbon dioxide concentration exhaled through the breath. The measurements are taken by a capnography filter attached to a face mask or nasal cannula or endotracheal tube. The graphic representation is displayed as a waveform (measured in millimeters of mercury) on a *capnogram* throughout the respiratory cycle. (A *capnometer* displays only the numerical value of $PaCO_2$, not the waveform.) Each waveform on the capnogram consists of four phases (Figure 24-3). Phase 1 (*A-B*) represents air that is exhaled from the conducting airways with a low level of CO_2. Phase 2 (*B-C*) represents the mixture of air from the anatomical dead space and alveolar gas. It is here that CO_2 concentration begins to rise. Phase 3 (*C-D*) represents a plateau as alveolar gas is exhaled (*alveolar plateau*). Phase 4 (*D-E*) represents inspiration (*inspiration washout*) where *D* is the end-tidal volume (the peak concentration) and *E* is the sharp decline in CO_2 concentration. Box 24-5 shows three primary waveforms that are important in monitoring medical patients in the prehospital setting.

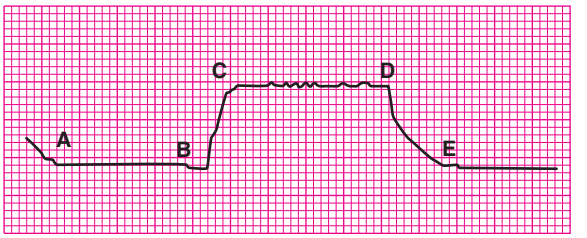

FIGURE 24-3 Capnography waveform.

The waveform helps to detect any rebreathing of CO_2 and is useful in diagnosing problems associated with increased dead space.[5] For example, patients with obstructive lung disease or a pulmonary embolism often have a decreased angle for phase 2, and the slope of the curve during phase 3 often will not reach the alveolar plateau. This is associated with unequal flow rates (ventilation-perfusion mismatch) and the uneven emptying of obstructed alveoli. Ventilation-perfusion mismatch can be caused by blood shunting, as seen with atelectasis. It also can be caused by dead space in the lungs, such as occurs with pulmonary embolism. All of these conditions result in a continuous increase in CO_2 concentration. A waveform that plateaus late in the expiration phase can indicate heart failure, chronic obstructive pulmonary disease (COPD), and pulmonary embolus (Figure 24-4).

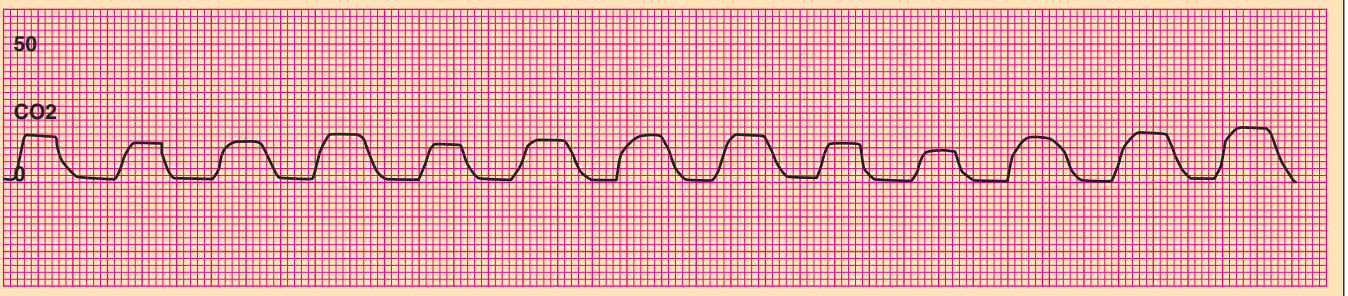
Peak Flow Meters

Peak flow meters (Figure 24-5) are used in pulmonary function tests to measure a patient's **peak expiratory flow rate** (PEFR). PEFR is a measurement of how fast a person can exhale air. These tests most often are used to help determine the severity of an asthma attack. They also can help assess the effectiveness of treatment of respiratory disease in the prehospital setting. Use of peak flow meters requires a cooperative patient who can make a maximal respiratory effort. It also requires coaching by the paramedic.

To determine baseline airflow (before drug administration), the paramedic should instruct the patient to inflate

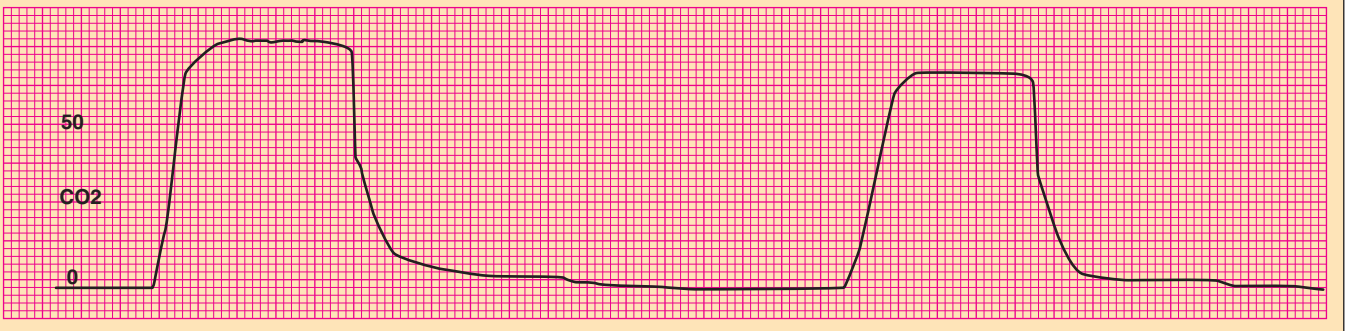
BOX 24-5 Three Important Waveforms for Monitoring Medical Patients

1. Hyperventilation—Decreased CO_2



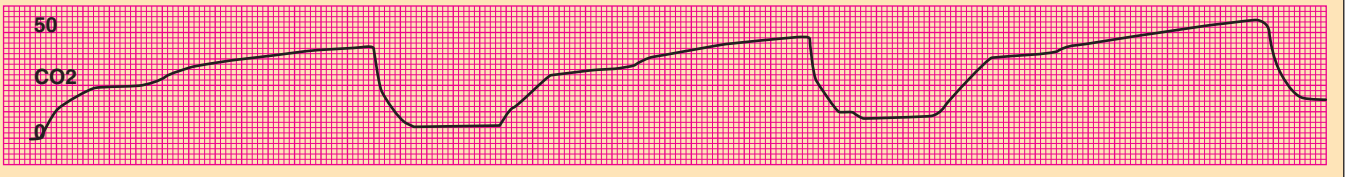
Possible causes: Anxiety, bronchospasm, pulmonary embolus, decreased cardiac output, hypotension, pulmonary edema

2. Hypoventilation—Increased CO_2



Possible causes: Sedation, overdose, dyspnea, chronic hypercapnia

3. Asthma, COPD, CHF—"Shark-fin" wave



Possible causes: Bronchospasm, uneven emptying of the alveoli, breath struggle

$EtCO_2$ Values

Normal: 35 to 45 mm Hg
Hypoventilation/hypercapnia: Greater than 45 mm Hg
Hyperventilation/hypocapnia: Less than 46 mm Hg

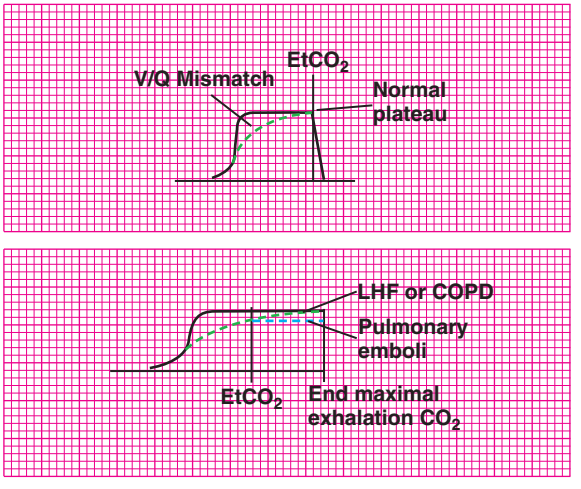


FIGURE 24-4 Abnormal $EtCO_2$ waveform.

FIGURE 24-5 Peak flow meter.

the lungs fully and forcefully exhale as quickly as possible into the flow meter. (Children should be reminded to breathe out as if they were blowing out candles or blowing up a balloon.) The reading is recorded in liters per minute. This measurement should be taken two more times. The highest of the three readings is chosen as the peak value flow. This measurement is then compared with standard tables based on height, gender, and race (Table 24-1). A PEFR measurement with variability less than 20% is considered mild; 20% to 30% is moderate; and more than 30% is severe.[6] Peak flow measurements should be repeated throughout the course of management to evaluate the patient's response to drug therapy.

NOTE
Most children younger than 5 years of age cannot adequately perform peak expiratory flow rate (PEFR) tests. Also, this test should not be used with a patient in severe respiratory distress. Drug therapy to reverse the bronchospasm is the priority.

OBSTRUCTIVE AIRWAY DISEASE

Obstructive airway disease is a major health problem in the United States. It affects nearly 32 million people in the United States.[7] Predisposing factors that contribute to some forms of obstructive pulmonary disease include smoking, environmental pollution, industrial exposures, and various pulmonary infectious processes. Obstructive airway disease is a triad of distinct diseases that often coexist. They are chronic bronchitis and emphysema (together referred to as chronic obstructive pulmonary disease [COPD]) and asthma. These diseases are presented separately in this chapter. However, different degrees of each frequently are present in the same patient.

NOTE
Pulmonary function tests are used by many physicians and other health care professionals to diagnose COPD. The tests also allow them to stage the severity of the illness. The mantra advocated by many respiratory support groups is "test your lungs and know your numbers"; it provides a way for patients with COPD to assess how well they are responding to treatment and if their disease is progressing.

CRITICAL THINKING
Will patients with chronic obstructive pulmonary disease (COPD) always be able to "name" their disease when you ask about their history?

Chronic Bronchitis

Chronic bronchitis is a condition involving inflammatory changes and excessive mucus production in the bronchial tree (Figure 24-6). Although preventable, it is the fourth leading cause of death in the United States.[8] The disease is characterized by an increase in the number and size of mucus-producing glands. This results from prolonged exposure to irritants. (Most often the irritant is cigarette smoke.) The condition is diagnosed clinically by the presence of cough with sputum production that is present half of the time for at least 2 consecutive years.[9] The alveoli are not seriously affected and diffusion remains relatively normal.

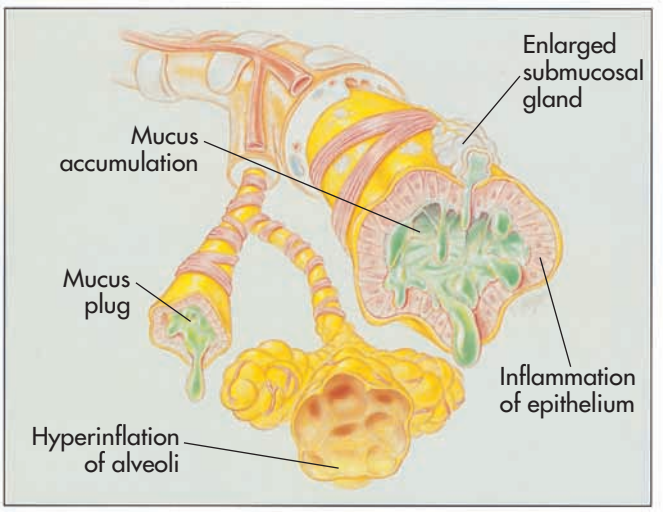

FIGURE 24-6 Chronic bronchitis. Bronchi are filled with excess mucus. (Modified from Desjardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 2006, Mosby.)

Patients with severe chronic bronchitis have a low oxygen pressure (P_{O_2}) because of changes in the ventilation-perfusion relationships in the lung and hypoventilation. (These patients sometimes are called "blue bloaters" because of their hypoxia and fluid retention.) The hypoventilation leads to hypercapnia (high levels of carbon dioxide [CO_2]), hypoxemia (low levels of oxygen [O_2]), and increases in arterial carbon dioxide pressure (P_{CO_2}). Patients with chronic bronchitis have frequent respiratory tract infections. These eventually cause scarring of lung tissue. In time, irreversible changes occur in the lung. These changes may lead to emphysema or bronchiectasis. **Bronchiectasis** is an abnormal dilation of the bronchi. It is caused by a pus-producing infection of the bronchial wall.

Emphysema

Emphysema results from pathological changes in the lung. It is the end stage of a process that progresses slowly for many years. The disease is characterized by permanent abnormal enlargement of the air spaces beyond the terminal bronchioles and by destruction and collapse of the alveoli (Figure 24-7). The disease reduces the number of alveoli available for gas exchange. It also reduces the elasticity of the remaining alveoli. This loss of elasticity leads to trapping of air in the alveoli. Thus residual volume increases, whereas vital capacity remains relatively normal.

NOTE: These charts are for informational purposes only. Spirometry should be used for diagnosis and staging. "Personal best" measures should be used for the asthma treatment plan.

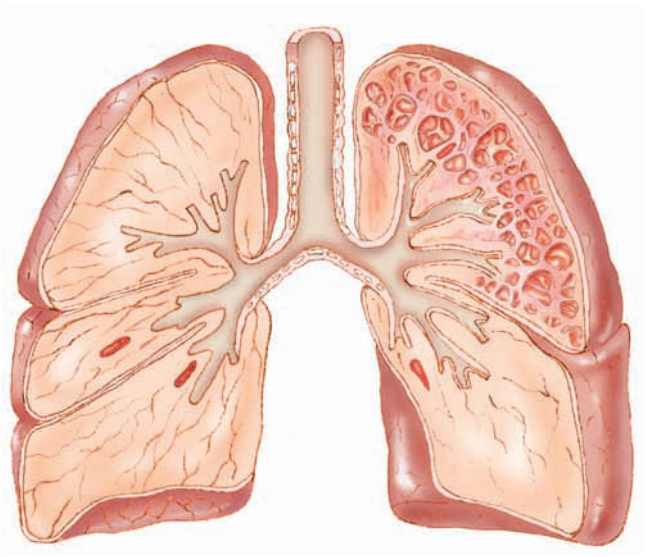

FIGURE 24-7 Cystic changes of lobar emphysema resulting from destruction of alveoli. (From Wilson SF, Thompson JM: *Mosby's clinical nursing series: respiratory disorders,* St Louis, 1990, Mosby.)

The associated reduction in arterial P_{O_2} leads to increased production of red blood cells and polycythemia (an elevated hematocrit value.) The elevation in hematocrit level is much more common in the patient with chronic bronchitis than in the patient who has primary emphysema. This is because the patient with chronic bronchitis is more often chronically hypoxemic. Decreases in alveolar membrane surface area and in the number of pulmonary capillaries in the lung reduce the area for gas exchange. These factors are also responsible for an increased resistance to pulmonary blood flow.

Patients with emphysema have some resistance to airflow into and out of the lungs. Yet most of the hyperexpansion is caused by air trapping secondary to loss of elastic recoil (Figure 24-8). Patients with chronic bronchitis have increased airway resistance during inspiration and expiration. In contrast, patients with emphysema have increased airway resistance only on expiration. Normally a passive, involuntary act, expiration becomes a muscular act in patients with COPD. (These patients are sometimes called "pink puffers" because of the red face they make during forced exhalation.) Over time, the chest becomes barrel-shaped from the trapping of air. Then, the patient must use accessory muscles of the neck, chest, and abdomen to move air into and out of the lungs. Full deflation of the lungs becomes more and more difficult. Finally, it becomes impossible. Often the patient with emphysema is thin because of poor dietary intake and increased caloric consumption required by the work of breathing (Table 24-2). Patients with emphysema often develop **bullae** (thin-walled cystic lesions in the lung) from the destruction of alveolar walls. **Blebs** (the collection of air within the visceral pleura) also may develop. When bullae collapse or blebs rupture, they increase the diffusion defect seen in these patients. They also can lead to pneumothorax.

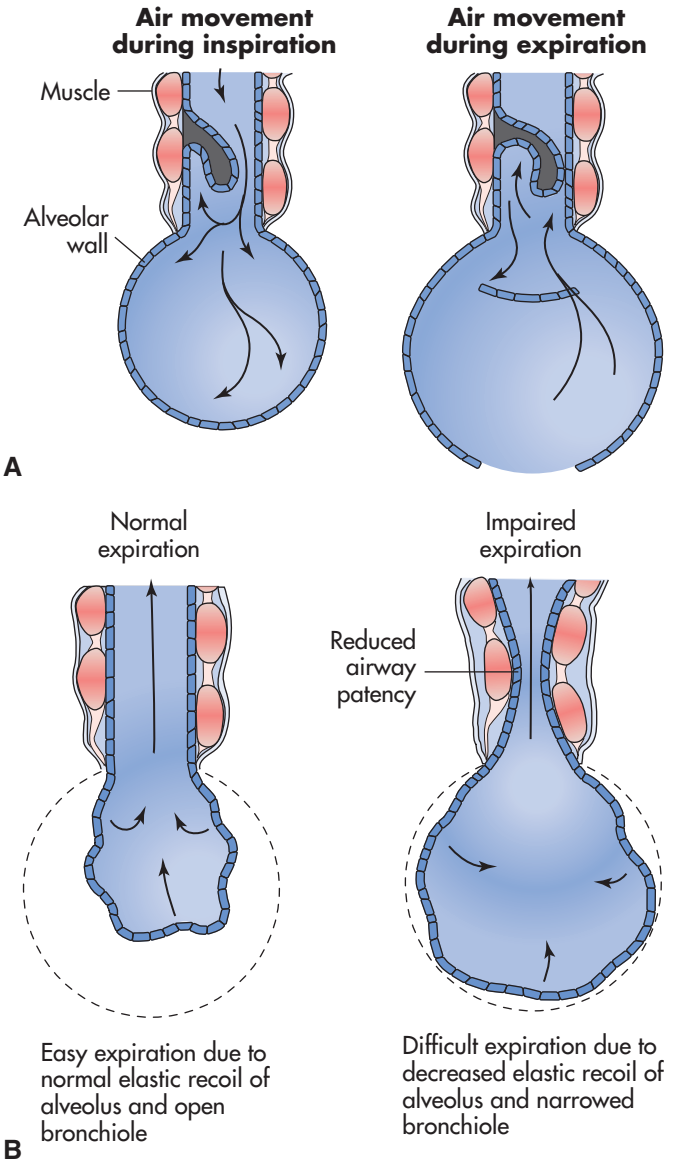

FIGURE 24-8 **A,** Mechanisms of air trapping in chronic obstructive pulmonary disease (COPD): Mucus plugs and narrowed airways cause air trapping and hyperinflation on expiration. During inspiration, the airways enlarge, allowing gas to flow past the obstruction. This mechanism of air trapping occurs in asthma and chronic bronchitis. **B,** Mechanism of air trapping in emphysema: Damaged or destroyed alveolar walls no longer support and hold open the airways, and alveoli lose their property of elastic recoil. Both these factors contribute to airway collapse during expiration. (Modified from Desjardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 2006, Mosby.)

CRITICAL THINKING

What effect might application of a cervical collar, use of a short spine board or vest, and immobilization supine on a long backboard have on a patient with chronic obstructive pulmonary disease (COPD) who has sustained trauma?

TABLE 24-2 Comparison of Signs and Symptoms of Emphysema and Chronic Bronchitis

Emphysema	Chronic Bronchitis
Thin, barrel-chest appearance	Typically overweight
Nonproductive cough	Productive cough with sputum
Wheezing and rhonchi	Coarse rhonchi
Pink complexion	Chronic cyanosis
Extreme dyspnea on exertion	Mild, chronic dyspnea
Prolonged inspiration (pursed-lip breathing)	Resistance on inspiration and expiration

FIGURE 24-9 Patient being treated with continuous positive airway pressure. (Courtesy Rick Brady, Baltimore, Md.)

ASSESSMENT OF COPD

Patients with COPD usually are aware of and have adapted to their illness. A request for emergency care indicates that a significant change has occurred in the patient's condition. The patient with COPD usually has an acute episode of worsening dyspnea that is manifested even at rest, an increase or change in sputum production, or an increase in the malaise that accompanies the disease. Other common complaints include inability to sleep and recurrent headaches.

On EMS arrival, the patient with COPD will likely be in respiratory distress. Often the patient is sitting upright and leaning forward to aid in breathing. The patient frequently is using pursed-lip breathing to maintain positive airway pressures, in addition to using accessory muscles. Increased hypoxemia and hypercarbia may be indicated by tachypnea, diaphoresis, cyanosis, confusion, irritability, and drowsiness.

Other physical findings include wheezes, rhonchi, and crackles (see Chapter 20). Breath sounds and heart sounds also may be diminished. This is due to reduced air exchange and the increased diameter of the thoracic cavity. In late stages of decompensation, the patient may have peripheral cyanosis, clubbing of the fingers, and signs of right-sided heart failure. As described in Chapter 22, the patient's electrocardiogram may reveal cardiac dysrhythmias or signs of right atrial enlargement; these include tall, peaked P waves in leads II, III, and aV_F.

LOOK AGAIN
See Chapter 22: Cardiology, pp. 689-692.

MANAGEMENT

The primary goal of prehospital care for these patients is the correction of hypoxemia through improved airflow. This can be achieved through administration of oxygen and drug therapy. Drug therapy may cause serious side effects and complications, especially if the patient has used medication before EMS arrival. Therefore it is crucial for paramedics to obtain a thorough medical history regarding medication use, home oxygen use, and drug allergies.

An intravenous (IV) line should be established in all patients in respiratory distress. A cardiac monitor also should be applied. If the patient has a productive cough, coughing should be encouraged. Any sputum should be collected and delivered with the patient for laboratory analysis.

Some patients with COPD rely on a hypoxic drive for ventilatory effort. However, *the paramedic should never withhold oxygen because of fear of decreasing hypoxic drive while providing emergency care in the prehospital setting*. High-concentration oxygen should be administered with a nonrebreather mask if indicated. Pulse oximetry to measure oxygen saturation is indicated. Some of these patients will require ventilatory assistance. In addition, their breathing may require augmentation with *continuous positive airway pressure* (CPAP) or *biphasic positive airway pressure* (BiPAP) (Figure 24-9). As described in Chapter 15, CPAP improves oxygenation, reduces the work of breathing, prevents atelectasis, and allows for drug administration. Positive-pressure ventilation also may prevent the need for intubation and the risks and complications associated with invasive airway procedures.

LOOK AGAIN
See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 422-424.

The medications used in the prehospital setting to relieve bronchospasm and reduce constricted airways are the beta agonists (e.g., ***levalbuterol*** and ***albuterol***). Other drugs that may be given after evaluation by a physician include steroids (***methylprednisolone***) and nebulized anticholinergics (e.g., ***ipratropium***). These drugs are given for bronchodilation and stimulation of the respiratory drive. (See the Emergency Drug Index for specific drug therapy.)

Asthma

Asthma, or reactive airway disease, is a common disorder that affects nearly 23 million Americans, including 7 million children. It is responsible for 4000 to 5000 deaths each year.[8] Asthma is most common in children and young adults. Yet it can occur in any decade of life. Exacerbating factors tend to be extrinsic (external) in children. In contrast, they tend to be intrinsic (internal) in adults (Figure 24-10). Childhood asthma often improves or resolves with age. Adult asthma usually is persistent.

SHOW ME THE EVIDENCE

An abstract by Lamba et al. examines how initial prehospital $EtCO_2$ values in 299 adult asthma patients relate to patient severity. Patients with $EtCO_2$ values between 14-28 and 50-82 mm Hg were more likely to be intubated, admitted to the intensive care unit, or die than patients with $EtCO_2$ values between 29 and 49 mm Hg.

Lamba S et al: Initial out-of-hospital end-tidal carbon dioxide measurements in adult asthma patients, *Ann Emerg Med* 54(3, suppl):S51, 2009.

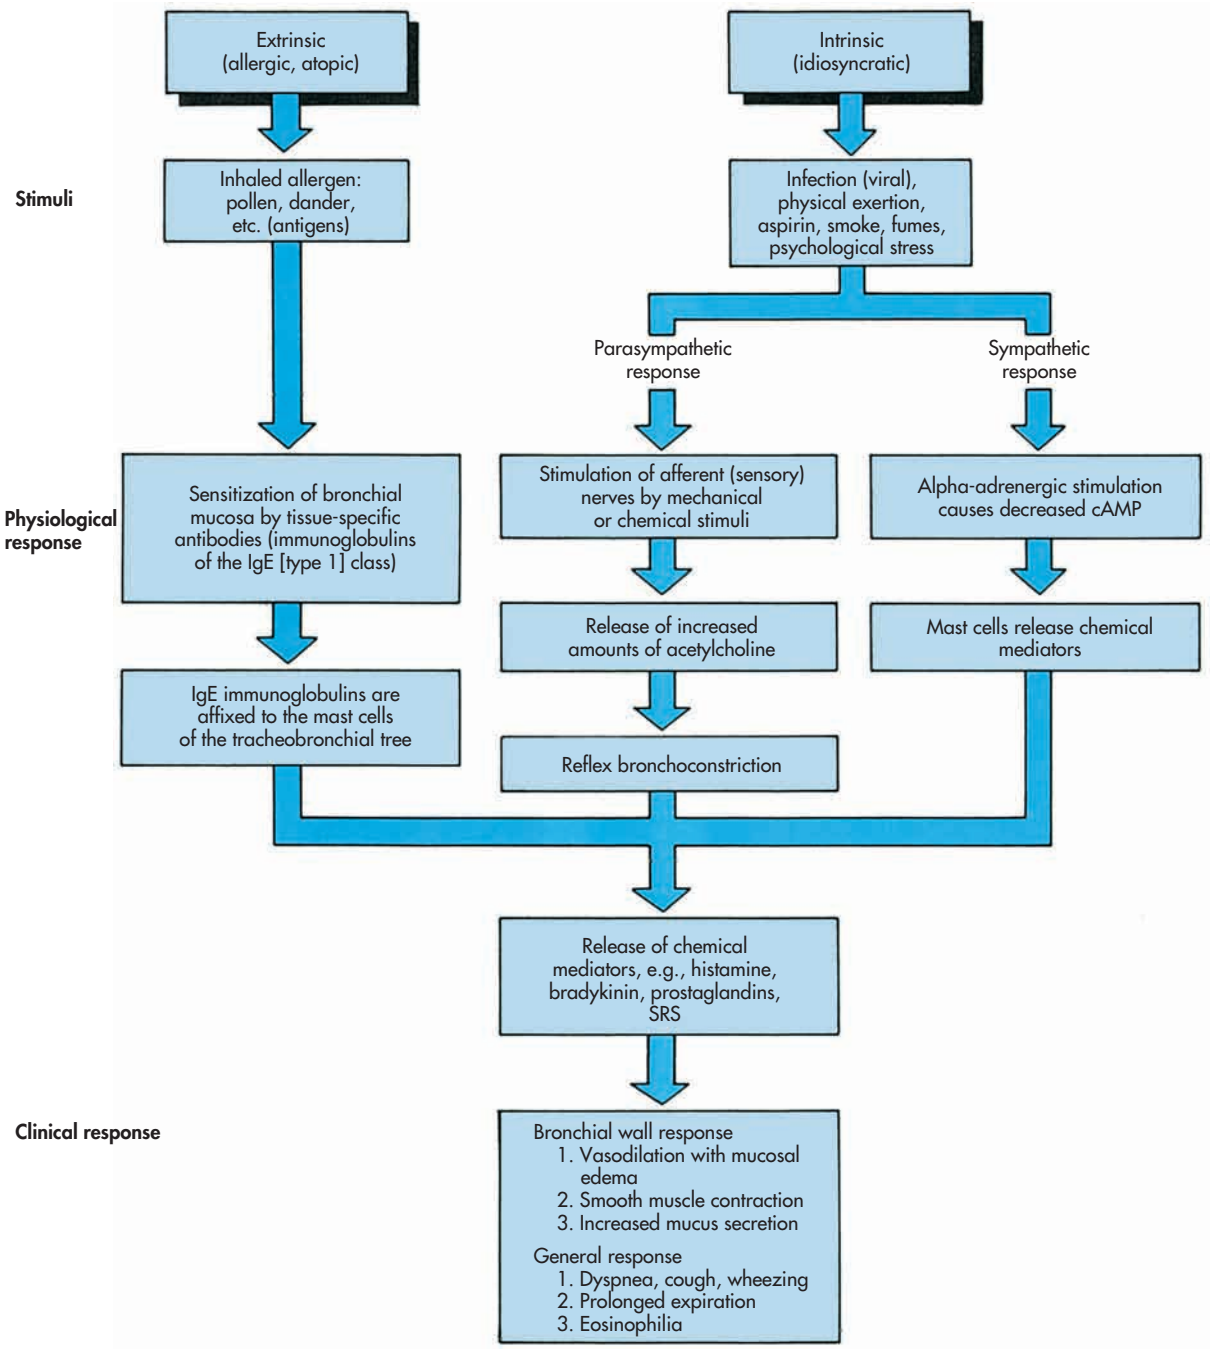

FIGURE 24-10 Extrinsic and intrinsic bronchial asthma. (From Wilson SF, Thompson JM: *Mosby's clinical nursing series: respiratory disorders,* St Louis, 1990, Mosby.)

PATHOPHYSIOLOGY OF AN ASTHMA ATTACK

Asthma generally occurs in acute episodes of variable duration. Between these episodes, the patient is relatively free of symptoms. The attack is characterized by reversible airflow obstruction caused by bronchial smooth muscle contraction; hypersecretion of mucus, resulting in bronchial plugging; and inflammatory changes in the bronchial walls. The increased resistance to airflow leads to alveolar hypoventilation, marked ventilation-perfusion mismatching (leading to hypoxemia), and carbon dioxide retention (stimulating hyperventilation) (Figure 24-11). The obstruction of inspiration and the marked obstruction of expiration cause pressure to remain high in the airways, as a result of air trapping in the lungs.

During an acute asthma attack, the combination of increased airway resistance, increased respiratory drive, and air trapping creates excessive demand on the muscles of respiration. This leads to greater use of accessory muscles and increases the chance of respiratory fatigue. If labored breathing continues, high pressures in the thorax can reduce the amount of blood returning to the left ventricle (left ventricular preload). The result is a drop in cardiac output and systolic blood pressure (**near-fatal asthma**). Pulsus paradoxus also may be seen. If the episode continues, hypoxemia and changes in blood flow and blood pressure may lead to death. Most asthma-related deaths occur outside the hospital. In the prehospital setting, cardiac arrest in patients with severe asthma has been linked to the following factors[10]:

- Severe bronchospasm and mucus plugging, which leads to asphyxia (the most common cause of asthma-related deaths)
- Cardiac dysrhythmias caused by hypoxia
- Tension pneumothorax (often bilateral)

Other conditions that may be present in patients with near-fatal asthma include cardiac disease, pulmonary disease, acute allergic bronchospasm or anaphylaxis, drug use or misuse (beta blockers, cocaine, and opiates), and recent discontinuation of long-term corticosteroid therapy (associated with adrenal insufficiency).

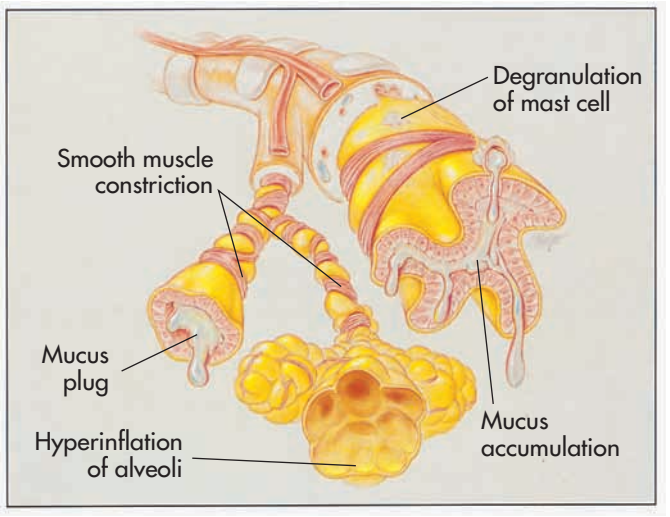

FIGURE 24-11 With bronchial asthma, thick mucus accumulation, mucosal edema, and smooth muscle spasm obstruct the small airways. Breathing becomes labored, and expiration is difficult. (Modified from Desjardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 2006, Mosby.)

ASSESSMENT

When paramedics arrive, the asthmatic patient usually is sitting upright. The person may be leaning forward with hands on knees (tripod position) and using accessory muscles to aid breathing. The typical asthmatic patient is in obvious respiratory distress. Respirations are rapid and loud, and audible wheezing may be present.

NOTE
The severity of wheezing does not correlate with the degree of airway obstruction. The absence of wheezing may indicate critical airway obstruction, whereas increased wheezing may indicate a positive response to bronchodilator therapy.

The patient's mental status should be noted and monitored carefully. Lethargy, exhaustion, agitation, and confusion are serious signs of impending respiratory failure. An initial history must be obtained quickly. Questions about the onset of the current episode, its relative severity, the precipitating cause, medication use, and allergies should be specific and to the point. It is crucial to find out whether the patient has needed intubation to manage his or her previous asthma.

On auscultation, a prolonged expiratory phase may be noted. Usually wheezing is heard from the movement of air through the narrowed airways. Inspiratory wheezing (unlike inspiratory stridor) does not indicate upper airway occlusion. It suggests that the large and middle-size muscular airways are obstructed. This indicates more obstruction than if only expiratory wheezes are heard. Inspiratory wheezes also may suggest that the large airways are filled with secretions. A silent chest (i.e., no audible wheezing or air movement) may indicate such severe obstruction that the flow of air is too low to generate breath sounds. Other signs of severe asthma include the following:

- Reduced level of consciousness
- Diaphoresis and pallor
- Retractions
- Inability to speak after only one or two words
- Poor, floppy muscle tone
- Pulse rate greater than 130 beats per minute
- Respirations greater than 30 breaths per minute
- Pulsus paradoxus greater than 20 mm Hg
- Altered mental status or severe agitation
- End-tidal CO_2 >45 mm Hg

NOTE
Asthma attacks are true medical emergencies. Paramedics should manage these episodes aggressively. Deterioration of the patient's condition can be expected, rapid, and fatal. Therefore the paramedic must monitor the patient carefully and continuously. Initial patient management should be directed at ensuring an adequate airway, providing supplemental oxygen, and reversing the bronchospasm.

MANAGEMENT

After administration of high-concentration oxygen, drug therapy is provided (Box 24-6). Drug therapy is based on the patient's age and medication use before EMS arrival. Nebulized ***albuterol*** is the current cornerstone of asthma treatment in the United States. This fast-acting beta$_2$ agonist stimulates beta-adrenergic receptors and thus acts as a rapid bronchodilator. Side effects include transient tachycardia and tremor. Other nebulized drugs used to manage asthma include ***levalbuterol, ipratropium,*** or a combination of ***albuterol*** and ***ipratropium.*** When combined with nebulized beta-adrenergic agents and corticosteroids, IV ***magnesium sulfate*** can moderately improve pulmonary function in patients with asthma.[10]

If the patient is not able to tolerate nebulized medications, subcutaneous (SubQ), intramuscular (IM), or IV drug therapy will likely be indicated to treat bronchoconstriction. These drugs include ***epinephrine*** and ***terbutaline*** (see the Emergency Drug Index). CPAP or BiPAP can be beneficial in managing reactive airway disease. As described in Chapter 15, CPAP or BiPAP should only be considered if the patient is alert and has adequate spontaneous respirations.

IV fluids may be indicated for rehydration. All patients with acute asthma should be transported in a position of comfort. This helps to maximize the use of respiratory muscles. These patients should also be monitored for cardiac rhythm disturbances.

CRITICAL THINKING
Consider that the patient is unable to hold the nebulizer mouthpiece or needs to be ventilated using a bag-mask device. What can you do to promote bronchodilation?

In rare cases, advanced airway management is required for a patient having a severe asthma attack. Absolute indications for immediate intubation of the wheezing patient are apnea and coma. In addition, intubation should be considered if[11]:

- P_{O_2} is less than 50 mm Hg with supplemental oxygen.
- P_{CO_2} is greater than 50 mm Hg with acute respiratory acidosis.
- P_{CO_2} is increasing, despite maximal therapy.
- Patient is fatigued.
- Mental status is depressed.

If a conscious patient requires intubation and the paramedic is trained and authorized to perform rapid sequence intubation (described in Chapter 15), consult with medical direction and consider the following critical actions[10]:

- Provide adequate sedation with ***ketamine*** or ***etomidate.***
- Paralyze the patient with ***succinylcholine*** or ***vecuronium*** (if credentialed or authorized in your state).
- Immediately after intubation, administer 2.5 to 5 mg of ***albuterol*** directly into the endotracheal (ET) tube.
- Confirm ET tube placement with primary and secondary confirmation methods.
- Ventilate the patient's lungs at 6 to 10 breaths per minute and with smaller tidal volumes (6 to 8 mL/kg). Deliver breaths with a shorter inspiratory time, and prolong the expiratory time to allow for the escape of air and to avoid sudden hypotension (especially in elderly patients with emphysema).

BOX 24-6 Asthma Medications

Nebulized Beta$_2$ Agonists
Albuterol, levalbuterol, pirbuterol, salmeterol
Inhaled anticholinergics
Ipratropium

Corticosteroids (IV)
Methylprednisolone
Hydrocortisone

Corticosteroids (Inhaled)
Triamcinolone

Montelukast, zafirlukast, zileuton
Aminophylline (IV)
Magnesium sulfate (IV)
Epinephrine or terbutaline (SubQ or IM)

IM, Intramuscular; *IV,* intravenous; *SubQ,* subcutaneous.

LOOK AGAIN
See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 460-464.

NOTE
Even after intubation, ventilating the patient's lungs may be difficult. The absence of any significant obstruction to airflow immediately after tracheal intubation suggests that the diagnosis of acute asthma may have been incorrect, and the problem may be in the upper airway.[10]

STATUS ASTHMATICUS

Status asthmaticus is a severe, prolonged asthma attack that has not been stopped with repeated doses of bronchodilators. It may be of sudden onset, resulting from spasm

of the airways. It can also be subtle in onset, resulting from a viral respiratory tract infection or prolonged exposure to one or more allergens. Status asthmaticus is a true emergency. It calls for early recognition and immediate transport of the patient. These patients are in danger of respiratory failure.

The treatment of patients with status asthmaticus is the same as that for acute asthma attacks. Yet the urgency of rapid transport is more important. In addition, these patients usually are dehydrated. They typically require IV fluid administration. The patient's respiratory status should be monitored closely. Also, high-concentration oxygen should be administered. The need for intubation and aggressive ventilatory support should be anticipated. Continuous bronchodilator therapy with nebulized and parenteral drugs may be indicated.

CRITICAL THINKING

When a patient treated for status asthmaticus is reassessed, would decreasing respiratory and heart rates indicate a good outcome or a bad one? Why?

Differential Considerations

Wheezing commonly is associated with asthma. However, it may be present in *all* types of diseases that cause dyspnea (Table 24-3). For example, tachypnea, wheezing, and respiratory distress may indicate heart failure, pneumonia, pulmonary edema, pulmonary embolism, pneumothorax, toxic inhalation, foreign body aspiration, and various other pathological states. Appropriate emergency care is based on the patient assessment and an accurate history.

PNEUMONIA

Pneumonia is a group of specific infections (not a single disease) that cause an acute inflammatory process of the respiratory bronchioles and the alveoli. The disease kills more than 60,000 Americans each year and is a leading cause of death in children worldwide[12] (Figure 24-12). Pneumonia can be caused by bacterial, viral, or fungal infection. Associated risk factors include cigarette smoking, alcoholism, exposure to cold, and extremes of age (the very young and very old). These diseases may be spread by respiratory droplets through contact with infected individuals. They also may be spread by inhaling bacteria from one's own nose and mouth.

Pneumonia may be classified as the viral, bacterial, mycoplasmal, or aspiration type. Pneumonia generally manifests with classic signs and symptoms (*typical pneumonia*). These include a productive cough, pleuritic chest pain, and fever that produces "shaking chills" (usually associated with the bacterial infection). It also may cause nonspecific complaints. (This particularly may be the case in older adults and debilitated patients.) Nonspecific complaints may include a nonproductive cough, headache, fatigue, and sore throat (*atypical pneumonia*).

NOTE

Community-acquired pneumonia is an infection that is acquired from the environment. This category includes infections acquired indirectly as a result of the use of medications that change the body's ability to fight disease. The occurrence of these infections has risen in recent years. This is due to the increased percentage of the population older than age 65. It also is due to the increasing number of patients taking immunosuppressive drugs for malignancy, transplantation, or autoimmune disease.

TABLE 24-3 Diseases and Symptoms Associated With Wheezing

Disease	Symptoms
Asthma	Productive cough, tightness in chest
Bacterial pneumonia	Productive cough, pleuritic pain
Chronic bronchitis	Chronic productive cough
Emphysema	Cough
Foreign body aspiration	Cough
Heart failure	Cough, orthopnea, nocturnal dyspnea
Pneumothorax	Sudden, sharp pleuritic pain
Pulmonary disease	Tachypnea, cough, congestion
Pulmonary embolism	Sudden, sharp pleuritic pain
Toxic inhalation	Cough, pain

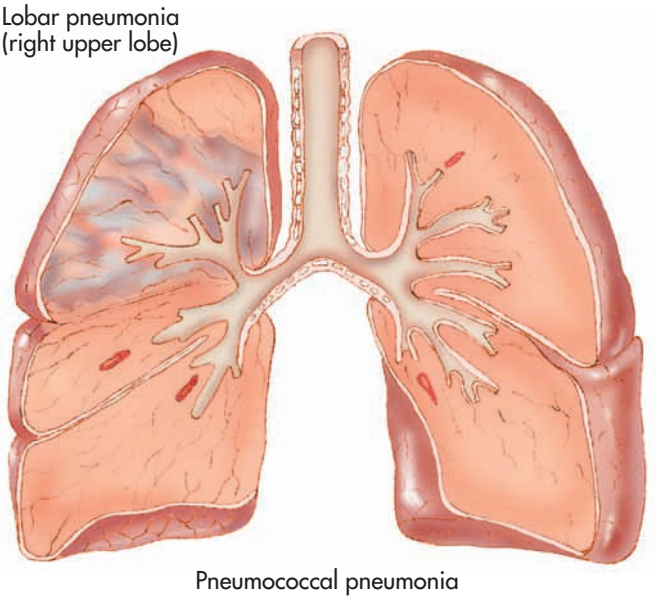

FIGURE 24-12 ***Pneumonia*** is an inflammatory process of the respiratory bronchioles and alveoli. It is caused by infection. (From Wilson SF, Thompson JM: *Mosby's clinical nursing series: respiratory disorders,* St Louis, 1990, Mosby.)

Viral Pneumonia

Influenza A is the most common type of **viral pneumonia** (Box 24-7). It often occurs as epidemics in populations of small groups such as schoolchildren, army recruits, and nursing home residents. The interstitial infection caused by the virus predisposes the patient to secondary bacterial pneumonia.

Bacterial Pneumonia

Until 2000, the pneumococcus bacillus (*Streptococcus pneumoniae*) accounted for 90% of bacterial pneumonias. It affected 1 in 500 people each year. The decline in cases is related to vaccination of infants against the pneumococcus bacteria. The peak incidence is in winter and early spring. A vaccine that is now available is effective against this type of pneumonia in adults.

DID YOU KNOW?

Pneumococcal Polysaccharide Vaccine (PPSV)

Pneumococcal disease is the leading cause of vaccine-preventable disease and death in the United States. The disease can lead to serious infections of the lungs (pneumonia), blood (bacteremia), and brain (meningitis). Pneumococcal pneumonia kills about 1 out of 20 people who contract the disease; bacteremia kills about 1 person in 5; and meningitis kills about 3 people in 10.

Pneumococcal polysaccharide vaccine (PPSV) protects against 23 types of pneumococcal bacteria, including those most likely to cause serious disease. Most healthy adults who are vaccinated develop protection to most or all of these types within 2 to 3 weeks of vaccination. Usually only one dose of PPSV is needed, but under some circumstances a second dose may be given. A second dose (given 5 years after the first dose) is recommended for:

- People 65 years and older who received their first dose when they were younger than 65 and it has been 5 or more years since the first dose
- People 2 through 64 years of age who:
  - Have a damaged spleen or no spleen
  - Have sickle cell disease
  - Have HIV infection or AIDS
  - Have cancer, leukemia, lymphoma, or multiple myeloma
  - Have nephrotic syndrome
  - Have received an organ or bone marrow transplant
  - Are taking medication that lowers immunity (such as chemotherapy or long-term steroids)

People to whom the vaccine should not be given include those who are allergic to the vaccine or a component of the vaccine; those who are moderately or severely ill; and women who are pregnant. Another type of pneumococcal vaccine (pneumococcal conjugate vaccine, or PCV) is routinely recommended for children younger than 5 years of age.[13]

Bacterial pneumonia also can result from the aspiration of mucus and saliva. Therefore, patients in a coma or with seizures, suppressed cough reflex, and increased secretions

BOX 24-7 Influenza

Influenza is an acute, febrile disease that affects the entire body. It is associated with viral infection of the upper and lower respiratory tracts. It usually is characterized by the abrupt onset of a severe protracted cough, fever, headache, muscle ache, and mild sore throat. Of all the viruses, the influenza and parainfluenza viruses are the most common causes of serious respiratory tract infections. Moreover, they have high morbidity and mortality rates.

Influenza viruses A, B, and C (and their many strains) are known for their potential to quickly cause respiratory tract infections after exposure. (It usually occurs within 24 to 48 hours.) The virus is inhaled in respiratory droplets from infected individuals (such as when an infected person sneezes). The droplets penetrate the surface of upper respiratory tract mucosal cells. The virus eventually spreads to the lower respiratory tract, where it causes cell inflammation and destruction of the cilia. Without the cilia, clearing the airways of infected mucus is more difficult. Consequently, a secondary bacterial infection often develops. This may result in pneumonia or acute respiratory failure. (This is particularly the case in patients with chronic lung disease.)

Influenza has the potential for widespread epidemics in high-risk populations. (These include adults and children with chronic cardiorespiratory or metabolic disorders, residents of nursing homes and other institutions, and health care workers.) Current vaccines are effective against some strains of the virus. These vaccines have minimal side effects. If uncomplicated, influenza is self-limiting. Acute symptoms last 2 to 7 days. These are followed by a convalescent period of about 1 week. *NOTE:* The H1N1 outbreak of 2009 affected healthy young people and pregnant women disproportionately, compared to other influenza viruses (see Chapter 28).

are predisposed to developing the disease. Other predisposing risk factors that may contribute to the development of bacterial pneumonia include the following:

- Infection
  - Upper respiratory tract infection (influenza)
  - Postoperative infection
- Foreign body aspiration
- Alcohol or other drug addiction
- Cardiac failure
- Stroke
- Syncope
- Pulmonary embolism
- Chronic illness
  - Chronic respiratory disease
  - Diabetes mellitus
  - Congestive heart failure
- Prolonged immobilization
- Compromised immune status

Mycoplasmal Pneumonia

Mycoplasmal pneumonia is caused by infection with *Mycoplasma pneumoniae.* It causes mild upper respiratory tract infection in school-age children and young adults.

Transmission is believed to occur by means of infected respiratory secretions. Therefore the condition spreads quickly among family members. This form of pneumonia can be treated effectively with antibiotics.

Aspiration Pneumonia

Aspiration pneumonia is an inflammation of the lung tissue (parenchyma). It results when foreign material enters the tracheobronchial tree. The syndrome is common in patients who have an altered level of consciousness (e.g., from head injury, seizure activity, use of alcohol or other drugs, anesthesia, infection, shock); patients who are intubated; and those who have aspirated foreign bodies. Factors common to victims of aspiration include depression of the cough or gag reflex, inability of the patient to handle secretions or gastric contents, and inability to protect the airway.

Aspiration pneumonia may be nonbacterial. (For example, it may develop after aspiration of stomach contents, toxic materials, or inert substances.) This typically is called *pneumonitis* to distinguish it from infectious pneumonia or bacterial pneumonia (as a secondary complication). Bacterial aspiration pneumonia has a poor prognosis, even with antibiotic therapy.

Management of Pneumonia

The pathophysiology of pneumonia depends on the agent that caused the disease. In viral and mycoplasmal pneumonias, the inflammatory response in the bronchi damages the cilia and the epithelium. This causes congestion. In some cases it causes hemorrhage. Signs and symptoms include chest pain, cough, fever, dyspnea, and occasionally hemoptysis. Patients usually complain of general malaise. They also complain of upper respiratory and gastrointestinal tract symptoms. Auscultation of the chest may reveal wheezing and fine crackles. In uncomplicated cases the symptoms usually resolve in 7 to 10 days.

Bacterial pneumonia begins with infection in the alveoli. In time, this infection fills the alveoli with fluid and purulent sputum. The infection spreads from alveolus to alveolus. As this occurs, large areas of the lung, even entire lobes, may become consolidated (filled with fluid and cellular debris). Consolidation reduces the available surface area of respiratory membranes. It also decreases the ventilation-perfusion ratio. Both of these effects may lead to hypoxemia. Patients with bacterial pneumonia usually have acute shaking chills, tachypnea, tachycardia, cough, and sputum production. The sputum may be rust-colored (classic for pneumococcus). More often, though, it is yellow, green, or gray. Additional symptoms include malaise, anorexia, flank or back pain, and vomiting. If the disease is uncomplicated and treated with antibiotics, the patient begins to recover within 3 to 5 days. Antibiotics usually are continued for a total of 7 to 10 days.

The physiological effects of aspiration pneumonia are based on the volume and pH of the aspirated substances. If the pH is below 2.5 (as may occur in the aspiration of stomach contents), atelectasis, pulmonary edema, hemorrhage, and cell necrosis may occur. The alveolar-capillary membrane may be damaged as well. This, in turn, may lead to the accumulation of fluid in the alveoli. In severe cases, it may lead to adult respiratory distress syndrome (described in the next section). The patient's signs and symptoms vary with the scenario and the severity of the insult (e.g., near-drowning, foreign body aspiration, aspiration of gastric contents). Clinical features may include dyspnea, cough, bronchospasm, wheezes, rhonchi, crackles, cyanosis, and pulmonary and cardiac insufficiency. Of these patients, a good percentage develop pulmonary infection.

CRITICAL THINKING

What measures can the paramedic take to reduce a patient's risk of aspiration?

Prehospital care for patients with pneumonia includes airway support, oxygen administration, ventilatory assistance as needed, IV fluids to support blood pressure and to thin and loosen mucus, cardiac monitoring, and transport for evaluation by a physician. (Bronchodilator drugs may also be used for some patients.) In cases of aspiration, suctioning of the airway may be required. General patient management usually includes bed rest, analgesics, decongestants, expectorants, antipyretics, and antibiotic therapy. In severe cases, bronchoscopy, intubation, and mechanical ventilation may be required for some patients.

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (ARDS) is a fulminant form of respiratory failure. It is characterized by acute lung inflammation and diffuse alveolar-capillary injury.[14] All disorders that result in ARDS cause severe noncardiogenic pulmonary edema (described in Chapter 22). The syndrome develops as a complication of injury or illness such as trauma, gastric aspiration, cardiopulmonary bypass surgery, gram-negative sepsis, multiple blood transfusions, oxygen toxicity, toxic inhalation, drug overdose, pneumonia, and infections. Regardless of the specific cause, increased capillary permeability (high-permeability noncardiogenic pulmonary edema) results in a clinical condition in which the lungs are wet and heavy, congested, hemorrhagic, and stiff, with decreased perfusion capacity across alveolar membranes (Figure 24-13). The lungs become noncompliant. This requires the patient to increase the pressure in the airways to breathe.

The pulmonary edema associated with ARDS leads to severe hypoxemia, intrapulmonary shunting, reduced lung compliance, and, in some cases, irreversible damage to lung tissue. Unique to this syndrome is the fact that most patients who develop this condition have healthy lungs before the event that caused the disease; that is, they have

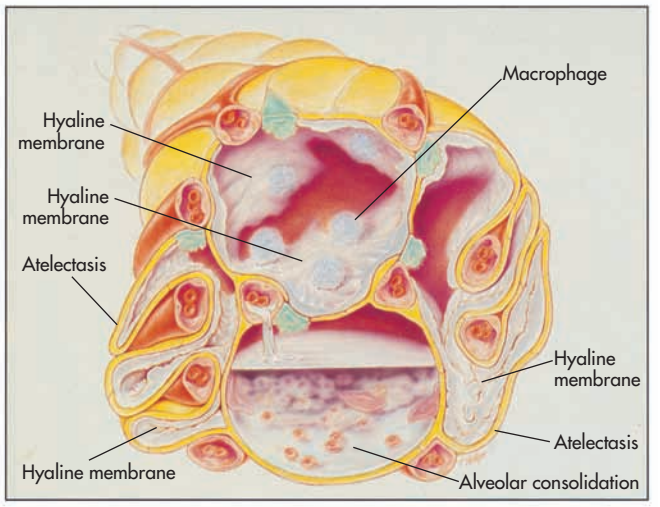

FIGURE 24-13 Cross-sectional view of alveoli in acute respiratory distress syndrome.

no history of recent respiratory illness or disease. ARDS is more common in men than in women. It affects about 190,000 people in the United States each year.[15] The death rate is greater than 65%. Complications include respiratory failure, cardiac dysrhythmias, disseminated intravascular coagulation, barotrauma, congestive heart failure, and renal failure.

Management

All patients with ARDS should be given high-concentration oxygen and ventilatory support. Depending on the underlying cause of ARDS, prehospital management may include fluid replacement to maintain cardiac output and peripheral perfusion; drug therapy to support mechanical ventilation; the use of pharmacological agents (e.g., corticosteroids) to stabilize pulmonary, capillary, and alveolar walls; and administration of diuretics.

Patients with ARDS usually have tachypnea, labored breathing, and impaired gas exchange 12 to 72 hours after the initial injury or medical crisis. The syndrome often results from another illness or injury. Therefore paramedics should consider the cause of the underlying problem. They also should provide supplemental oxygen and ventilatory support to improve arterial oxygenation (assessed by pulse oximetry). Most patients with moderate to severe respiratory distress require mechanical ventilation. This ventilation includes the use of positive end-expiratory pressure (PEEP, described in Chapter 15) or continuous positive airway pressure (CPAP). Both of these provide positive-pressure ventilation.

LOOK AGAIN
See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 422-425.

PULMONARY EMBOLISM

Pulmonary embolism (PE) is a blockage of a pulmonary artery. The artery is blocked by a clot or other foreign material that has traveled there from another part of the body (Figure 24-14). Usually pulmonary embolisms originate in the lower extremities. PE is a relatively common disorder that affects about 650,000 people each year in the United States. Of this number 30% to 50% die, 10% within the first few hours after blockage.[16] In cases of severe pulmonary embolism, where shock and heart failure occur, the death rate may be greater than 50%.[17] Pulmonary embolism is responsible for 5% of all sudden deaths.[18]

PE usually begins as a venous disease. It most often is caused by migration of a thrombus from the large veins of the lower extremities, but it also can occur as a result of fat, air, sheared venous catheters, amniotic fluid, or tumor tissue. The clot or embolus dislodges and travels through the venous system to the right side of the heart. From there it migrates to the pulmonary arteries, obstructing the blood supply to a section of lung. The most common sites of thrombus formation are the deep veins of the legs and pelvis. Six factors that contribute to the development of venous thrombosis are listed in Box 24-8.

When one or more pulmonary arteries are blocked, an area does not receive blood flow; however, it continues to be ventilated. In response to the lack of blood flow, vasoconstriction occurs. If the vascular obstruction is severe (blockage of 60% or more of the pulmonary vascular supply), hypoxemia, acute pulmonary hypertension, systemic hypotension, and shock may rapidly occur, with subsequent death.

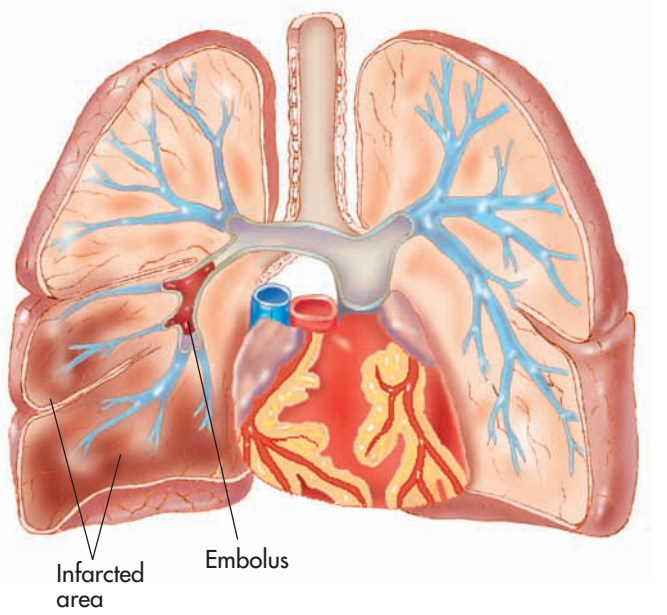

FIGURE 24-14 *Pulmonary embolism (PE)* is the blockage of a pulmonary artery by foreign matter, such as a thrombus. The blockage usually arises from a peripheral vein, fat, air, or tumor tissue. The result is obstruction of the blood supply to the lung tissue. (From Wilson SF, Thompson JM: *Mosby's clinical nursing series: respiratory disorders,* St Louis, 1990, Mosby.)

BOX 24-8 Contributing Factors in the Development of Venous Thrombosis

Venostasis
- Extended travel
- Prolonged bed rest
- Obesity
- Advanced age
- Burns
- Varicose veins

Venous Injury
- Surgery of the thorax, abdomen, pelvis, or legs
- Fractures of the pelvis or legs

Increased Blood Coagulability
- Malignancy
- Use of oral contraceptives
- Congenital or acquired coagulation disorders

Disease
- Chronic lung disease with polycythemia
- Congestive heart failure
- Sickle cell anemia
- Cancer
- Atrial fibrillation
- Myocardial infarction
- Previous pulmonary embolism
- Previous deep vein thrombosis
- Infection
- Diabetes mellitus

Multiple Trauma
- Long bone fracture
- Pelvic fracture

Signs and Symptoms

An embolus may be small, moderate, or massive. Thus patients with PE may have very different presentations and a wide variety of signs and symptoms. These depend on the location and size of the clot. They may include dyspnea, cough, hemoptysis (rare), pain, anxiety, syncope, hypotension, diaphoresis, tachypnea, tachycardia, fever, and distended neck veins. In addition, chest splinting, pleuritic pain, pleural friction rub, crackles, and localized wheezing may be present. If the embolism is large, sudden cardiac arrest can occur. The paramedic should consider a pulmonary embolism in any patient who has cardiorespiratory problems that cannot be otherwise explained, particularly when risk factors are present. As mentioned earlier, continuous capnometry may be useful in identifying a patient with PE.

CRITICAL THINKING

Consider that you need to distinguish a pulmonary embolism (PE) from other conditions with similar signs and symptoms. What information in the patient assessment may help?

Management

Prehospital care mainly is supportive. Supplemental high-concentration oxygen should be administered, a cardiac monitor and pulse oximeter applied, and an IV line of normal saline or lactated Ringer's solution established. The patient should be transported in a position of comfort. Definitive care requires hospitalization and in-hospital treatment with fibrinolytic or ***heparin*** therapy.

NOTE

The ECG may show an *S1Q3T3 pattern* in a patient with PE. This pattern is a prominent S wave in lead I, a Q wave in lead III, and a T wave in lead III. However, the ECG pattern needed for the diagnosis of pulmonary embolism is debatable. Once the diagnosis of PE has been established, however, the ECG could allow the massive forms to be distinguished. T-wave inversion in the precordial leads is the most common abnormality (68%). This represents the ECG findings that are best correlated to the severity of the PE.[19]

UPPER RESPIRATORY INFECTION

Upper respiratory infections (URIs) affect the nose, throat, sinuses, and larynx. They are among the most common of all illnesses, affecting nearly 80 million people each year.[1] These illnesses include the common cold, pharyngitis, tonsillitis, sinusitis, and laryngitis (see Chapter 23). They rarely are life-threatening. However, they often exacerbate underlying pulmonary conditions. They also may lead to significant infections in patients with suppressed immune function. A key action for preventing the spread of respiratory tract infections is hand washing. Another crucial action is covering the mouth when sneezing or coughing.

A variety of bacteria and viruses can cause URIs. Group A streptococci are responsible for 20% to 30% of cases; 50% of cases have no demonstrated bacterial or viral cause.[1] Signs and symptoms of upper respiratory tract infection include the following:
- Sore throat
- Fever
- Chills
- Headache
- Facial pain (sinusitis)
- Purulent nasal drainage
- Halitosis (bad breath)
- Cervical adenopathy (enlarged cervical lymph nodes)
- Erythematous pharynx (pharyngeal inflammation/irritation)

CRITICAL THINKING

When might an upper respiratory infection (URI) become life threatening? Give two or three examples.

Management

Most URIs are self-limiting and require little or no prehospital treatment. Prehospital care is aimed at relieving the symptoms. This is especially true for patients who have underlying lung conditions. With such conditions, oxygen administration may be indicated. Other interventions that may be indicated for patients with underlying lung conditions include administration of bronchodilators or corticosteroids. If throat cultures are obtained at the scene, the family must be notified of the results. Follow-up by a physician is also required. The paramedic should follow local protocol.

SPONTANEOUS PNEUMOTHORAX

A primary **spontaneous pneumothorax** usually results when a bleb ruptures. This allows air to enter the pleural space from within the lung. This type of pneumothorax may occur in seemingly healthy individuals who are usually between 20 and 40 years of age. Often these patients are tall, thin men with long, narrow chests. (In contrast, a secondary spontaneous pneumothorax sometimes may develop from an underlying disease, such as COPD.) In recent years the number of spontaneous pneumothoraces has increased in some populations. These groups include individuals with acquired immunodeficiency syndrome (AIDS) who have pneumonia, and drug abusers who deeply inhale free-base cocaine, marijuana, or inhalants (e.g., glue or solvents). The condition should also be considered in a patient with COPD, especially if the patient has been treated with positive-pressure ventilation.

Most primary spontaneous pneumothoraces that are well tolerated by the patient occupy less than 20% of a lung (partial pneumothorax). Signs and symptoms include shortness of breath and chest pain that often is sudden in onset, pallor, diaphoresis, and tachypnea. In severe cases in which the pneumothorax occupies more than 20% of the hemithorax, the following signs and symptoms may be present:

- Altered mental status
- Cyanosis
- Tachycardia
- Decreased breath sounds on the affected side
- Local hyperresonance to percussion
- Subcutaneous emphysema

NOTE

In severe cases a spontaneous pneumothorax may generate a *tension pneumothorax*. When this occurs, venous return to the heart is impaired. This can lead to total cardiovascular collapse. Tension pneumothorax is further described in Chapter 42.

Management

Prehospital care is based on the patient's symptoms and degree of respiratory distress. Administration of high-concentration oxygen is indicated to help resolve the pneumothorax, and airway, ventilatory, and circulatory support may be required in severe cases. These patients should be transported in a position of comfort for evaluation by a physician and possible decompression of the pleural space. Surgery may be indicated in some cases. This may be done to allow for lung reexpansion or to prevent recurrence. If signs and symptoms of tension pneumothorax develop, needle chest decompression should be performed (see Chapter 42).

HYPERVENTILATION SYNDROME

Hyperventilation syndrome is abnormally deep or rapid breathing that results in an excessive loss of carbon dioxide. (This, in turn, produces respiratory alkalosis.) As a result, the syndrome produces hypocarbia. The hypocarbia leads to cerebrovascular constriction, reduced cerebral perfusion, paresthesia, dizziness, or even feelings of euphoria. Several conditions can cause hyperventilation syndrome, including the following:

- Anxiety
- Hypoxia
- Pulmonary disease
- Cardiovascular disorders
- Metabolic disorders
- Neurological disorders
- Fever
- Infection
- Pain
- Pregnancy
- Drug use

CRITICAL THINKING

How can you distinguish between hyperventilation caused by anxiety and hyperventilation caused by a serious medical illness or toxic ingestion?

Signs and symptoms of hyperventilation syndrome include dyspnea with rapid breathing and a high minute volume, chest pain, facial tingling, and carpopedal spasm. Other assessment findings vary, based on the cause of the syndrome. A low end-tidal carbon dioxide concentration ($EtCO_2$) measurement is <35 mm Hg.

Management

If the syndrome clearly is caused by anxiety (*psychogenic dyspnea,* which is a diagnosis of exclusion), prehospital care is mainly supportive. It consists of calming measures and reassurance. Paramedics may suspect that the syndrome is a result of illness (e.g., diabetes, renal disease). They also may suspect drug ingestion. In either case care includes both oxygen administration and airway and ventilatory support. All patients who are hyperventilating should be calmed and the paramedic should coach the patient's ventilations. Attempts should not be made to slow ventilations

if patients are compensating for hypoxia or metabolic acidosis. If the hyperventilation is severe or complicated by illness or drug ingestion, transport for evaluation by a physician is indicated.

LUNG CANCER

Lung cancer is an epidemic in the United States. An estimated 219,000 new cases are reported each year.[20] Most cases of lung cancer develop in individuals between 55 and 65 years of age. Of the new cases reported, most patients die of the disease within 1 year; 20% have local lung involvement, 25% have metastasis to the lymph system, and 55% have distant metastatic cancer.[21] The most common cause of lung cancer is cigarette smoking. Heavy smokers (more than 20 cigarettes a day) have a 25 times greater chance of developing lung cancer than nonsmokers.[22] Other risk factors include passive smoking (exposure to someone else's cigarette smoke) and exposure to asbestos, radon gas, dust, coal products, ionizing radiation, and other toxins.

Pathophysiology

Like other cancers, lung cancer is the uncontrolled growth of abnormal cells. At least a dozen different cell types of tumors are associated with primary lung cancer (Figure 24-15). The two major cell types of lung cancer are *small cell lung cancer* and *non–small cell lung cancer* (which is subcategorized as *squamous cell carcinoma, adenocarcinoma,* and *large cell carcinoma*). Each cell type has a different growth pattern. Each also has a different response to treatment. Most abnormal cell growth begins in the bronchi or bronchioles. The lung also is a fairly common site of **metastasis** (the spread of cancer) to other primary sites (e.g., breast cancer).

Signs and Symptoms

The signs and symptoms of early-stage disease often are nonspecific. Smokers often attribute them to the effects of smoking. These include coughing, sputum production, lower airway obstruction (noted by wheezing), and respiratory illness (e.g., bronchitis). As the disease progresses, signs and symptoms may include the following:

- Cough
- Hemoptysis (which may be severe)
- Dyspnea
- Hoarseness or voice change
- Dysphagia
- Weight loss/anorexia
- Weakness

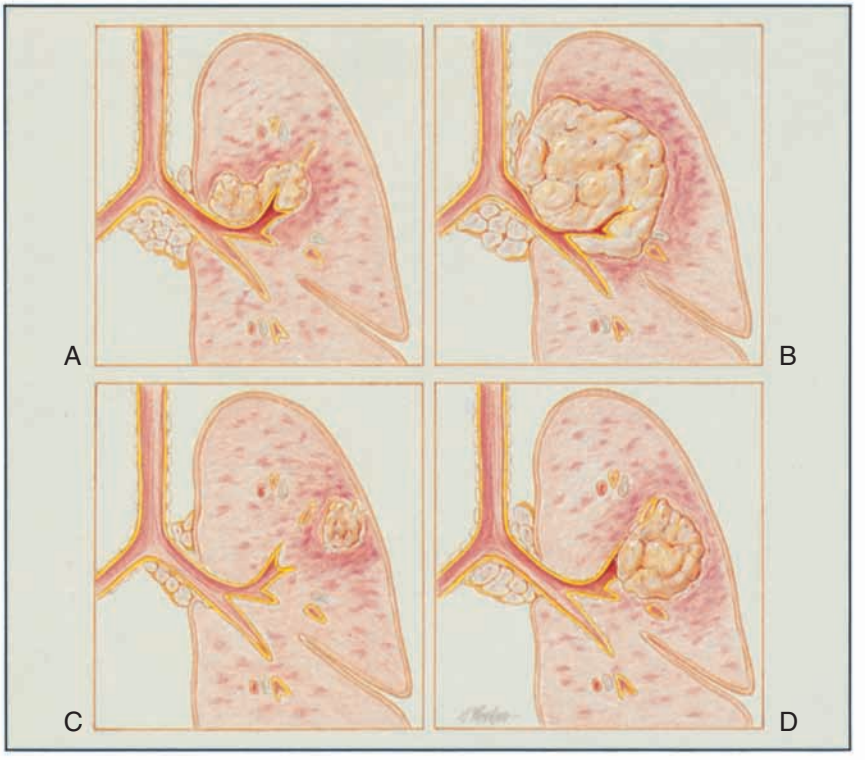

FIGURE 24-15 Cancer of the lung. **A,** Squamous cell carcinoma. **B,** Small cell (oat cell) carcinoma. **C,** Adenocarcinoma. **D,** Large cell carcinoma. (Modified from Desjardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 2006, Mosby.)

Patients with cancer may call paramedics because of complications resulting from chemotherapy or radiation therapy. Such therapy is toxic to both normal body cells and malignant cells. Associated complaints often include nausea and vomiting, fatigue, and dehydration. These patients should be offered emotional and psychological support.

CRITICAL THINKING

Should you assume that patients who have been diagnosed with lung cancer want "do not resuscitate" (DNR) status?

Management

Most patients with lung cancer are aware of their disease. Prehospital management includes airway, ventilatory, and circulatory support; oxygen administration (based on symptoms and pulse oximetry); and transport for evaluation by a physician. Depending on the severity of the patient's condition, IV fluids may be needed to improve hydration and to thin sputum. Drug therapy (e.g., bronchodilators and corticosteroids) may be needed to improve breathing. Analgesics may be required to relieve pain. End-stage patients may have advance directives or "do not resuscitate" (DNR) orders. In these cases emotional support should also be offered to the family and loved ones.

SUMMARY

- Diseases responsible for respiratory emergencies include those related to ventilation, diffusion, and perfusion. Ventilation moves air into and out of the lungs. Diffusion is the process of gas exchange. Perfusion is circulation of blood through the tissues.
- Patients should be assessed for chief complaint, signs and symptoms of respiratory distress, and past medical history. The physical examination should determine vital signs, indicators of increased work of breathing, breath sounds, and peripheral edema or cyanosis. Capnometry, oximetry, and peak flow measurements supplement the physical examination findings.
- Obstructive airway disease is a triad of distinct diseases that often coexist. These are chronic bronchitis, emphysema, and asthma. The main goal of prehospital care for these patients is the correction of hypoxemia through improved airflow.
- Chronic bronchitis is characterized by inflammatory changes and excessive mucus production in the alveoli. These patients often have low blood oxygen levels and excess carbon dioxide levels.
- Emphysema causes abnormal enlargement of air spaces beyond the terminal bronchioles and destruction and collapse of the alveoli.
- Asthma, or reactive airway disease, is characterized by reversible airflow obstruction caused by bronchial smooth muscle contraction; hypersecretion of mucus, resulting in bronchial plugging; and inflammatory changes in the bronchial walls. The typical patient with asthma is in obvious distress. Respirations are rapid and loud. Treatment focuses on bronchodilation, hydration, and reduction of inflammation.
- Pneumonia is a group of specific infections (bacterial, viral, or fungal). These infections cause an acute inflammatory process of the respiratory bronchioles and the alveoli. Pneumonia usually manifests with classic signs and symptoms. These include a productive cough and associated fever that produces "shaking chills." Prehospital care of patients with pneumonia includes airway support, oxygen administration, ventilatory assistance as needed, IV fluids, cardiac monitoring, and transport.
- Adult respiratory distress syndrome is a fulminant form of respiratory failure. It is characterized by acute lung inflammation and diffuse alveolar-capillary injury. It develops as a complication of illness or injury. In ARDS, the lungs are wet and heavy, congested, hemorrhagic, and stiff, with decreased perfusion capacity across alveolar membranes. Prehospital management includes airway and ventilatory support.
- Positive end-expiratory pressure (PEEP) maintains pressure at the end of exhalation. Adding PEEP in the respiratory circuit keeps alveoli open and pushes fluid from the alveoli back in the interstitium or capillaries. Continuous positive airway pressure maintains constant airway pressure throughout the entire respiratory cycle. CPAP improves diffusion and helps reexpand collapsed alveoli. Biphasic positive airway pressure delivers variable airway pressure throughout the respiratory cycle.
- Pulmonary thromboembolism is a blockage of a pulmonary artery by a clot or other foreign material. When one or more pulmonary arteries are blocked by an embolism, a section of lung is ventilated but hypoperfused. Hypotension, shock, and death can occur. Prehospital care is mainly supportive and includes oxygen administration, IV access, and transport for definitive care.
- Upper respiratory infections affect the nose, throat, sinuses, and larynx. Signs and symptoms of a URI include sore throat, fever, chills, headache, cervical adenopathy, and an erythematous pharynx. Prehospital care is based on the patient's symptoms.
- A primary spontaneous pneumothorax usually results when a subpleural bleb ruptures. This allows air to enter the pleural space from within the lung. Signs and symptoms include shortness of breath and chest pain that

often are sudden in onset, pallor, diaphoresis, and tachypnea. Prehospital care is based on the patient's symptoms and degree of distress.

- Hyperventilation syndrome is abnormally deep or rapid breathing. This type of breathing results in an excessive loss of carbon dioxide. If the syndrome clearly is caused by anxiety, prehospital care is mainly supportive (i.e., calming measures and reassurance). The paramedic may suspect that the syndrome is a result of illness or drug ingestion. If this is the case, care may include oxygen administration and airway and ventilatory support.
- Lung cancer is an expression of the uncontrolled growth of abnormal cells. As the disease progresses, signs and symptoms may include cough, hemoptysis, dyspnea, hoarseness, and dysphagia. Prehospital management includes airway, ventilatory, and circulatory support.

CHAPTER

25 Neurology

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the anatomy and physiology of the nervous system.
2. Outline pathophysiological changes in the nervous system that may alter the cerebral perfusion pressure.
3. Describe the assessment of a patient with a nervous system disorder.
4. Describe the pathophysiology, signs and symptoms, and specific management techniques for each of the following neurological disorders: coma, stroke and intracranial hemorrhage, seizure disorders, headaches, brain neoplasm and brain abscess, and degenerative neurological diseases.

KEY TERMS

absence seizures Seizures characterized by brief lapses of consciousness without loss of posture; also known as *petit mal seizures.*

acoustic neuroma A noncancerous tumor that involves the vestibular portion of the acoustic nerve (cranial nerve VIII).

action potential A change in membrane potential in an excitable tissue that acts as an electrical signal and is propagated in an all-or-none fashion.

Alzheimer's disease A disease characterized by confusion, memory failure, disorientation, speech disturbances, and inability to carry out purposeful movements.

amyotrophic lateral sclerosis (ALS) One of a group of rare disorders in which the nerves that control muscular activity degenerate in the brain and spinal cord; also called *Lou Gehrig's disease.*

arteriovenous (AV) malformation An abnormal connection between veins and arteries; it is believed to arise during fetal development or soon after birth.

atonic seizures Seizures that cause an abrupt loss of muscle tone, loss of posture, or sudden collapse ("drop attacks").

aura A sensation that may precede a migraine or seizure activity.

automatism Abnormal repetitive motor behavior (e.g., lip smacking, chewing, or swallowing), during which the patient is amnestic.

axon The main central process of a neuron that normally conducts action potentials away from the cell body of the neuron.

Babinski's sign A reflex movement in which the great toe bends upward when the outer edge of the sole is scratched; also known as *Babinski's reflex.*

Bell's palsy A paralysis of the facial muscles caused by inflammation of the facial nerve (cranial nerve VII); the condition usually is one-sided and temporary and often develops suddenly.

brain abscess An accumulation of purulent material (pus) surrounded by a capsule within the brain.

brain tumors Masses in the cranial cavity.

cell body The part of the cell that contains the nucleus and surrounding cytoplasm, exclusive of any projections or processes; it is concerned more with metabolism of the cell than with a specific function.

central nervous system (CNS) The brain and spinal cord.

cerebral aneurysm A weak or thin spot on a blood vessel in the brain that balloons and fills with blood.

cerebral blood flow (CBF) A function of the cerebral perfusion pressure and the resistance of the cerebral vascular bed.

cerebral embolism An obstruction in a cerebral artery by an embolus, usually resulting in transient or permanent impairment of cognitive, motor, or sensory function.

cerebral perfusion pressure (CPP) A measure of the amount of blood flow to the brain. It is calculated by subtracting the intracranial pressure from the mean systemic arterial blood pressure.

cerebral thrombosis The formation of a blood clot (thrombus) in an artery that supplies blood to the brain.

cerebrospinal fluid (CSF) The fluid that fills the subarachnoid space in the brain and spinal cord and in the cerebral ventricles.

cerebrovascular accident (CVA) An abnormal condition of the blood vessels of the brain characterized by occlusion by an embolus, thrombus, or cerebral hemorrhage; also called a *stroke* or "brain attack."

circle of Willis The circle of interconnected blood vessels at the base of the brain.

cluster headache A type of headache that occurs in bursts, or clusters; also known as a histamine headache.

coma An abnormally deep state of unconsciousness from which the patient cannot be aroused by external stimuli.

complex partial seizure A seizure that originates in the temporal lobe; it usually begins with an aura and is followed by repetitive motor behavior.

confabulation The invention of stories to make up for gaps in memory.

conjugate gaze Deviation of both eyes to either side at rest; the condition implies a structural lesion.

Creutzfeldt-Jakob disease (CJD) A rare, fatal brain disorder characterized by rapidly progressive dementia.

Cushing's reflex An attempt by the body to compensate for a decline in cerebral perfusion pressure by increasing the mean arterial pressure.

decerebrate rigidity A position in which a comatose patient's arms are extended and internally rotated and the legs are extended with the feet in forced plantar flexion; it usually is seen with compression of the brainstem; also known as *decerebrate posturing.*

decorticate rigidity A position in which a comatose patient's upper extremities are rigidly flexed at the elbows and at the wrists; it usually is seen with a lesion in the mesencephalic region of the brain; also known as *decorticate posturing.*

dementia A slow, progressive loss of awareness of time and place. It usually involves an inability to learn new things or recall recent events.

dendrites The branching processes of a neuron that receive stimuli and conduct potentials toward the cell body.

dysconjugate gaze Deviation of the eyes to opposite sides at rest; it implies a structural brainstem dysfunction in the pathways that traverse the brainstem from the upper midbrain to at least the level of the lower pons.

dystonia A condition characterized by local or diffuse changes in muscle tone, resulting in painful muscle spasms, unusually fixed postures, and strange movement patterns.

effector organ A muscle or gland that responds to nerve impulses from the central nervous system.

epilepsy A condition characterized by the tendency to have recurrent seizures (excluding those that arise from correctable or avoidable circumstances).

generalized seizure A seizure without an identifiable focus in the brain.

gingival hypertrophy Swelling of the gums; often associated with chronic phenytoin therapy.

Glasgow Coma Scale A standardized system for assessing the degree of impairment of consciousness in a critically ill patient and for predicting the duration and ultimate outcome of coma.

glossopharyngeal neuralgia Irritation of the glossopharyngeal nerve (cranial nerve IX).

Guillain-Barré syndrome (GBS) A rare disease associated with a viral infection or immunization that affects the peripheral nervous system, especially the spinal nerves, but also the cranial nerves.

hemifacial spasm A neuromuscular disorder characterized by frequent involuntary contractions of the muscles on one side of the face.

hemiparesis One-sided weakness.

hemorrhagic stroke A stroke caused by bleeding.

Huntington's disease (HD) A rare, hereditary disease characterized by quick, involuntary movements, speech disturbances, and mental deterioration; it is caused by degenerative changes in the cerebral cortex and basal ganglia; also known as *Huntington's chorea.*

intracranial pressure (ICP) The pressure inside the skull, brain tissue, and cerebrospinal fluid.

ischemic stroke A stroke caused by blockage of a cerebral blood vessel; also called an *occlusive stroke.*

jacksonian seizure A transitory disturbance in motor, sensory, or autonomic function resulting from abnormal neuronal discharges in a localized part of the brain; also known as a *focal seizure.*

mean arterial pressure (MAP) The arithmetic mean of the blood pressure in the arterial portion of the circulation.

migraine A severe, incapacitating headache that often is preceded by visual and/or gastrointestinal disturbances.

motor neurons Neurons are efferent neurons that innervate skeletal, smooth, or cardiac muscle fibers.

multiple sclerosis (MS) A progressive disease of the central nervous system in which scattered patches of myelin in the brain and spinal cord are destroyed.

muscular dystrophy An inherited muscle disorder of unknown cause marked by a slow but progressive degeneration of muscle fibers.

myoclonic seizures Seizures that cause brief muscle contractions, which usually occur at the same time and on both sides of the body.

neoplasm An abnormal growth; a malignant or benign tumor.

neuroglia Specialized connective tissue cells that protect and hold functioning neurons together.

neurons The functional units of the nervous system; they consist of the nerve cell body, the dendrites, and the axon.

nonepileptic seizure A seizure that stems from psychological causes rather than electrical disturbances in the brain.

nuchal rigidity Neck stiffness with flexion, which suggests meningeal irritation.

Parkinson's disease A disease caused by degeneration or damage (of unknown origin) to nerve cells in the basal ganglia in the brain.

partial seizure A seizure that originates from an identifiable cortical lesion.

peripheral nervous system (PNS) A subdivision of the nervous system consisting of nerves and ganglia.

peripheral neuropathy Diseases and disorders that affect the peripheral nervous system, including the spinal nerve roots, cranial nerves, and peripheral nerves.

Pick's disease A rare neurodegenerative disease associated with the shrinking of the frontal and temporal anterior lobes of the brain.

poliomyelitis An infectious disease caused by one of three polio viruses; asymptomatic, mild, and paralytic forms of the disease occur.

Ranvier's nodes The short intervals in the myelin sheath of a nerve fiber between adjacent Schwann cells.

reflex An automatic response to a stimulus that occurs without conscious thought; it is produced by a reflex arc.

Schwann cells Cells that form a myelin sheath around each nerve fiber of the peripheral nervous system.

seizure A temporary change in behavior or consciousness caused by abnormal electrical activity in one or more groups of neurons in the brain.

sensory neurons Neurons that transmit impulses to the spinal cord and brain from all parts of the body.

simple partial seizure A seizure that originates in the motor or sensory cortex; it usually manifests as clonic activity that is limited to one body part.

sinus headache A headache characterized by pain in the forehead, nasal area, and eyes.

spina bifida A congenital defect in which part of one or more vertebrae fails to develop completely, leaving a portion of the spinal cord exposed.

spinal cord tumors Benign or malignant tumors that originate in the cells within or next to the spinal cord.

status epilepticus Continuous seizure activity lasting 30 minutes or longer, or a recurrent seizure without an intervening period of consciousness.

subarachnoid hemorrhage Bleeding within the subarachnoid space.

synapse Functional membrane-to-membrane contact of a nerve cell with another nerve cell, muscle cell, gland cell, or sensory receptor; it transmits action potentials from one cell to another.

tension headache A headache caused by muscle contraction in the face, neck, and scalp.

tonic-clonic seizures Generalized seizures involving the entire body; also known as *grand mal seizures.*

transient ischemic attack (TIA) An acute episode of temporary neurological dysfunction resulting from focal cerebral ischemia; also called a "mini stroke."

trigeminal neuralgia Infection or disease of the trigeminal nerve (cranial nerve V); also known as *central pain syndrome.*

Acute medical disorders of the nervous system require rapid assessment and management. Paramedics must combine knowledge and skills with appropriate, aggressive intervention. These actions can help reduce mortality and morbidity. Proper recognition and treatment are the foundation for the greatest potential for rehabilitation and recovery.

ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM

As described in Chapter 10, the nervous system is divided into two parts: the **central nervous system (CNS)** and the **peripheral nervous system (PNS)** (Figure 25-1).The ability of the human body to maintain a state of balance **(homeostasis)** is chiefly the result of the nervous system's ability to coordinate and regulate the body's activities. To review, the CNS consists of the brain and the spinal cord. Both of these are encased in and protected by bone. A total of 43 pairs of nerves originate from the CNS to form the PNS. Twelve pairs of cranial nerves originate from the brain. Thirty-one pairs of spinal nerves originate from the spinal cord.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 171-177.

Cells of the Nervous System

The cells of the nervous system include **neurons** (the basic units of the nervous system) and connective tissue cells known as **neuroglia** (specialized cells that protect and hold functioning neurons together). Each neuron has three main parts: (1) the **cell body,** which has a single, relatively

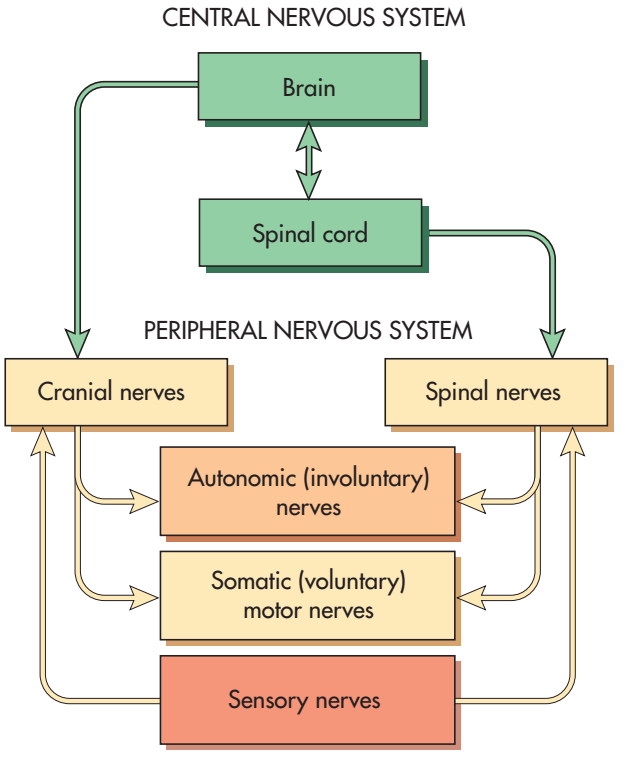

FIGURE 25-1 Divisions of the nervous system. (McSwain N: *The basic EMT: comprehensive prehospital patient care,* St Louis, 1999, Mosby.)

large nucleus with a prominent nucleolus; (2) one or more branching projections, called **dendrites;** and (3) a single, elongated projection, known as an **axon** (Figure 25-2). Dendrites transmit impulses to the cell bodies. Axons transmit impulses away from the cell bodies. Axons are surrounded by supportive and protective sheaths formed by the cytoplasmic extensions of neuroglial cells in the CNS *(unmyelinated axons)*. Axons are also surrounded by **Schwann cells** in the PNS *(myelinated axons)*.

Bundles of parallel axons with their associated sheaths are white and therefore are called *white matter*. The **action potential,** which is initiated in the neuron body, is propagated through the axons via conduction pathways or nerve tracts from one area of the CNS to another. In the PNS, bundles of axons and their sheaths are called *nerves*. Collections of nerve cells are grayer and are called *gray matter*. Gray matter is the site of integration in the nervous system. The outer surface of the cerebrum and the cerebellum consists of gray matter, which forms the cerebral cortex and the cerebellar cortex.

Types of Neurons

Neurons are classified as sensory neurons, motor neurons, or interneurons. This is based on the direction in which they transmit impulses. **Sensory neurons** transmit impulses to the spinal cord and brain from all parts of the body. **Motor neurons** transmit impulses in the opposite direction, away from the brain and spinal cord. In addition, they transmit impulses only to muscle and glandular epithelial tissue. **Interneurons** conduct impulses from sensory neurons to motor neurons. Sensory neurons also are called *afferent neurons.* Motor neurons are called *efferent neurons.* Interneurons are called *central* or *connecting neurons.*

Impulse Transmission

The transmission of nerve impulses in the nervous system is similar to the conduction of electrical impulses through the heart. In its resting state, the neuron is positively charged on the outside and negatively charged on the inside. When the neuron is stimulated by pressure, temperature, or chemical changes, the cell membrane's permeability to sodium ions increases. As a result, positively charged sodium ions rush into the interior of the neuron. This inward movement begins a wave of depolarization. The wave travels down the axon, resulting in the propagation of an action potential (Figure 25-3).

CRITICAL THINKING

Think of examples of a pressure, a temperature, and a chemical stimulus to a nerve.

In unmyelinated axons, action potentials are spread along the entire axon membrane. Myelinated axons, however, have interruptions in the myelin sheaths. These are known as **Ranvier's nodes.** These nodes allow nerve impulses to "jump" from one node to the next without spreading along the entire length of the cell *(saltatory conduction)*. Myelinated axons, therefore, conduct action potentials faster than unmyelinated axons.

Synapse

The membrane-to-membrane contact that separates the axon endings of one neuron *(presynaptic neuron)* from the dendrites of another neuron *(postsynaptic neuron)* is known as a **synapse.** The structures that compose a synapse are the presynaptic terminal, the synaptic cleft, and the plasma membrane of the postsynaptic neuron. Within each presynaptic terminal are synaptic vesicles that contain neurotransmitter chemicals (Figure 25-4).

Each action potential arriving at the presynaptic terminal initiates a series of specific events. These events result in the release of the neurotransmitter. The neurotransmitter rapidly diffuses the short distance across the synaptic cleft. It then binds to specific receptor molecules on the postsynaptic membrane. After an impulse has been generated and conducted by the postsynaptic neurons, neurotransmitter activity ends quickly. Several substances have been identified as neurotransmitters; others are thought to be neurotransmitters. Well-known neurotransmitters include acetylcholine, norepinephrine, epinephrine, and dopamine (Table 25-1).

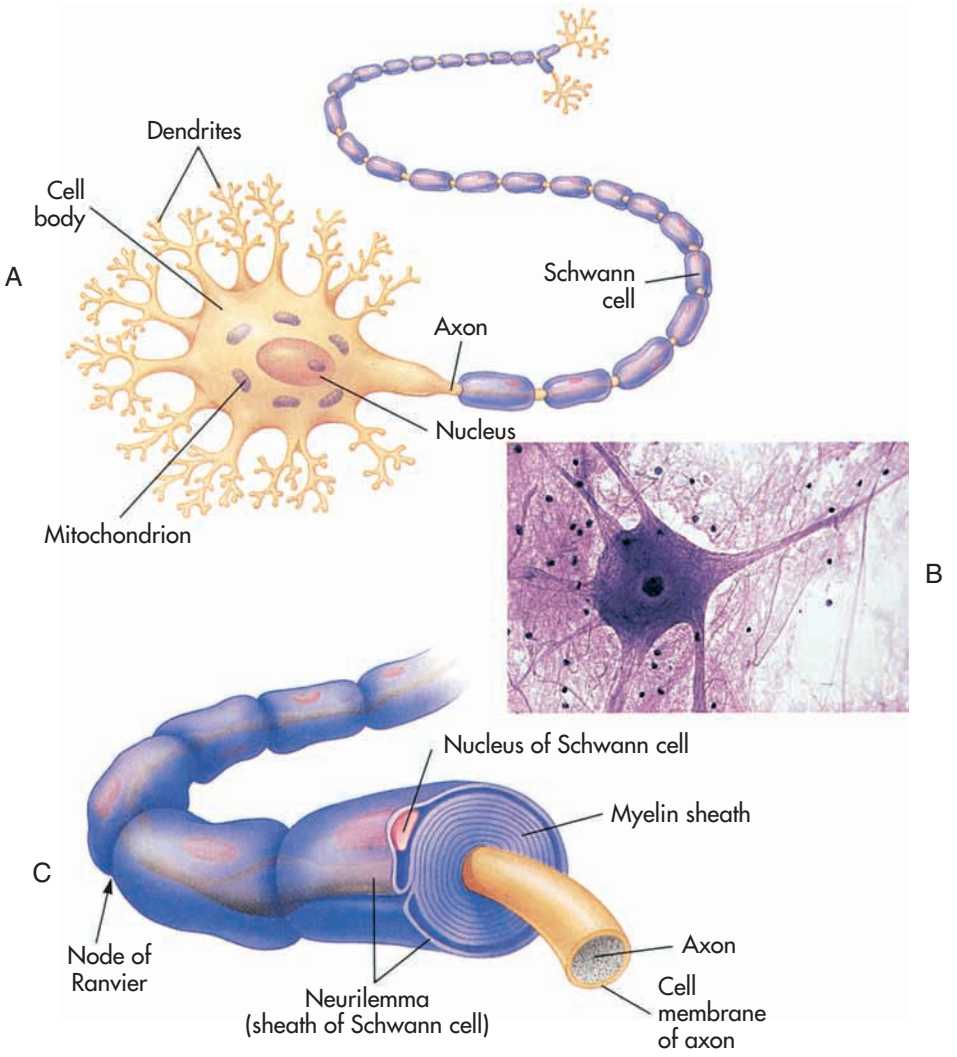

FIGURE 25-2 **A,** Typical neuron showing dendrites, a cell body, and an axon. **B,** Photomicrograph of a neuron. **C,** Segment of a myelinated axon cut to show details of the concentric layers of the Schwann cell filled with myelin. TABLE 25-1 Major Neurotransmitters

Neurotransmitter	Postsynaptic Effect
Acetylcholine	Excitatory
Norepinephrine	Excitatory
Epinephrine	Excitatory
Dopamine	Excitatory

Reflexes

One type of route traveled by nerve impulses is a reflex, or reflex arc. A **reflex** is the basic unit of the nervous system capable of receiving a stimulus and generating a response. Reflexes allow conduction of impulses in one direction. They have several basic components: a sensory receptor, a sensory neuron, interneurons, a motor neuron, and an effector organ. (An **effector organ** is a muscle or gland that contracts or secretes, respectively, in direct response to nerve impulses.) Individual reflexes vary in complexity. Some act to remove the body from painful stimuli. Some prevent the body from suddenly falling or moving as a result of external forces. Others are responsible for maintaining a relatively constant blood pressure, body fluid pH, blood carbon dioxide level, and water intake. All reflexes are homeostatic; that is, they function to maintain healthy survival.

Action potentials initiated in sensory receptors spread along sensory axons in the PNS to the CNS. There they synapse with interneurons. Interneurons synapse with motor neurons in the spinal cord; the motor neurons send their axons out of the spinal cord and through the PNS to muscles or glands. This causes the effector organ to respond. Figure 25-5 shows the transmission of nerve impulses that result in the patellar (knee jerk) reflex.

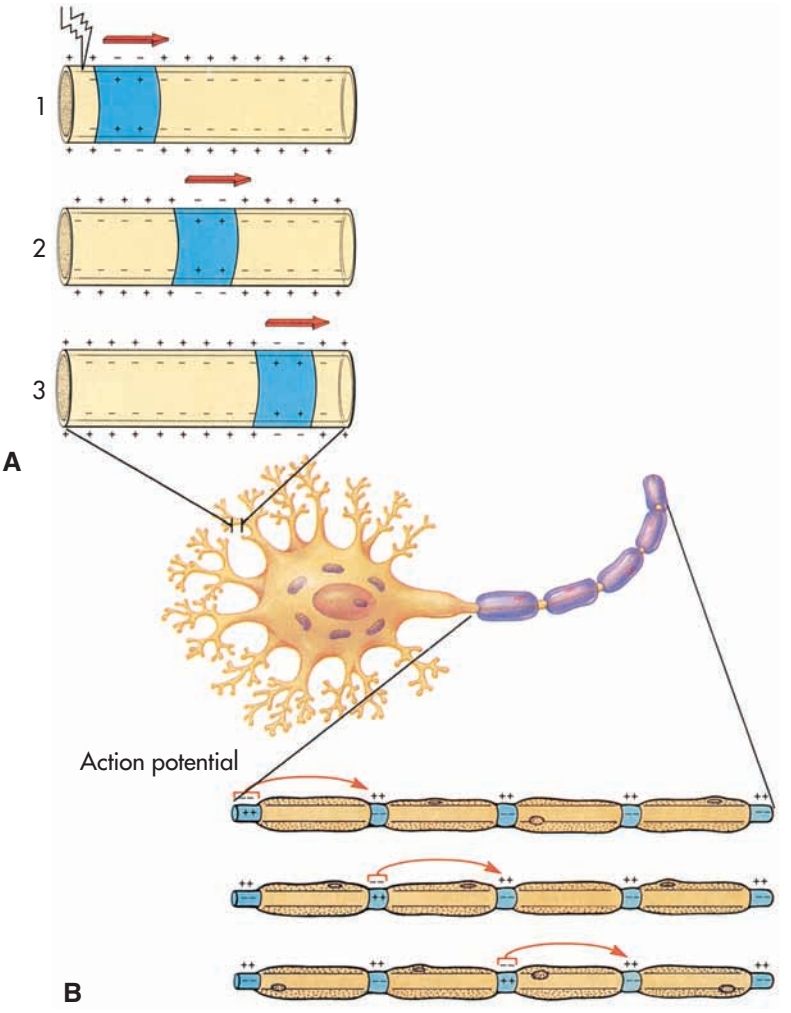

FIGURE 25-3 Conduction of nerve impulses. **A,** In unmyelinated fiber, a nerve impulse (action potential) is a self-propagating wave of electrical disturbance. **B,** In myelinated fiber, the action potential "jumps" around the insulating myelin in a rapid type of conduction called *saltatory conduction.* (Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

Blood Supply

The arterial blood supply to the brain comes from the vertebral arteries and the internal carotid arteries (Figure 25-6). The right and left vertebral arteries (supplying the cerebellum) enter the cranial vault through the foramen magnum. They unite to form the midline basilar artery. The basilar artery branches to supply the pons and the cerebellum. It divides again to form the posterior cerebral arteries. These supply the posterior portion of the cerebrum.

The internal carotid arteries enter the cranial vault through the carotid canals. These vessels give rise to the anterior cerebral arteries. The anterior cerebral arteries supply blood to the frontal lobes of the brain. They end by forming the middle cerebral arteries. These supply a large portion of the lateral cerebral cortex. A posterior communicating artery branches off each internal carotid artery and connects with the ipsilateral posterior cerebral artery. The two posterior cerebral arteries are connected at their common origin from the basilar artery. The anterior cerebral arteries are connected by an anterior communicating artery. Thus they complete a circle around the pituitary gland and the brain; this is the **circle of Willis.** The circle of Willis provides an important safeguard. It helps to ensure the supply of blood to all parts of the brain in the event of a blockage in one of the vertebral or internal carotid arteries.

The veins that drain blood from the head form the venous sinuses. (These are the spaces in the dura mater surrounding the brain.) Eventually they drain into the internal jugular veins (Figure 25-7). These veins exit the cranial vault and join with several other veins that drain the external

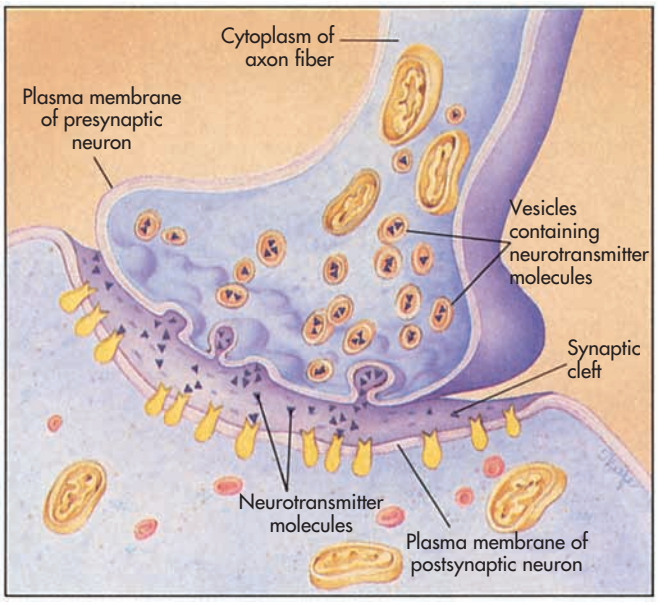

FIGURE 25-4 Components of a synapse. The diagram shows an axon terminal of a presynaptic neuron and a synaptic cleft. When an action potential arrives at the axon terminal of a presynaptic neuron, neurotransmitter molecules are released from vesicles in the axon terminal into the synaptic cleft. The combining of neurotransmitter and receptor molecules in the plasma membrane of the postsynaptic neuron initiates impulse conduction in the postsynaptic neuron. (Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

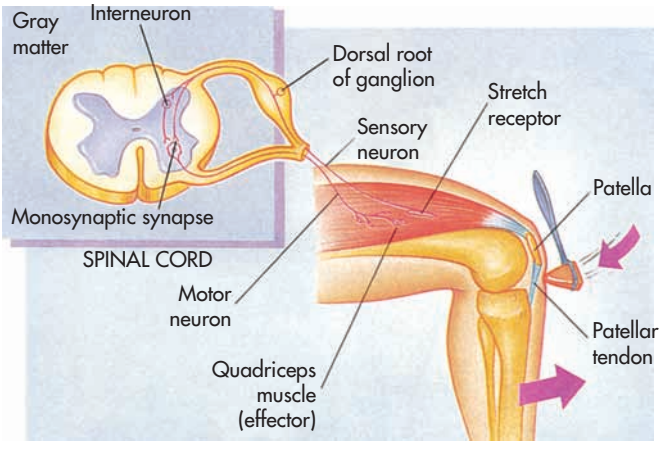

FIGURE 25-5 Neural pathway involved in the patellar (knee jerk) reflex. (Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

head and face. The internal jugular veins join the subclavian veins on each side of the body.

Ventricles

Each cerebral hemisphere contains a large space filled with **cerebrospinal fluid (CSF).** This space is known as a *lateral ventricle.* The lateral ventricles are connected posteriorly. A third ventricle is located in the center of the diencephalon between the two halves of the thalamus. The two lateral ventricles communicate with the third ventricle through two interventricular foramina. The third ventricle communicates with the fourth ventricle (located in the superior region of the medulla) by way of a narrow canal. This canal is known as the *cerebral aqueduct.* The fourth ventricle is continuous with the central canal of the spinal cord.

CRITICAL THINKING
What happens if the flow in one of these canals becomes obstructed?

Divisions of the Brain

The major divisions of the adult brain are the brainstem (medulla, pons, midbrain, and site of the reticular formation), cerebellum, diencephalon (hypothalamus and thalamus), and cerebrum (Figure 25-8). (See Chapter 10 to review these structures.)

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 171-174.

NEUROLOGICAL PATHOPHYSIOLOGY

Some neurological emergencies are a consequence of structural changes or damage, circulatory changes, or alterations in **intracranial pressure (ICP)** that affect **cerebral blood flow (CBF).** Three structures occupy the intracranial space: brain tissue, blood, and water. Brain tissue contains mostly water, both intracellular and extracellular. Blood is contained in the major arteries in the base of the brain; in arterial branches, arterioles, capillaries, venules, and veins in the substance of the brain; and in the cortical veins and dural sinuses. Water is located in the ventricles of the brain, in the CSF, and in extracellular and intracellular fluid. Normally the volumes of brain tissue, blood, and water are such that the pressure inside the skull is maintained within 1 mm of mercury above atmospheric pressure.

Cerebral Blood Flow

Although the brain accounts for only 2% of adult weight, 20% of total body oxygen use and 25% of total body glucose use are devoted to brain metabolism.[1] Oxygen and glucose delivery are controlled by cerebral blood flow.

Cerebral blood flow is a function of the **cerebral perfusion pressure (CPP)** and the resistance of the cerebral vascular bed. To measure the CPP, the intracranial pressure is subtracted from the **mean arterial pressure (MAP).** (The MAP is the diastolic blood pressure [DBP] plus one third of the pulse pressure [PP]: MAP = DBP + ⅓ PP). The

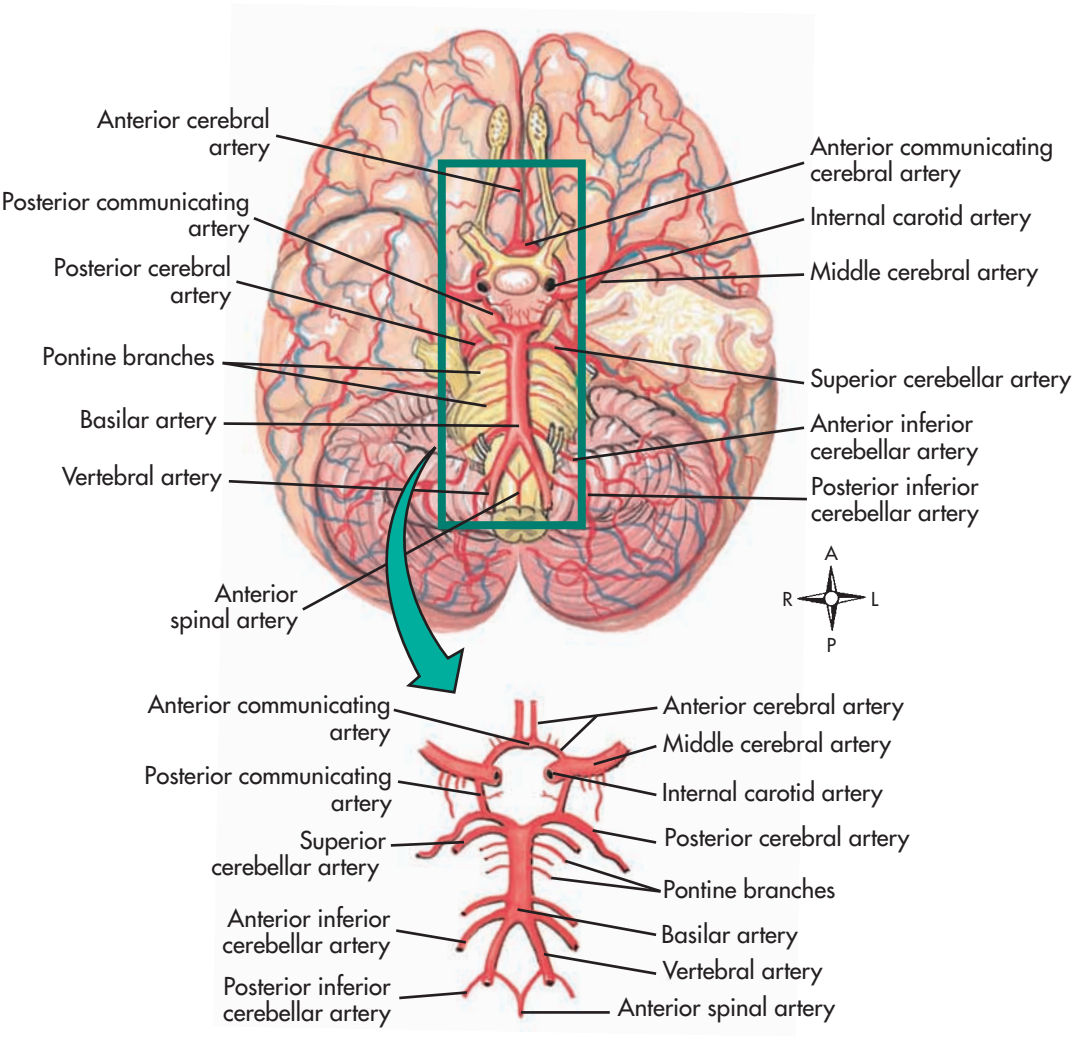

FIGURE 25-6 Inferior view of the brain showing vertebral, basilar, and internal carotid arteries and their branches. (Modified from Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

cerebral blood flow is the difference between the MAP and the ICP (CPP = MAP − ICP). The normal ICP is 10 to 15 mm Hg or less. The normal MAP ranges from 70 to 95 mm Hg. Therefore, the normal CPP is 60 to 80 mm Hg. (A CPP of 60 mm Hg is thought to be the critical minimum threshold for organ blood flow.[2]) As the ICP rises and approaches the MAP, the gradient for flow decreases and cerebral blood flow decreases; that is, when the ICP increases, the CPP decreases (Figure 25-9). As the CPP decreases, vessels in the brain dilate (cerebral vasodilation). This results in increased cerebral blood volume (increasing the ICP) and further cerebral vasodilation. In most EMS systems, the CPP is not calculated, because the MAP and ICP are not measured in the prehospital setting. Maintaining a systolic blood pressure of at least 90 mm Hg may help maintain an adequate mean arterial pressure.[3]

NOTE

Vascular tone in the normal brain is regulated by the partial pressure of arterial carbon dioxide (P_{CO_2}), the partial pressure of arterial oxygen (P_{O_2}), and by autonomic and neurohumoral control. The P_{CO_2} has the greatest effect on intracerebral vascular diameter and subsequent resistance. For example, a 40 to 80 mm Hg increase in the P_{CO_2} doubles the cerebral blood flow.[4] This results in increased brain blood volume and intracranial pressure.

Cerebral Perfusion Pressure

As stated previously, cerebral blood flow depends on the CPP, which is the pressure gradient across the brain. The CBF remains constant when the CPP is 50 to 160 mm Hg. If the CPP falls below 40 mm Hg, cerebral blood flow

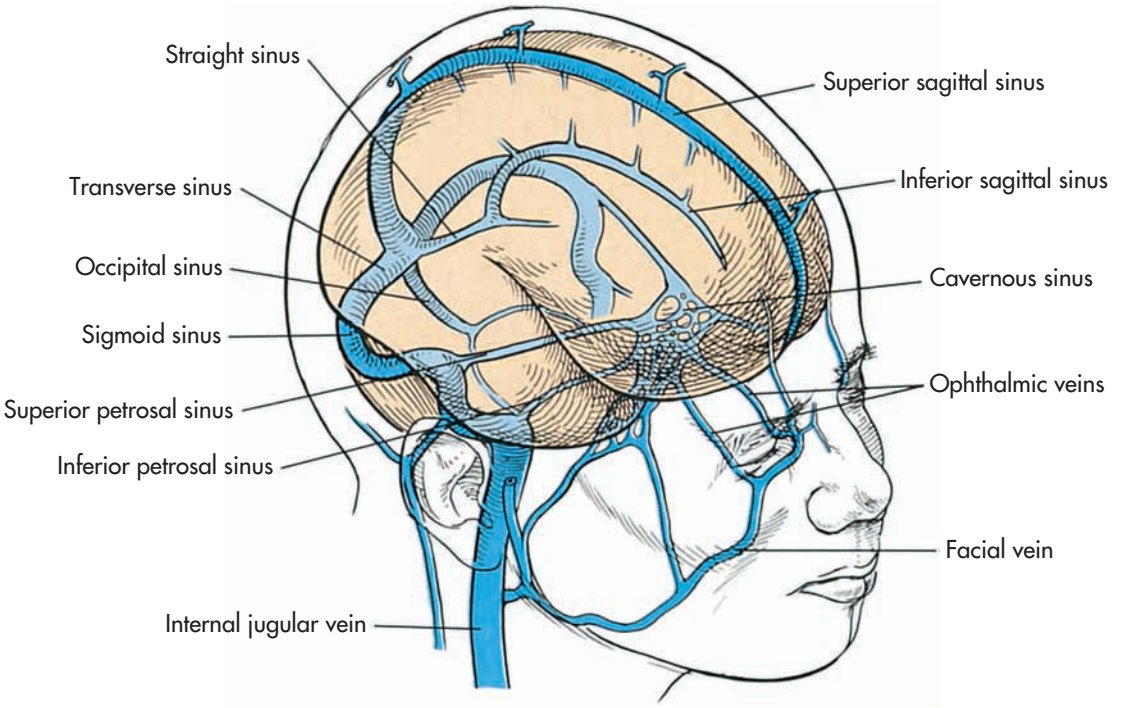

FIGURE 25-7 Venous sinuses associated with the brain.

declines. This critically affects cerebral metabolism. With mild to moderate elevation of the ICP, the MAP usually rises. The rise in the MAP causes cerebral blood vessels to constrict and prevents the increase in blood volume and CBF that normally would occur.

CRITICAL THINKING

Relate the difficulty created for cerebral blood flow by increased intracranial pressure to having a person push on a door from the outside while you try to open it from the inside. How much more difficult is it for you to open the door?

On the other hand, if the MAP falls, the cerebral arteries dilate, increasing the CBF. Therefore, with an MAP of 60 to 150 mm Hg, cerebral blood flow may be maintained in a constant state. However, when ICP elevations are marked (greater than 22 mm Hg), perfusion of brain tissue often decreases despite a rise in the systemic arterial pressure. Therefore, if a mass or cerebral edema develops, an immediate reduction in the volume of one or more of these components (brain tissue, blood, or water) must occur to prevent the ICP from rising and compressing brain tissue.

Assessment of the Nervous System

As with all patient encounters, care of a patient with a nontraumatic neurological emergency begins with the primary survey. Paramedics should have a systematic approach for examining these patients. This helps to ensure that signs and symptoms that may indicate an urgent condition are not overlooked. The goals of emergency care are (1) control of the airway, (2) stabilization and support of the cardiovascular system, (3) intervention to interrupt ongoing cerebral injury, and (4) protection of the patient from further harm while at the scene and during transport to an appropriate medical facility for definitive care.

PRIMARY SURVEY

The paramedic should begin the primary survey by determining the patient's level of consciousness. An open and patent airway also must be ensured. If the patient is unconscious when paramedics arrive and there is reason to suspect a cervical spine injury, the patient's airway should be opened with spinal precautions and the cervical spine should be immobilized (see Chapter 41). It is important to remember that an unconscious patient is unable to maintain the airway. Therefore, airway adjuncts (including the placement of advanced airways) may be indicated. The patient also should be closely monitored for respiratory arrest, which may result from an increase in the ICP. The patient should be closely watched for vomiting or aspiration of stomach contents. Suction should be readily available.

NOTE

The mantra of the cardiologist is "time is muscle." Many neurologists consider that time also is brain tissue. Rapid stabilization of the patient's condition and transport for definitive care may be the most prudent course of action in a neurological emergency.

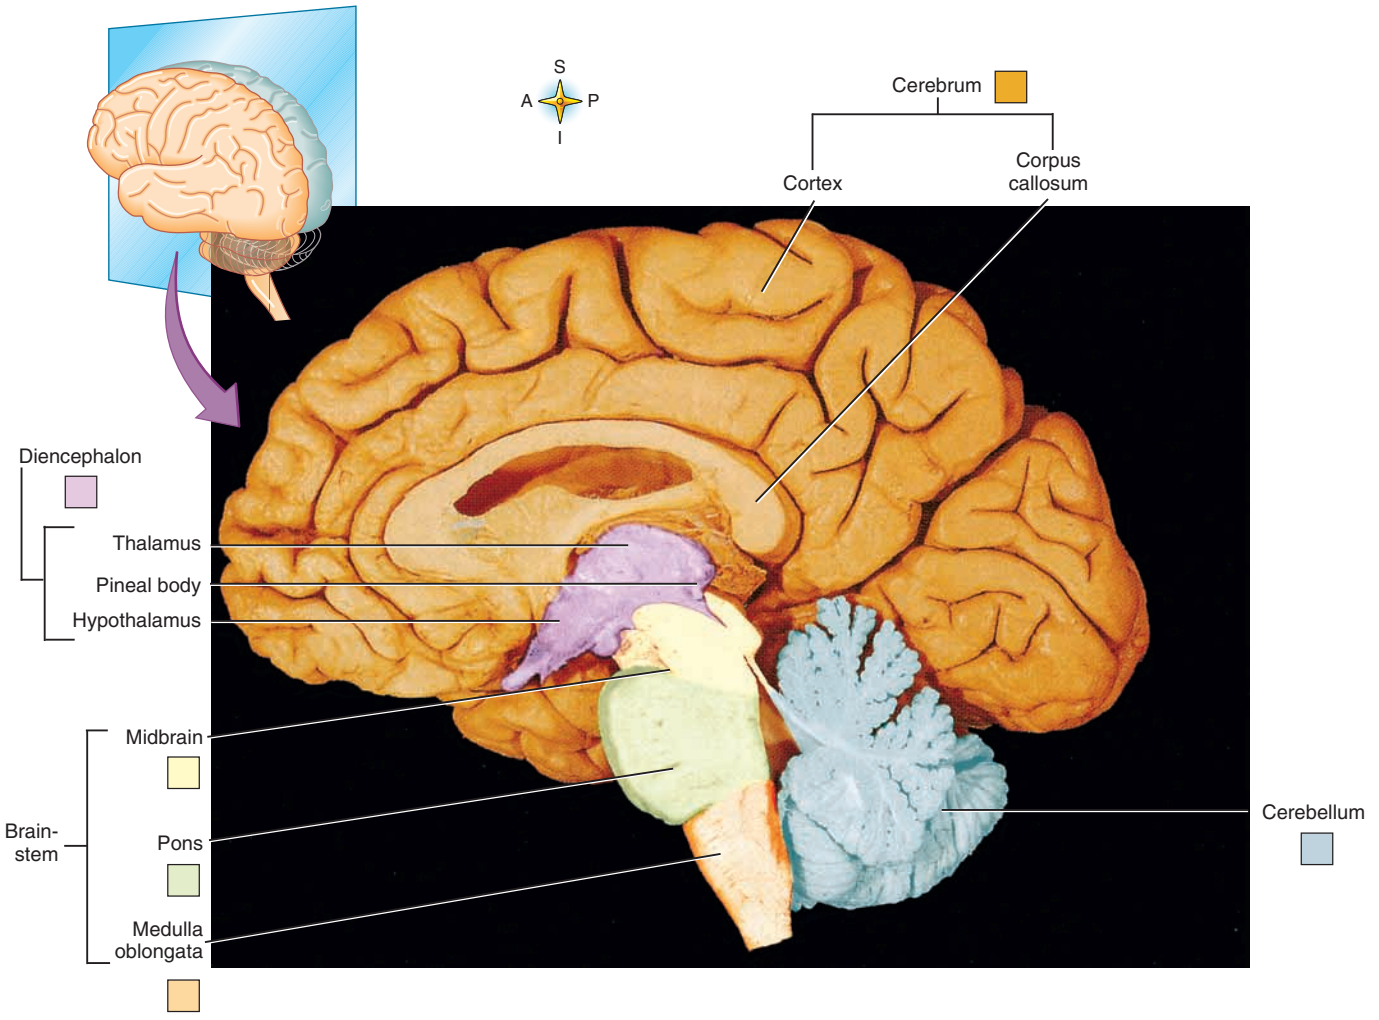

FIGURE 25-8 Divisions of the brain. A midsagittal section of the brain reveals features of its major divisions. (From Thibodeau G, Patton K: *Anatomy and physiology,* ed 18, St Louis, 2007, Elsevier.)

Support of breathing and supplemental oxygen should be provided for most patients experiencing a neurological emergency. An increase in the partial pressure of arterial carbon dioxide (P_{CO_2}) or a decrease in the partial pressure of arterial oxygen (P_{O_2}) results in dilation of the blood vessels. This occurs presumably because of an increase in cerebral metabolic needs. As the P_{CO_2} drops, blood volume and blood flow to the brain are reduced.

PHYSICAL EXAMINATION

A patient with a neurological illness may be difficult to assess. This is particularly true if the patient's mental function is impaired. Key elements of the physical examination may offer clues to the cause of the neurological emergency. These include the patient history, the history of the event, vital signs, and respiratory patterns.

History. After any life-threatening problems have been identified and managed, the paramedic should attempt to compile a thorough history. This information can be obtained from the patient (when possible) or from family members or bystanders. The following are six important elements of the patient history.

1. The patient's chief complaint
2. Details of the presenting illness
3. Pertinent underlying medical problems
   a. Cardiac disease
   b. Lung disease
   c. Neurological disease (e.g., multiple sclerosis)
   d. Previous stroke
   e. Chronic seizures
   f. Diabetes
   g. Hypertension

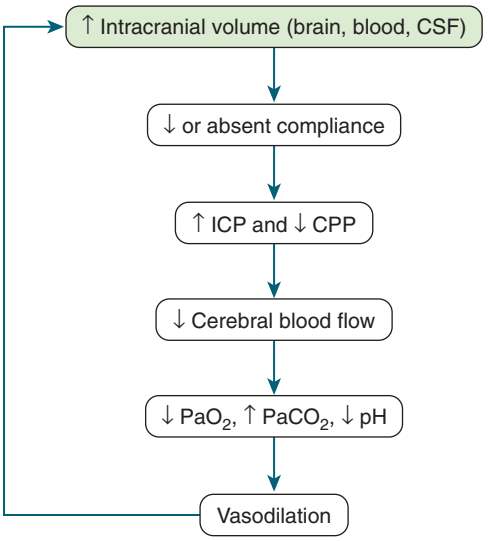

FIGURE 25-9 Pathophysiology flow diagram for increased intracranial pressure. (Sole ML: *Introduction to critical care nursing,* ed 5, St Louis, 2009, Saunders.)

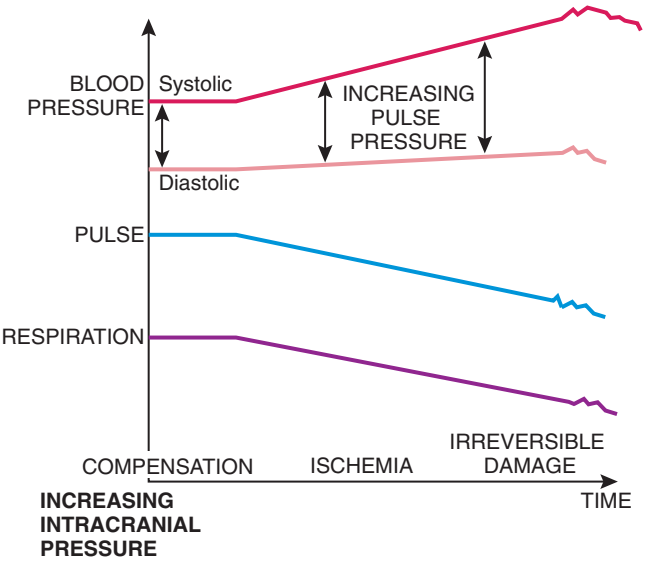

FIGURE 25-10 Vital signs with increased intracranial pressure. (Gould BE, Dyer R: *Pathophysiology or the health professional,* ed 4, St Louis, 2011, Saunders.)

4. Alcohol or other drug use
5. Previous history of similar symptoms
6. Recent injury (particularly head trauma)

If a loss of consciousness was involved, the paramedic should ascertain the events that led up to the unconscious state. This information may include the patient's position (sitting, standing, lying down), whether the person complained of a headache, and whether seizure activity or a fall occurred. At times no history is available. In such cases paramedics should assume that the onset of unconsciousness was acute. They also should assume that an intracranial hemorrhage is likely. In addition, they should be alert for any environmental clues. Examples include evidence of current prescribed medications, medical alert identification, recreational drugs, alcohol, or drug paraphernalia.

CRITICAL THINKING

How could having one of the conditions listed in the six important elements of the patient history result in a change in the patient's neurological status?

Vital Signs. The patient's vital signs should be checked and recorded often. This is important because the vital signs may change rapidly in patients with a neurological emergency. The patient's electrocardiogram (ECG) should be monitored for dysrhythmias, which are common in these situations.

When the ICP begins to rise, a conscious patient may complain of headache, nausea, and vomiting. Progressive hypertension associated with bradycardia and diminished respiratory effort is a response to lethal increases in the ICP.[5] This reflex is known as **Cushing's reflex.** The late stages of increased ICP are marked by an increase in systolic pressure, a widened pulse pressure, and a decrease in the pulse and respiratory rate (Figure 25-10). In the terminal stages, as the ICP continues to rise and brain tissue is compressed, the pupils become unequal and the body temperature usually remains elevated. The pulse rate generally decreases and the blood pressure falls, particularly after herniation occurs. Therefore, hypotension is a late and ominous sign in these patients.

Respiratory Patterns. The respiratory pattern of a patient with a neurological emergency may be normal or abnormal. In the absence of respiratory arrest caused by damage to the lower respiratory centers in the medulla, abnormalities of the respiratory rate and rhythm may occur. These abnormalities may provide clues to which area of the brain is involved. They also may indicate the severity of the neurological problem. Apnea can occur with loss of consciousness even with relatively minor head trauma. However, acute respiratory arrest usually results from involvement of the medullary respiratory center (brainstem compression or infarct). Damage to neural pathways (anywhere from the cortex down to the medulla) produces problems with the respiratory rhythm more often than respiratory arrest. Abnormal respiratory patterns (described in detail in Chapter 15) include the following:

- Cheyne-Stokes respiration
- Central neurogenic hyperventilation
- Ataxic respiration
- Apneustic respiration
- Diaphragmatic breathing

CRITICAL THINKING
Consider a patient who has ataxic or apneustic respirations. Which respiratory control center likely is affected?

NEUROLOGICAL EVALUATION

Some neurological complications are obvious (e.g., paralysis). Others may be subtle (e.g., a decreasing level of awareness). A sudden or rapidly worsening level of consciousness is the single most suggestive sign of a serious neurological condition.[6]

As described in Chapter 20, the mnemonic device AVPU (*a*lert, *v*erbal, *p*ainful, *u*nresponsive) can help determine the patient's baseline neurological status. The **Glasgow Coma Scale** (Box 25-1) should also be calculated during the initial assessment. These evaluations should be repeated and recorded often. This allows changes in the patient's mental state to be detected quickly.

When evaluating a patient's neurological status, the paramedic should report and record patient information with descriptive terms. These terms should be specific to responses to certain stimuli. (For example, "The patient has no recall of the event"; "The patient moves on command"; and "The patient does not open his eyes to painful stimuli.") Clear descriptions of the patient's response allow others involved in the patient's care to follow the progression of the condition.

Posturing, Muscle Tone, and Paralysis

Significant neurological emergencies may be associated with abnormal or unusual posturing, paralysis of a limb or several limbs, or both. Generally, disturbances of posture result from flexor spasms, extensor spasms, or flaccidity. Abnormal flexor response of one or both arms with extension of the legs is called **decorticate rigidity.** This abnormal posturing is thought to result from damage to the cortex of the brain. Abnormal extensor response of the arms with extension of the legs is called **decerebrate rigidity.** Decerebrate rigidity has a worse prognosis than decorticate rigidity. It is thought to result from damage to the subcortical areas of the brain. Flaccidity usually is caused by brainstem or cord dysfunction. It has a dismal prognosis.

Abnormal reflexes are not uncommon with decorticate or decerebrate rigidity. Babinski's sign *(plantar reflex)* may be associated with such posturing. **Babinski's sign** is an abnormal extensor reflex in adults. (It may be normal in children in the first few years of life.) It is characterized by dorsiflexion or extension of the great toe, with or without fanning or abduction of the other toes, when the outer edge of the foot is scratched. It indicates neurological injury (Figure 25-11). A patient with a severe injury may also have relaxation of sphincter tone and may be incontinent of urine or feces or both.

NOTE
There is no "positive" or "negative" Babinski's sign. The presence of this response indicates the existence of a pathological condition.

Pupillary Reflexes

Examination of the pupils is very important in an unconscious patient. Often the diagnosis of drug use can at least be suspected based on the appearance and reaction of the pupils. If deviations from normal (in relative symmetry, size, and prompt reaction to light) are observed, it is crucial to note whether these deviations are unilateral or bilateral. If both pupils are dilated and do not react to light, the brainstem probably has been affected. This also may occur with severe cerebral anoxia.

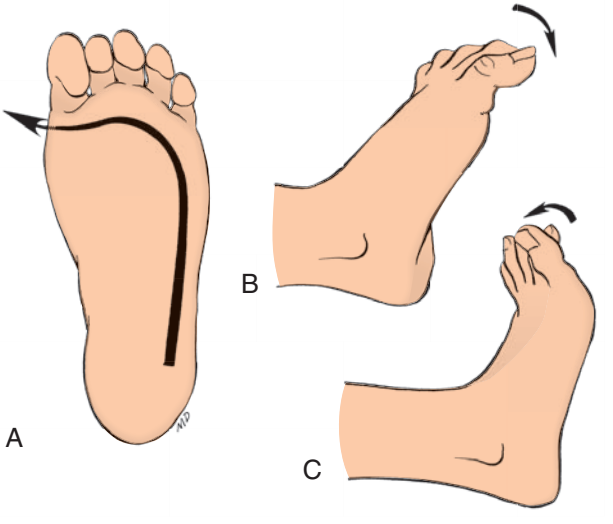

FIGURE 25-11 Babinski's reflex. **A,** Light pressure is applied with a hard object to the lateral surface of the sole, starting at the heel, going over the ball of the foot, and ending beneath the great toe. **B,** The normal response is flexion of all the toes. **C,** Babinski's reflex is seen as dorsiflexion or extension of the great toe, with or without fanning or abduction of the other toes. (Sole ML: *Introduction to critical care nursing,* ed 5, St Louis, 2009, Saunders.)

BOX 25-1 Glasgow Coma Scale

The Glasgow Coma Scale (GCS) evaluates eye opening, verbal and motor responses, and brain stem reflex function. The scale is considered one of the best indicators of eventual clinical outcome and should be part of every examination of a patient with a medical or traumatic neurological emergency (see Table 25-1). A GCS score of 9 to 12 indicates moderate brain injury; a score of 8 or lower indicates severe brain injury.[5] (The lowest possible score is 3; the highest possible score is 15.) Hypoxemia and hypotension have been shown to cause falsely low GCS scores. Therefore, the GCS score should be measured after the primary survey and after a clear airway has been established.

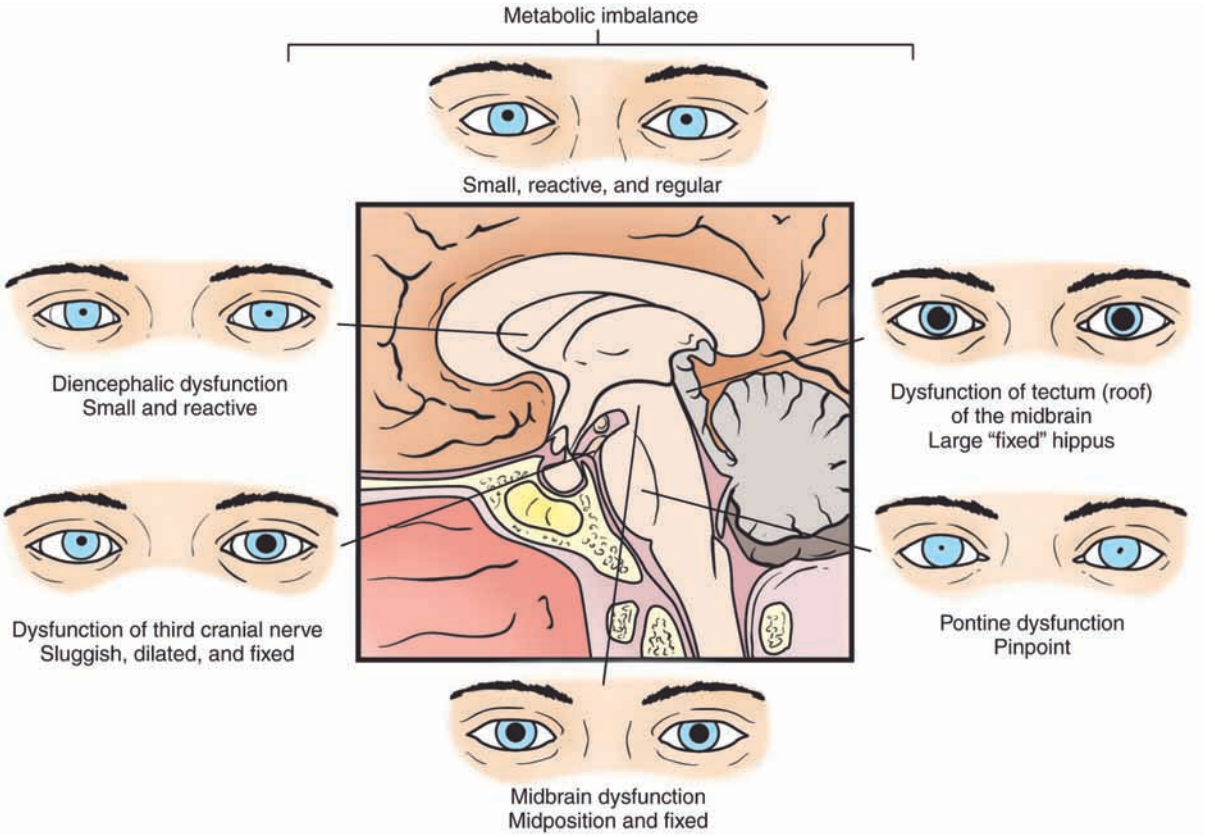

FIGURE 25-12 Pupils at different levels of consciousness.

NOTE
The response of the pupils must be considered in conjunction with the patient's mental status. Unresponsive, dilated pupils in a patient who is awake, alert, and oriented most likely are the result of topical medications used to induce pupillary dilation.

Pupillary constriction is controlled by parasympathetic fibers. These fibers originate in the midbrain and accompany the oculomotor nerve (cranial nerve III) (Figure 25-12). Pupillary dilation involves fibers that travel the entire brainstem and return in the cervical sympathetic nerves. Midbrain injury interrupts both pathways. Generally it results in fixed, midsize pupils. Compression of cranial nerve III interrupts parasympathetic nerve actions. It is manifested by a unilateral, fixed, dilated pupil. Any unconscious patient who suddenly develops a fixed, dilated pupil probably has suffered a significant neurological event.[5] This requires immediate transport to a proper medical facility. (Parasympathetic nerve roots and the functions of the cranial nerves are described in Chapter 10; methods of cranial nerve assessment are addressed in Chapter 20. Table 25-2 serves as a review of this information.)

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 177-179.

Extraocular Movements

A conscious patient should be able to move the eyes in full directional ranges. As described in Chapter 20, paramedics can evaluate extraocular movements by asking the patient to follow the paramedic's finger movements. For this test, the paramedic moves a finger to the extreme left and then up and down and to the extreme right and then up and down. Any deviations from normal should be recorded.

LOOK AGAIN
See Chapter 20: Secondary Assessment, pp. 531-532.

CRITICAL THINKING
Which cranial nerves control eye movements?

TABLE 25-2 Cranial Nerve Assessment

Nerve	Name	Function	Test
I	Olfactory	Smell	Have patient smell a familiar odor
II	Optic	Visual acuity	Have patient identify fingers
		Visual field	Check peripheral vision
III	Oculomotor	Pupillary reaction	Shine a light in patient's eye
IV	Trochlear	Eye movement	Have patient follow finger without moving the head
V	Trigeminal	Facial sensation	Touch the face
		Motor function	Have patient hold the mouth open
VI	Abducens	Motor function	Check lateral eye movements
VII	Facial	Motor function	Have patient smile, wrinkle the face, and puff the cheeks
		Sensory	Check different tastes
VIII	Acoustic	Hearing	Snap fingers by the ear
		Balance	Perform Romberg's test
IX	Glossopharyngeal	Swallowing and voice	Have patient swallow and say "Ah"
X	Vagus	Gag reflex	Check with tongue depressor
XI	Spinal accessory	Neck motion	Have patient shrug shoulders
XII	Hypoglossal	Tongue movement and strength	Have patient stick out tongue; exert resistance with a tongue depressor

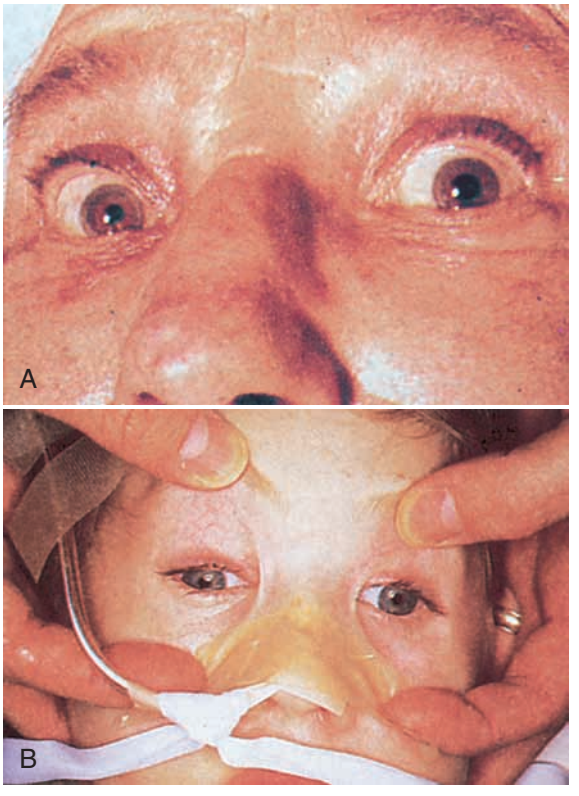

FIGURE 25-13 A, Conjugate gaze. **B,** Dysconjugate gaze. (London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications.)

Deviation of both eyes to either side **(conjugate gaze)** at rest implies damage to brain tissue (a lesion). If the lesion has an *irritative focus,* the eyes look away from the lesion. If it has a *destructive focus,* the eyes look toward the lesion.[7] Deviation of the eyes to opposite sides **(dysconjugate gaze)** at rest implies damage to the brainstem (Figure 25-13).

PATHOPHYSIOLOGY AND MANAGEMENT OF SPECIFIC CENTRAL NERVOUS SYSTEM DISORDERS

Disorders of the nervous system have many causes. Specific causes discussed in this chapter include structural and metabolic coma, stroke and intracranial hemorrhage (including transient ischemic attack), seizure disorders, headaches, and brain neoplasm and brain abscess. Several degenerative neurological diseases also are discussed.

Coma

Coma is an abnormally deep state of unconsciousness from which the patient cannot be aroused by external stimuli. In general terms, only two mechanisms produce coma: *structural lesions* and *toxic/metabolic states*. Structural lesions (e.g., a tumor or an abscess) depress consciousness by destroying or encroaching on the reticular activating system in the brainstem. Toxic/metabolic conditions involve the presence of toxins or the lack of oxygen or glucose. Either mechanism may result in depression of the cerebrum, with or without depression of the reticular activating system. Within these two primary mechanisms are six general causes of coma (Box 25-2). A mnemonic that may be helpful for remembering the common causes of coma is AEIOU-TIPS (Box 25-3).

DIFFERENTIATION OF STRUCTURAL AND TOXIC-METABOLIC CAUSES OF COMA

Structural and toxic/metabolic causes of coma differ in two primary ways. In coma of structural origin, the neurological signs often are one-sided, or asymmetrical. In toxic/metabolic coma, the neurological findings often are the same on the two sides of the body. In addition, coma of

BOX 25-2 Six General Causes of Coma

Structural Origin
- Intracranial bleeding
- Head trauma
- Brain tumor or other space-occupying lesion

Metabolic System
- Anoxia
- Hypoglycemia
- Diabetic ketoacidosis
- Thiamine deficiency
- Kidney and liver failure
- Postictal phase of seizure

Drugs
- Barbiturates
- Narcotics
- Hallucinogenics
- Depressants
- Alcohol

Cardiovascular System
- Hypertensive encephalopathy
- Shock
- Dysrhythmias
- Stroke

Respiratory System
- Chronic obstructive pulmonary disease
- Toxic inhalation (e.g., carbon monoxide poisoning)

Infection
- Meningitis
- Sepsis

BOX 25-3 Common Causes of Coma AEIOU-TIPS

A—Acidosis or alcohol
E—Epilepsy
I—Infection
O—Overdose
U—Uremia
T—Trauma
I—Insulin
P—Psychosis
S—Stroke

toxic/metabolic origin often is slow in onset, whereas structural lesions occur acutely. Changes in pupil responses are the most important physical sign in distinguishing between structural and toxic/metabolic causes of coma. Normal pupil responses suggest that the coma has a toxic/metabolic cause. Unresponsive or asymmetrical pupils suggest a structural cause.

NOTE
Some psychiatric conditions (e.g., a *hysterical coma*) can mimic comalike states. In these conditions, the state of unconsciousness has no physical cause. Patients who appear unconscious as a result of a psychiatric condition often vigorously blink and move the eyes. They also usually respond to annoying physical or verbal stimuli. In contrast, patients with organic sources of coma are unresponsive.

Unlike toxic/metabolic coma, structural coma follows a progressive pattern of deterioration. This pattern is caused by focal pressure or compression in the brain. The syndrome often is sudden in onset, and the examination results are asymmetrical, such as muscle weakness on one side of the body **(hemiparesis).** As a rule, structural lesions damage the reticular activating system as a result of increased ICP and herniation of the brain. This type of injury requires rapid surgical correction. Knowledge of the difference between toxic/metabolic coma and structural coma can help the paramedic anticipate the course of the patient's condition.

ASSESSMENT AND MANAGEMENT

Regardless of the cause of the coma, prehospital care is directed at supporting vital functions, preventing further deterioration of the patient's condition, and administering medications, intravenous (IV) fluids, or both to manage potentially reversible causes of coma. As always, airway maintenance and ventilatory support with supplemental high-concentration oxygen are the first priorities in patient care. Rapid transport for definitive care may be indicated.

If respirations are abnormally slow or shallow, ventilations should be supported. If the patient is unconscious and has no gag reflex, the trachea should be intubated. After securing the airway, the paramedic should take the following steps to treat a patient in a coma of unknown origin.

1. Establish an IV line to keep the vein open or to manage hypotension (if present).
2. Monitor the patient's ECG.
3. Per protocol, draw a blood sample for laboratory analysis. If hypoglycemia is suspected, use a glucometer or other device to measure the serum glucose level (see Chapter 26). Administer ***50% dextrose*** if indicated (per protocol). If alcohol is suspected as the cause of the coma, consider administration of ***thiamine*** before glucose.
4. If no response is obtained with glucose administration, administer ***naloxone*** per protocol. This rules out or reverses narcotic depression.
5. If the patient remains comatose, transport the person in a lateral recumbent position (if not contraindicated). This aids drainage of secretions. It also minimizes the chance of aspiration of stomach contents.

Closely monitor the patient's airway. Have suction readily available. Protect the patient's eyes from corneal drying by gently closing them and covering the lids with moist gauze pads.

NOTE

Thiamine is a B vitamin (B_1). It usually is found in adequate amounts in the normal diet. However, chronic alcoholism interferes with the intake, absorption, and utilization of thiamine. Serious neurological disease may result. The incidence of these alcohol-related neurological syndromes varies markedly in different regions of the United States. Therefore, administration of ***thiamine*** may be a local consideration. Paramedics should follow established protocols and consult with medical direction.

NOTE

Patients who are dependent on narcotics may have frank withdrawal symptoms. The paramedic should be prepared to restrain a patient who may become violent as the ***naloxone*** reverses the narcotic effects. Repeated doses of ***naloxone*** may be needed. This is because the duration of some narcotics may be longer than that of ***naloxone.*** Doses should be titrated to keep the patient free of respiratory depression.

Stroke and Intracranial Hemorrhage

A **cerebrovascular accident (CVA)** (also called a *stroke* or "brain attack") is a sudden interruption in blood flow to a portion of the brain, resulting in a neurological deficit. Stroke is a serious disease that affects more than 700,000 Americans each year.[8] It is associated with a 30-day mortality of 10% to 15%. It also is the third leading cause of death in the United States. A stroke frequently leaves its survivors severely disabled. According to the American Heart Association (AHA), individuals who are more likely to suffer a stroke have prior risk factors that can be classified as modifiable or nonmodifiable. Modifiable risk factors include the following:

- High blood pressure
- Cigarette smoking
- Transient ischemic attacks
- Heart disease
- Atrial fibrillation
- Diabetes mellitus
- Hypercoagulopathy
- High red blood cell count and sickle cell anemia
- Carotid stenosis

Nonmodifiable risk factors include the following:

- Age
- Gender (men are at greater risk than women)
- Race (African Americans are at greater risk than Caucasians)
- Previous stroke
- Heredity

The best way to prevent strokes is to identify individuals who are at risk and then to control as many risk factors as possible. This can be achieved with modification of poor health habits and drug therapy.

PATHOPHYSIOLOGY

As described previously, blood reaches the brain through four major vessels. These are the two carotid arteries and the two vertebral arteries. (The two carotid arteries provide about 80% of cerebral blood flow.) The two vertebral arteries combine to form the single basilar artery (supplying the remaining 20% of CBF). These two systems are interconnected at various levels. The principal level is the circle of Willis. In addition, collateral blood flow can be supplied to the brain through connections from blood vessels in the face and scalp to the dura and arachnoid coverings of the brain. The amount of collateral circulation varies from individual to individual. Beyond this, however, there is no collateral circulation in the depths of the brain.[9] Therefore, occlusion of any one of the more distal vessels may result in ischemia and infarction.

Normally, the CBF is maintained through autoregulation of cerebral vessels. These vessels constrict or dilate to preserve perfusion pressure even when the patient is hypotensive. Arterial cerebral perfusion is regulated by the level of oxygen and glucose supplied (ischemia and acidosis are profound vasodilators). Vessel occlusion or hemorrhage causes a sudden cessation of circulation to a portion of the brain. Autoregulatory mechanisms cannot readily correct this problem. The uncorrected ischemia that results within a short period leads to neuronal dysfunction and death. The onset and symptoms of the stroke depend on the area of the brain involved.

CRITICAL THINKING

How much oxygen and glucose can the brain store for emergency situations?

TYPES OF STROKE

Stroke is a general term that refers to the neurological manifestations of a critical decrease in blood flow to a portion of the brain, regardless of the cause. The AHA has defined two primary categories of stroke: **ischemic stroke,** also called *occlusive stroke* (stroke caused by clots); and **hemorrhagic stroke** (stroke caused by bleeding). Each of these categories is subdivided into two classes. For ischemic stroke, these are **cerebral thrombosis** and **cerebral embolism.** For hemorrhagic stroke, they are **intracerebral hemorrhage** and **subarachnoid hemorrhage** (Box 25-4).

Determining the origin of a stroke frequently is difficult and often unnecessary in the prehospital setting. (The best care for all stroke patients is support of vital functions and rapid transport for definitive care.) However, a paramedic who understands the various signs and symptoms of each

BOX 25-4 Classification of Strokes

Ischemic Strokes

Ischemic strokes are caused by blood clots. This type of stroke accounts for 85% of all strokes. This is the only type of stroke for which fibrinolytics are administered. Ischemic strokes are divided into two classes, depending on the cause:

- Cerebral thrombosis
- Cerebral embolism

Hemorrhagic Strokes

Hemorrhagic strokes are caused by ruptured blood vessels. The two classes of hemorrhagic stroke are:

- Intracerebral hemorrhage
- Subarachnoid hemorrhage

TABLE 25-3 Differentiation of Ischemic and Hemorrhagic Stroke

Ischemic Stroke	Hemorrhagic Stroke
• Most common	• Least common
• Usually the result of atherosclerosis or a tumor in the brain	• Usually the result of cerebral aneurysms, arteriovenous (AV) malformations, hypertension
• Develops slowly	• Develops abruptly
• Long history of vessel disease	• Commonly occurs during stress or exertion
• May be associated with valvular heart disease and atrial fibrillation	• May be associated with use of cocaine and other sympathomimetic amines
• History of angina, previous strokes	• May be asymptomatic before rupture

type of stroke is better equipped to anticipate the course of patient care (Table 25-3). Documentation of a thorough history and physical examination also helps others involved in the patient's care.

Ischemic Stroke. About 85% of strokes are the ischemic type.[10] Some of these are caused by cerebral thrombosis. The thrombosis occurs as a result of atherosclerotic plaques or pressure from a mass in the brain itself. Stroke caused by cerebral thrombosis usually is associated with a long history of blood vessel disease. Therefore, most of these patients are older. Most also have evidence of atherosclerotic disease in other areas of the body (angina pectoris, claudication, previous strokes). The signs and symptoms of thrombotic stroke usually are slower to develop than those of cerebral hemorrhage. These signs and symptoms include the following:

- Hemiparesis or hemiplegia on the side of the body opposite the lesion
- Numbness (decreased sensation) on the side of the body opposite the lesion
- Aphasia
- Confusion or coma
- Convulsions
- Incontinence
- Diplopia (double vision)
- Monocular blindness (painless visual loss in one eye)
- Numbness of the face
- Dysarthria (slurred speech)
- Headache
- Dizziness or vertigo
- Ataxia

A stroke caused by cerebral embolism occurs when an intracranial vessel is blocked by a foreign substance. The vessel is occluded by a fragment of a foreign substance originating outside the CNS. Common sources of cerebral emboli include atherosclerotic plaques (originating from large vessels of the head, neck, or heart). Thrombi that develop on the valves or in the chambers of the heart are very common in patients with heart valve disease and atrial fibrillation. Other, rare causes include air embolism from a chest injury and fat embolism after long-bone injury. Bacterial and fungal infections of the heart also can produce emboli. Women taking oral contraceptives and patients with sickle cell disease have an increased risk of stroke, by both thrombotic and embolic origins. Signs and symptoms of a cerebral embolus are similar to those of thrombotic stroke. However, embolic signs and symptoms develop more quickly. Also, they often are associated with an identifiable cause (e.g., atrial fibrillation).

Hemorrhagic Stroke. Cerebral hemorrhage accounts for about 15% of all strokes.[10] A hemorrhage may occur anywhere in the brain and its structures. This includes the epidural, subdural, subarachnoid, intraparenchymal, and intraventricular spaces. The most common causes are cerebral aneurysms, arteriovenous (AV) malformations, and hypertension. Cerebral aneurysms and AV malformations are congenital anomalies. They can run in families. They often are asymptomatic until they rupture. Unlike thrombotic and embolic strokes, which have relatively high survival rates, cerebral hemorrhages are fatal in 50% to 80% of cases.[11]

NOTE

A **cerebral aneurysm** is a weak or thin spot on a blood vessel in the brain that balloons and fills with blood. This bulging can put pressure on a nerve or brain tissue. The aneurysm also can rupture or leak, spilling blood into surrounding tissue. Cerebral aneurysms can occur anywhere in the brain, but most are located along a loop of arteries that run between the underside of the brain and the base of the skull.

An **arteriovenous (AV) malformation** is an abnormal connection between veins and arteries. These defects in the circulatory system are believed to arise during fetal development or soon after birth.[12] AV malformations can develop in many sites in the body. Those in the brain or spinal cord can result in hemorrhage and stroke.

Hemorrhagic strokes often occur during stress or exertion. Cocaine and other sympathomimetic-type drugs also may contribute to intracranial hemorrhage by a drug-induced rapid elevation of blood pressure. The onset of the stroke is sudden. It often begins with a headache (sometimes described as a "thunderclap headache" or the worst headache of the patient's life). The headache is accompanied by nausea, vomiting, and progressive deterioration in mental status. Some patients complain of a stiff neck. Often the patient loses consciousness or experiences a seizure at the time of the hemorrhage. As the hemorrhage expands, the ICP rises. As this occurs, the patient becomes comatose, with increasing hypertension, bradycardia, and diminished respiratory effort *(Cushing's reflex)*.

CRITICAL THINKING

Why do you think mortality is higher for hemorrhagic stroke than for embolic stroke?

TRANSIENT ISCHEMIC ATTACKS

A **transient ischemic attack (TIA)** often is referred to as a "mini stroke." TIAs are episodes of cerebral dysfunction that affect a specific portion of the brain. They may last minutes to several hours. The patient returns to normal within 24 hours without permanent neurological deficit. A TIA is thought to be the most important indicator of impending stroke; about 5% of patients who have a TIA go on to have a complete stroke within 1 month if left untreated.[2] A TIA is the most important forecaster of a brain infarction.

The signs and symptoms of a TIA are the same as those that characterize stroke: weakness, paralysis, numbness of the face, and speech disturbances. All of these correspond to vascular occlusion of a specific cerebral artery. Most patients who experience a TIA are hospitalized for close observation, evaluation, and treatment of vascular disease (e.g., endarterectomy or anticoagulant or antiplatelet therapy).

Role of Paramedics in Stroke Care

In stroke care, the paramedic's role is to identify a stroke event quickly; notify medical direction; and transport the patient rapidly to a proper facility for hospital-based evaluation and treatment. Key points in the management of stroke include the eight *Ds*: detection, dispatch, delivery, door, data, decision, drug, and disposition (Box 25-5). (The first three *D*s are the responsibility of the public and EMS personnel.)

BOX 25-5 Eight *Ds* of Stroke Management

The first three *D*s are the responsibility of the public and emergency medical services (EMS) providers. The fourth *D* is the responsibility of EMS, and the last three *D*s are performed in the hospital.

- **Detection:** A patient, family member, or bystander recognizes the signs and symptoms of a stroke or transient ischemic attack (TIA) and calls EMS for help.
- **Dispatch:** EMS dispatchers prioritize the call about a suspected stroke and dispatch the appropriate EMS team with high transport priority.
- **Delivery:** EMS providers respond rapidly, confirm the signs and symptoms of stroke, and transport the patient (delivery) to an appropriate medical facility.
- **Door:** An appropriate medical facility is a hospital that can provide fibrinolytic therapy within 1 hour of arrival at the emergency department door.
- **Data:** A computed tomography (CT) scan is obtained.
- **Decision:** Candidates for fibrinolytic therapy are identified.
- **Drug:** Eligible patients are treated with fibrinolytic therapy.
- **Disposition:** Rapid transfer to a stroke or critical care unit.

DID YOU KNOW?

Primary Stroke Centers

The Joint Commission's Certificate of Distinction for Primary Stroke Centers recognizes centers that make exceptional efforts to foster better outcomes for stroke care. Achievement of certification signifies that the services provided have the critical elements to achieve long-term success in improving outcomes. These centers are deemed qualified to effectively provide care for the unique and specialized needs of stroke patients. The Joint Commission's Primary Stroke Center Certification program[14] was developed in collaboration with the American Stroke Association. It is based on the Brain Attack Coalition's recommendations for the establishment of primary stroke centers. As of October 1, 2009, there were more than 600 certified primary stroke centers in 49 states.

NOTE

About 85% of strokes occur at home. Public education programs focused on individuals at risk for stroke, their friends, and family members have been shown to reduce the time to arrival at the emergency department[13] (see Chapter 3). The "chain of survival" described by the American Heart Association (AHA) and the American Stroke Association (ASA) to improve stroke survival is made up of four links:

1. Rapid recognition and reaction to stroke warning signs
2. Rapid EMS dispatch
3. Rapid EMS transport and hospital prenotification
4. Rapid diagnosis and treatment in the hospital

ASSESSMENT

The primary survey of a patient who may have suffered a stroke or TIA follows the same sequence as that for any other ill or injured patient in the emergency setting. The priorities are to maintain a patent airway and to provide adequate ventilatory support with appropriate supplemental oxygen. If the patient is conscious and able to speak, a thorough history should be obtained. The following are important components of the patient history for these patients:

- Time of symptom onset
- Previous neurological symptoms (e.g., TIAs)
- Previous neurological deficits
- Initial symptoms and their progression
- Alterations in level of consciousness
- Precipitating factors
- Dizziness
- Palpitations
- Significant past medical history
  - Hypertension
  - Diabetes mellitus
  - Cigarette smoking
  - Oral contraceptive use
  - Cardiac disease
  - Sickle cell disease
  - Previous stroke

Cincinnati Prehospital Stroke Scale. In addition to the abnormal neurological signs and symptoms described previously, other methods can be used to diagnose stroke. One such method is the Cincinnati Prehospital Stroke Scale (CPSS).[15] This scale evaluates three major physical findings: facial droop, arm drift, and speech (Box 25-6). The paramedic can use this scale to help identify a patient who may be having a stroke and who needs rapid transport to a hospital. It also allows for prearrival notification of the receiving hospital. The CPSS has a sensitivity of 59% and a specificity of 89% when scored by prehospital personnel.[10]

SHOW ME THE EVIDENCE

Kothari and colleagues sought to validate and verify the reproducibility of the Cincinnati Prehospital Stroke Scale (CPSS) when performed by prehospital personnel. Twenty-four EMTs and paramedics assessed 171 patients with and without diagnosis of stroke using the CPSS. One or two physicians simultaneously evaluated the same patients. The researchers found that the scale was reliably reproduced between EMS personnel and between physicians. The CPSS was 66% sensitive and 87% specific when any single component on the scale was abnormal. Of the stroke patients the scale did not identify, 10 of 13 were posterior strokes, and 21 of 24 anterior strokes were identified (88% sensitivity).

Kothari RU, et al: Cincinnati Prehospital Stroke Scale, *Ann Emerg Med* 33:373-378, 1999.

BOX 25-6 Cincinnati Prehospital Stroke Scale*

Facial Droop (have the patient show the teeth or smile)

- Normal: The two sides of the face move equally well.
- Abnormal: One side of the face does not move as well as the other side.

Arm Drift (have the patient close the eyes and hold out both arms)

- Normal: Both arms move the same *or* both arms do not move at all (other findings, such as pronator grip, may be helpful).
- Abnormal: One arm does not move *or* one arm drifts down compared with the other.

Speech (have the patient say, "You can't teach an old dog new tricks.")

- Normal: The patient uses the correct words with no slurring.
- Abnormal: The patient slurs words, uses inappropriate words, *or* is unable to speak.

*The presence of a single abnormality on the CPSS has a sensitivity of 59% and a specificity of 89% when scored by prehospital providers.[2]

Los Angeles Prehospital Stroke Screen. The Los Angeles Prehospital Stroke Screen (LAPSS) is another means of diagnosing stroke. This screening tool requires the examiner to rule out other causes of altered level of consciousness (e.g., hypoglycemia or seizure). The examiner then must identify asymmetry (right versus left) in facial smile/grimace, grip, and arm strength (Box 25-7). Asymmetry in any category indicates a possible stroke. Like the CPSS, the LAPSS can be used quickly in the prehospital setting. The LAPSS has a specificity of 97% and a sensitivity of 93%.[10]

MANAGEMENT (FIGURE 25-14)

Once the diagnosis of stroke is suspected, *time in the field must be reduced,* because limited time is available to begin therapy. Fibrinolytics should be given less than 4 hours from the onset[2] (some centers have expanded this time frame to 6 hours or more in certain cases). Whenever possible, the paramedic should establish the time of onset of the stroke signs and symptoms. If the patient awoke with the symptoms, the time of onset should be recorded as the last time the patient was known to be normal *(last seen well).* This is important for determining whether fibrinolytics can be administered. Prehospital care is directed at managing the patient's airway, breathing, and circulation and monitoring vital signs. Besides life support, the most important care a paramedic can provide a stroke victim is quick identification of the possible stroke and rapid transport of the patient for definitive care.

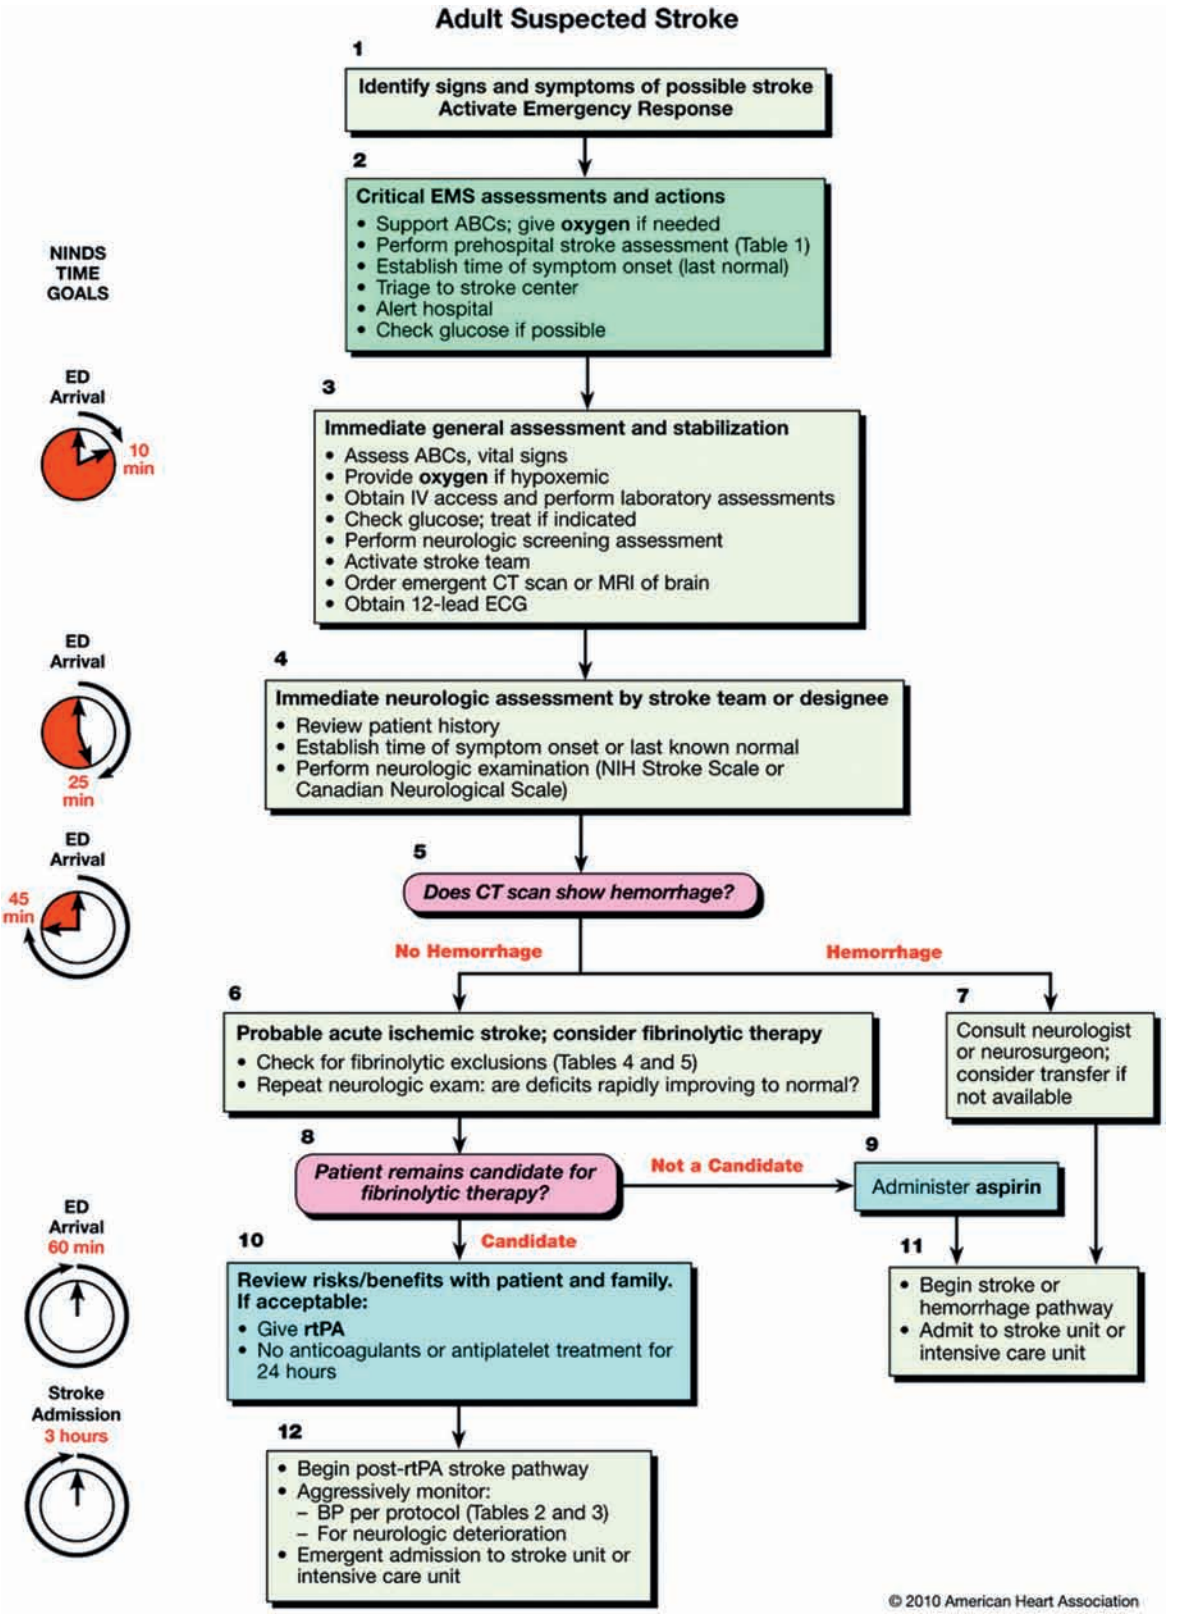

FIGURE 25-14 Goals for management of suspected cases of stroke. (American Heart Association: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovasular care, *Circulation* 122 (18 suppl): S639-S946, 2010.)

BOX 25-7 Los Angeles Prehospital Stroke Screen

The Los Angeles Prehospital Stroke Screen (LAPSS) is used to evaluate patients who may have an acute, noncomatose, nontraumatic neurological condition. If items 1 through 6 are **all checked Yes** (or Unknown), notify the receiving hospital before arrival of the potential stroke patient. If any are checked No, follow the appropriate treatment protocol.

Interpretation: Ninety-three percent of patients with stroke have positive findings (all items checked Yes or Unknown [sensitivity, 93%]). Of those with positive findings, 97% have a stroke (specificity, 97%). A patient may be having a stroke even if LAPSS criteria are not met.

	Yes	Unknown	No
1. Age >45	{}	{}	{}
2. History of seizures or epilepsy **absent**	{}	{}	{}
3. Symptom duration >24 hours	{}	{}	{}
4. At baseline, patient is **not** wheelchair bound or bedridden	{}	{}	{}
5. Blood glucose level is 60 to 400 mg/dL	{}	{}	{}
6. **Obvious asymmetry** (right vs. left) in **any** of the following three categories **(must be unilateral):**	{}	{}	{}

	Equal	R Weak	L Weak
Facial smile/grimace	{}	{} Droop	{} Droop
Grip	{}	{} Weak grip	{} Weak grip
	{}	{} No grip	{} No grip
Arm strength	{}	{} Drifts down	{} Drifts down
	{}	{} Falls rapidly	{} Falls rapidly

Modified from Kidwell CS, et al: Design and retrospective analysis of the Los Angeles Prehospital Stroke Screen (LAPSS), *Prehosp Emerg Care* 2:267-273, 1998.

NOTE

Some hospitals have dedicated stroke units staffed with a multidisciplinary team experienced in managing stroke. When such a facility is available within a reasonable transport interval, stroke patients who require hospitalization should be admitted there (class I).[11] The paramedic should consult with medical direction.

Airway. Paralysis of the muscles of the throat, tongue, and mouth can lead to partial or complete airway obstruction. (This is a major problem in acute stroke.) Frequent suctioning of the oropharynx and nasopharynx is required to prevent aspiration of saliva. If possible, the patient should be positioned to aid drainage of oral secretions.

CRITICAL THINKING

How can you detect paralysis of the muscles of the throat, tongue, and mouth on your physical exam?

Breathing. Inadequate ventilation should be managed with supplemental oxygen and positive-pressure ventilation. Hypoxia and hypercarbia can occur as a result of inadequate ventilation, contributing to cardiac and respiratory instability. Supplemental oxygen should be given to stroke patients who are hypoxic (oxygen saturation less than 94%) and to patients whose oxygen saturation is unknown.[11]

Circulation. Cardiac arrest is uncommon. However, it may result from a respiratory arrest. Cardiac dysrhythmias occur frequently. Therefore, the patient's ECG and blood pressure require constant monitoring. As described in Chapter 22, a difference in blood pressure readings in the upper extremities of 10 mm Hg or more may indicate aortic dissection and compromise of the brain's blood supply.

LOOK AGAIN

See Chapter 22: Cardiology, pp. 693-696.

NOTE

Many patients develop hypertension after a stroke. However, this usually does not require emergency treatment. Elevated blood pressure after a stroke is not a hypertensive emergency unless the patient has other medical indications, such as an acute myocardial infarction (AMI) or left ventricular failure. Management of hypertension in the prehospital setting is not recommended in cases of suspected stroke.[11] The paramedic should notify the receiving facility and transfer the patient to a stroke center if available.

Other Supportive Measures. If the airway is patent and the patient's condition permits, the person should be kept supine. The head should be elevated 15 degrees to aid venous drainage. Other patient care measures the paramedic can provide while en route to the receiving hospital include the following:

1. Initiate an IV line of lactated Ringer solution or normal saline (50 mL per hour).
2. Monitor ECG.
3. Perform serum glucose analysis (*50% dextrose* should be administered only if indicated).

4. If the patient cannot communicate, consider transporting a witness to confirm the time of onset. If that is not possible, obtain the most reliable information.
5. Protect paralyzed extremities.
6. Maintain normal body temperature.
7. Control seizure activity with benzodiazepines.
8. Provide comfort measures and reassurance.
9. Notify ED of possible stroke. Provide gentle transport to the appropriate receiving hospital.

Paramedics must keep in mind that a stroke patient has experienced a catastrophic event, one that may seriously affect the person's quality of life. These patients often are frightened, embarrassed, confused, and frustrated with their inability to move or communicate. They have special physical and emotional needs. As do all other patients, they deserve a compassionate, caring approach.

IN-HOSPITAL TREATMENT

On arrival at the emergency department (ED), a patient suspected of having a nonhemorrhagic stroke is evaluated as a possible candidate for fibrinolytic therapy. This evaluation includes an emergency neurological stroke assessment, which identifies the patient's level of consciousness. It also identifies the type, location, and severity of the stroke. This assessment is aided by use of the Glasgow Coma Scale and other standardized scales. These scales and other in-hospital diagnostic studies help measure neurological function. This function correlates with the severity of the stroke and the long-term outcome. These studies also help identify stroke patients who would benefit from fibrinolytic therapy. Rapid evaluation of the computed tomography (CT) scan is critical to rule out an intracranial hemorrhage. An intracranial hemorrhage is a contraindication to fibrinolytic therapy. As described in Chapter 22, fibrinolytics have potential adverse effects. Patients must be evaluated by a physician with inclusion-exclusion criteria to make sure they are candidates for fibrinolytic therapy.

See Chapter 22: Cardiology, pp. 685-687.

Seizure Disorders

A **seizure** is a brief alteration in behavior or consciousness. It is caused by abnormal electrical activity of one or more groups of neurons in the brain. It is estimated that 300,000 people in the United States experience a first-time seizure each year.[16] The highest incidence is among feverish children under 5 years of age. (Febrile seizures are further addressed in Chapter 48.)

CRITICAL THINKING

What feelings may parents experience after seeing their child have a febrile seizure? How should you respond to those feelings?

The underlying cause of seizures is not well understood. However, a seizure generally is believed to result from a structural lesion or problems with brain metabolism. This results in changes in the brain cell's permeability to sodium and potassium ions. When such changes occur, the neurons' ability to depolarize and emit an electrical impulse sometimes results in seizure activity. Seizures may be caused by several factors, including the following[5]:

- Stroke
- Head trauma
- Toxins (including alcohol or other drug withdrawal)
- Hypoxia
- Hypoperfusion
- Hypoglycemia
- Infection
- Metabolic abnormalities
- Brain tumor or abscess
- Vascular disorders
- Eclampsia
- Drug overdose

In the prehospital setting, determining the cause of a seizure is less important than managing the complications and recognizing whether the seizure is reversible with therapy (e.g., resulting from hypoglycemia). A tendency to have recurrent seizures is called **epilepsy** (Box 25-8). Epilepsy does not include seizures that arise from correctable or avoidable causes, such as alcohol withdrawal.

SHOW ME THE EVIDENCE

In a retrospective study in Pittsburgh, Martin-Gill and coworkers reviewed the prehospital treatment of patients whose chief complaint was seizure. The researchers' goal was to determine whether treatment followed the system's EMS seizure protocol and to evaluate patient outcomes. Of the 87 patients who met the inclusion criteria, only 11 (12.6%) had electrocardiographic (ECG) monitoring; in 55 (63.2%), attempts were made to establish an intravenous (IV) line; and 56 (64.4%) had blood glucose analysis. Twenty-eight patients (32.2%) had another seizure (17 were in the prehospital setting). Among the 17 patients who had another seizure in the field, eight had seizures that lasted longer than 1 minute. Only four of the eight patients were given diazepam. The researchers concluded that adherence to the seizure protocol was poor. They noted that individual patient differences made following one specific policy difficult.

Martin-Gill C, et al: Management of prehospital seizure patients by paramedics, *Prehosp Emerg Care* 13:179-184, 2009.

TYPES OF SEIZURES

All seizures are pathological; they are never considered normal. They may arise from almost any region of the brain and therefore have many clinical manifestations. The two most common types are generalized seizures and partial (focal) seizures.

Generalized Seizures. As the name implies, a **generalized seizure** does not have a definable origin (focus) in the

BOX 25-8 Epilepsy Statistics

- Each year, 200,000 new cases of epilepsy are diagnosed in the United States.
- The incidence is highest in infants under age 2 years and in adults over age 65.
- Each year, 45,000 children under age 15 develop epilepsy.
- Males are slightly more likely to develop epilepsy than females.
- The incidence is higher in African Americans and the socially disadvantaged.
- Trends show a decreased incidence in children and an increased incidence in the elderly.
- No cause is apparent in 70% of new cases.
- Among people with new cases of epilepsy, 50% will have generalized onset seizures.
- Generalized seizures are more common in children under age 10; after that age, more than 50% of individuals with new cases of epilepsy will have partial seizures.[16]

brain, although focal seizures may progress to generalized seizures. This class includes absence seizures and atonic, myoclonic, and tonic-clonic seizures.

Absence seizures (also known as *petit mal seizures*) occur most often in children between the ages of 4 and 12 years. They are characterized by brief lapses of consciousness without loss of posture. Often no motor activity is seen. However, some children have eye blinking, lip smacking, or isolated contraction of muscles. These seizures usually last less than 15 seconds. During this time, the patient is unaware of the surroundings. The seizures are followed by the patient's immediate return to normal. Most patients have remission by age 20 but later may develop generalized tonic-clonic (grand mal) seizures.

Atonic seizures produce an abrupt loss of muscle tone, loss of posture, or sudden collapse ("drop attacks"). These seizures can result in physical injury from falls. Children and adults with this condition sometimes wear protective headgear. These seizures tend to be resistant to drug therapy.

Myoclonic seizures cause brief muscle contractions that usually occur at the same time and on both sides of the body. (Occasionally they involve one arm or one foot.) Individuals with this disorder compare the sensation to the sudden jerk of a foot during sleep.

Tonic-clonic seizures are common and are associated with significant morbidity and mortality. They may be preceded by an **aura** (an olfactory or auditory sensation). Often the patient recognizes the aura as a warning of the imminent convulsion. The seizure itself is characterized by a sudden loss of consciousness associated with loss of organized muscle tone. The tonic phase is marked by a sequence of extensor muscle tone activity (sometimes flexion) and apnea. Tongue biting and bladder or bowel incontinence may occur. The tonic phase lasts only seconds. It is followed by a bilateral clonic phase (rigidity alternating with relaxation). This usually lasts 1 to 3 minutes. During the clonic phase, a massive autonomic discharge occurs. This results in hyperventilation, salivation, and tachycardia. After the seizure, the patient usually experiences a period of drowsiness or unconsciousness. This resolves over minutes to hours. On regaining consciousness, the patient often is confused and fatigued. The person also may show signs of a transient neurological deficit. This part of the seizure is known as the *postictal phase*. Tonic-clonic seizures may be prolonged or may recur before the patient regains consciousness. When this occurs, the patient is said to be in status epilepticus (described later in this chapter).

CRITICAL THINKING

What could cause death after a grand mal seizure?

Partial Seizures. In contrast to generalized seizures, in which a specific seizure focus is unknown, a **partial seizure** arises from identifiable cortical lesions. Partial seizures may be classified as *simple* or *complex*. A **simple partial seizure** results mainly from seizure activity in the motor or sensory cortex. Simple motor seizures usually manifest as clonic activity that is limited to one body part. (For instance, this might be one hand, one arm or leg, or one side of the face.) *Simple sensory seizures* result in symptoms such as tingling or numbness of a body part or abnormal visual, auditory, olfactory, or taste symptoms. Patients with partial seizures generally do not lose consciousness. They usually maintain a somewhat normal mental status. However, the seizure focus may spread and lead to a generalized tonic-clonic seizure. Partial seizure activity that spreads in an orderly way to surrounding areas is known as a **jacksonian seizure.**

A **complex partial seizure** arises from focal seizures in the temporal lobe (psychomotor seizures). These manifest mainly as changes in behavior. The classic complex partial seizure is preceded by an aura. It is followed by abnormal repetitive motor behavior **(automatism),** such as lip smacking, chewing, or swallowing. During this time the patient has no memory of the event. These seizures usually are brief, lasting less than 1 minute. The patient usually regains normal mental status quickly. Like simple partial seizures, complex partial seizures also may progress to a generalized tonic-clonic seizure.

NOTE

A **nonepileptic seizure** can mimic a true seizure. However, it stems from psychological causes rather than electrical disturbances in the brain. Also, such seizures do not respond to the usual treatments. Nonepileptic seizures (*hysterical seizures* or *pseudoseizures*) sometimes can be ended by sharp commands or painful stimuli (e.g., a sternal rub). These maneuvers may help distinguish between pathological and psychogenic seizure activity. It should be noted that some nonepileptic diseases can cause life-threatening seizures. Paramedics should remember that a seizure is *never* normal. Any seizure should be taken seriously.

ASSESSMENT

The assessment process is determined by the patient's seizure state. In most cases the patient's seizure has ended before paramedics arrive. If possible, the assessment should include a thorough history and physical examination, including a neurological evaluation.

History. If the patient is in the postictal phase of the seizure, information can be gathered from family members or bystanders who witnessed the event. The following are important components of the patient history.

1. History of seizures
   a. Frequency
   b. Compliance in taking prescribed medications (e.g., ***phenytoin,*** phenobarbital)
   c. Use of home medicines to control seizures (herbal medicines, vitamins)
2. Description of seizure activity
   a. Duration of seizure
   b. Typical or atypical pattern of seizure for the patient
   c. Presence of aura
   d. Generalized or focal
   e. Incontinence
   f. Tongue biting
3. Recent or past history of head trauma
4. Recent history of fever, headache, nuchal rigidity (neck stiffness with flexion, suggesting meningeal irritation)
5. Past significant medical history
   a. Diabetes
   b. Heart disease
   c. Stroke

Physical Examination. During the physical examination, maintaining a patent airway is always of prime importance. The paramedic also should be alert for signs of trauma (head and neck trauma, tongue injury, oral lacerations). These injuries may have occurred before or during the seizure. Also, the patient's mouth should be inspected for **gingival hypertrophy** (swelling of the gums). This is a sign of chronic ***phenytoin*** therapy. Other components of the physical examination include the following:

- Level of sensorium, including presence or absence of amnesia
- Cranial nerve evaluation, particularly pupillary findings
- Motor and sensory evaluation, including coordination (abnormalities may be caused by metabolic disturbances, meningitis, intracranial hemorrhage, and drug use)
- Evaluation for hypotension, hypoxia, and hypoglycemia
- Presence of urine or feces (suggesting bladder or bowel incontinence)
- Automatisms
- Cardiac dysrhythmias

CRITICAL THINKING
What are signs and symptoms of phenytoin toxicity?

NOTE
A *vagal nerve stimulator* (VNS) is used to treat some patients who have frequent partial seizures unresponsive to medication therapy. (The device also is used to manage some forms of depression.) This device usually is implanted in the left chest; lead wires are fed through the neck and tethered to the vagus nerve (cranial nerve X). The VNS sends electrical impulses regularly to the vagus nerve, causing the widespread release of gamma aminobutyric acid (GABA) and glycine in the brain. (The device also can be activated and deactivated manually by the patient.) Although the precise mode of action is unknown, a VNS is effective in controlling seizures in some patients.[17]

Differentiation of Syncope and Seizure. As described in Chapter 22, *syncope* is a complete loss of consciousness caused by a temporary reduction in cerebral blood flow. Because syncope and seizure have similar presentations, determining whether a patient has experienced a syncopal episode or a seizure can be difficult. The main difference is in the symptoms the patient experiences before and after the event. The factors listed in Table 25-4 may aid differentiation of these two conditions.

LOOK AGAIN
See Chapter 22: Cardiology, p. 676.

MANAGEMENT

The first step in the management of a patient with seizure activity is to protect the patient from injury. This is best achieved by removing obstacles in the patient's immediate area. If necessary, the patient can be moved to a safe environment, such as a carpeted or soft, grassy area. *At no time should a patient with seizure activity be restrained, nor should objects be forced between the patient's teeth to maintain an airway.* Restraining activity may harm the patient or paramedic crew. Forcing objects into the oral cavity in an effort to secure an airway or prevent the patient from biting the tongue may evoke vomiting, aspiration, or spasm of the larynx. Placement of a nasopharyngeal airway, along with end-tidal carbon dioxide ($EtCO_2$) monitoring should be considered.

Most patients with an isolated seizure can be properly managed in the postictal phase by being placed in a lateral recumbent position. This allows drainage of oral secretions

TABLE 25-4 Differentiation of Syncope and Seizure

Characteristic	Syncope	Seizure
Position	Syncope usually starts when patient is in a standing position.	Seizure may start with patient in any position.
Warning	Patient usually has a warning period of lightheadedness.	Patient has little or no warning.
Level of consciousness	Patient usually regains consciousness immediately on becoming supine; fatigue, confusion, and headache last less than 15 minutes.	Patient may remain unconscious for minutes to hours; fatigue, confusion, and headache last longer than 15 minutes.
Clonic-tonic activity	Clonic movements (if present) are of short duration.	Tonic-clonic movements occur during unconscious state.
Electrocardiographic (ECG) analysis	Bradycardia is caused by increased vagal tone associated with syncope.	Tachycardia is caused by muscular exertion associated with seizure activity.

and aids suctioning (if needed). Supplemental oxygen should be administered via a nonrebreather mask. The patient should be moved to a quiet place (away from onlookers). Patients often are embarrassed or self-conscious after a seizure. This is especially the case if incontinence has occurred. Paramedics should be sensitive to the physical and emotional needs of the patient.

All seizure patients should be encouraged to seek care. Some patients should always be transported to the ED for care and evaluation by a physician. These include patients who have a history of seizures but who experienced a seizure that is different from the usual one, and patients with a seizure that is complicated by an unusual event (e.g., trauma). All patients who have experienced a seizure for the first time should be transported to the ED for evaluation by a physician. Depending on the patient's status and seizure history, an IV line may be necessary to administer drug therapy. However, few patients who experience an isolated seizure require drug therapy in the prehospital setting.

STATUS EPILEPTICUS

Status epilepticus is ongoing seizure activity that lasts 30 minutes or longer. The term also refers to recurrent seizures without a period of consciousness between them.[5] Status epilepticus is a true emergency. Without immediate management, it can result in permanent neurological damage, respiratory failure, and death. Associated complications of status epilepticus include aspiration, brain damage, and fracture of long bones and the spine. The most common cause in adults is failure to take prescribed anticonvulsant medications.

Management. As for all patients with seizures, management priorities include securing the airway and providing ventilatory support, protecting the patient from injury and, if indicated, transporting the patient to a medical facility for evaluation by a physician. In addition, management includes stopping the seizure activity with anticonvulsant medications (e.g., ***diazepam, lorazepam,*** or ***midazolam***).[18]

After the airway has been secured with oral or nasal adjuncts (or with intubation of the trachea during the flaccid period between seizures), high-concentration oxygen should be administered. Also, ventilation should be supported with a bag-valve device. An IV line should be established to keep the vein open and secured well with tape and roller bandage. A sample of the patient's blood should be drawn for laboratory analysis (per protocol). Medications administered in the prehospital setting may include the following:

- ***50% dextrose*** given by slow IV infusion (only if hypoglycemic). In some cases, hypoglycemia causes the seizure.
- ***Lorazepam, diazepam,*** or ***midazolam*** (IV route preferred) to stop the spread of the seizure focus. (If vascular access cannot be established, ***lorazepam*** may be given intramuscularly [IM]. It is the preferred drug choice, followed by ***diazepam*** and then ***midazolam.***)

While administering these drugs, paramedics should closely monitor the patient's blood pressure and respiratory status. They should be prepared for respiratory arrest. If the patient's blood pressure begins to fall or if the respiratory rate or effort decreases, paramedics should stop the drug therapy and consult with medical direction.

Headache

Headaches are painful and bothersome. However, most are minor health concerns and are easily managed with analgesics. Headaches are categorized according to their underlying cause. The types of headaches are tension headache, migraine, cluster headache, and sinus headache. Therapies that may be useful in managing these headaches include prescription and over-the-counter medications, herbal remedies, meditation, acupressure, aromatherapy, and others. Headache is an extremely common medical complaint; 40% of Americans have what they consider a serious headache at some time during their lives.[19] The pain associated with headaches arises from the meninges and from the scalp and its blood vessels and muscles.

NOTE

The paramedic should always first consider that a severe headache could be a sign of serious illness. Life-threatening causes of headache include hypertension, stroke, tumor, and toxic exposure (e.g., carbon monoxide [CO] poisoning), among others. A thorough history and assessment are crucial.

A **tension headache** is caused by muscle contractions of the face, neck, and scalp. This type of headache has a variety of causes, including stress, persistent noise, eyestrain, and poor posture. The pain of tension headaches (usually described as dull, persistent, and nonthrobbing) may last for days or weeks. The pain can cause variable degrees of discomfort. These headaches can be short-lived and infrequent or chronic. Most tension headaches can be managed effectively with analgesics such as ***aspirin,*** acetaminophen, or ibuprofen.

A **migraine** is a severe, incapacitating headache. These headaches often are preceded by visual or gastrointestinal (GI) disturbances or both. They usually begin with an intense, throbbing pain on one side of the head that may spread. They often are accompanied by nausea and vomiting. The symptoms of migraines are associated with constriction and dilation of blood vessels, which may be brought on by an imbalance of serotonin or hormone fluctuations. Migraines also can be triggered by excessive caffeine use, various foods, changes in altitude, and extremes of emotions. A wide range of medications are prescribed for migraines. These include beta blockers, calcium channel blockers, antidepressants, and serotonin-inhibiting drugs.

Cluster headaches are headaches that occur in bursts (clusters). They often begin several hours after a person falls asleep. The pain may be severe. It usually is located in and around one eye and generally is accompanied by nasal congestion and tearing. The painful episode often lasts 30 minutes to 2 hours. It then diminishes or disappears, recurring a day or so later. The headaches may occur every day for weeks or months before going into long periods of remission. Cluster headaches also are known as *histamine headaches.* This is because they are associated with the release of histamine from the body tissues. They are marked by symptoms of dilated carotid arteries, fluid accumulation under the eyes, tearing or lacrimation, and rhinorrhea. Cluster headaches generally are managed with antihistamines, corticosteroids, and calcium channel blockers. Cluster headaches seem to be more common in heavy smokers than in nonsmokers. Alcohol consumption and certain foods also may be implicated. These headaches are much more common in men.

A **sinus headache** is characterized by pain in the forehead, nasal area, and eyes. These headaches often produce a feeling of pressure behind the face. Allergies, inflammation, or infection of the membranes lining the sinus cavities usually is responsible for the discomfort. Sinus headaches are managed with medications such as analgesics, antihistamines, and antibiotics to treat infection.

MANAGEMENT

Many causes of headaches can be prevented. For example, triggers can be identified, such as irregular meals, prolonged travel, noisy environments, and food additives (in susceptible individuals). Headaches such as those described in the preceding paragraphs seldom require prehospital emergency care. However, a full history of the headache should be obtained. This helps identify a more serious cause of the headache, should one be present. For example, the headache may be a sign of an aneurysm or a stroke.

Important assessment findings include the following:

- The patient's general health
- Previous medical conditions
- Medications used
- Previous experience with headaches
- The time of onset

After a patient history has been obtained and a neurological examination has been performed, prehospital care for patients with tension headaches, migraines, cluster headaches, and sinus headaches is mainly supportive. Transport of the patient for evaluation by a physician may be indicated. These patients often have light sensitivity. Lights in the ambulance should be dimmed.

Central Nervous System Tumors

CNS tumors include **brain tumors** and **spinal cord tumors.** The incidence of these tumors tends to increase up to age 70 and then decrease. CNS tumors are the second most common group of tumors in children.[20]

A brain tumor, or **neoplasm,** is a mass in the cranial cavity. This mass may be either malignant or benign. Heredity may play a role in the development of brain tumors. They also are associated with several risk factors, including exposure to radiation, tobacco use, dietary habits, some viruses, and the use of some medications. The effects of the tumor depend on its size, location, and growth rate and whether any evidence of hemorrhage or edema exists. Brain tumors may cause local and generalized manifestations. Local effects are caused by the destructive action of the tumor on a particular site in the brain and by compression, which reduces cerebral blood flow (Figure 25-15). These effects are varied and may include the following[20]:

- Seizures
- Visual disturbances
- Unstable gait
- Cranial nerve dysfunction

Lesions inside the cranial vault produce pain by distending or stretching the arteries and other pain-sensitive structures of the head and neck. Headache may be present but often is a late finding in the absence of hemorrhage, which may cause a sudden onset of pain.[19] The main treatment for a cerebral tumor is surgical or radiosurgical excision. Surgical decompression may be used if total excision is not possible. Chemotherapy and radiation also may be used.

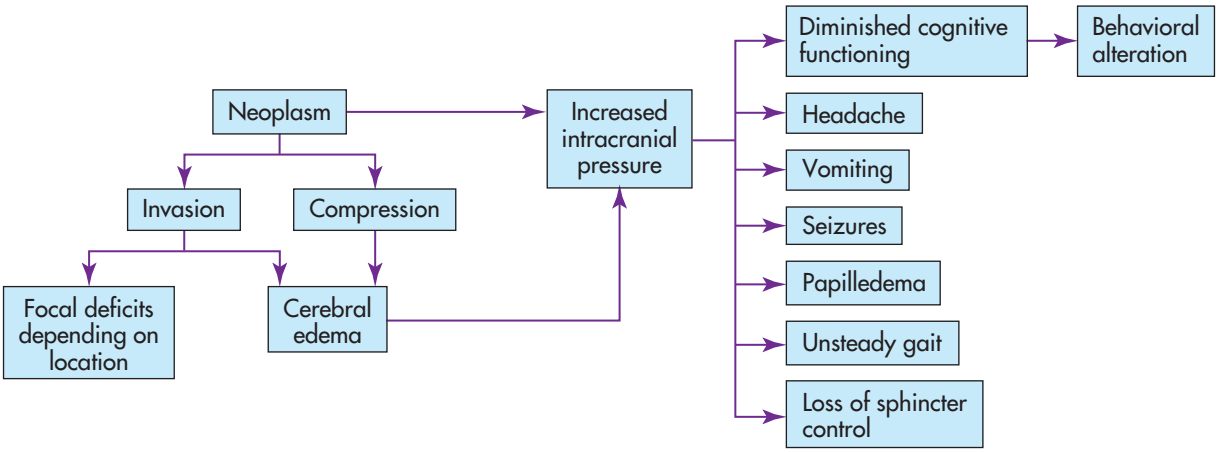

FIGURE 25-15 Origin of signs and symptoms associated with an intracranial neoplasm.

A **brain abscess** is an accumulation of purulent material (pus) surrounded by a capsule within the brain. It develops from a bacterial infection that often begins in the nasal cavity, middle ear, or mastoid cells. The condition also may develop after surgery or penetrating cranial trauma, especially when bone fragments are retained in cranial tissue. Clinical manifestations of a brain abscess are associated with intracranial infection (e.g., fever). They also are associated with an expanding intracranial mass (e.g., nausea, vomiting, seizures, and changes in mental status). Headache is the most common early symptom. Removal of fluid from the abscess or excision, accompanied by antibiotic therapy, generally is recommended to manage this disorder. The incidence of brain abscess is about 1 per 100,000 hospital admissions. The condition is twice as common in men as in women. The median age for abscess formation is 30 to 40 years.[20]

Like the brain, the spinal cord can become compressed. In the absence of trauma, compression of the spinal cord can be caused by bone, blood, abscesses, tumors, or a ruptured disk. (Compression of the spinal cord that results from trauma and associated spinal cord syndromes is discussed in Chapter 41.) Compression of the cord can disrupt normal functions, as a result of pressure on the roots of spinal nerves. Spinal cord compression can occur suddenly, causing immediate symptoms. It also may occur gradually, over weeks to months. Slight compression may cause mild symptoms, such as back pain (that may or may not radiate to the leg or foot), slight muscle weakness, and tingling in the extremities. In men, difficulty urinating and erectile dysfunction may occur. If the cause of compression is cancer, an abscess, or a hematoma, the back may be tender to the touch in the affected area. Significant compression of the cord may block nerve impulses. This can result in severe muscle weakness, numbness, retention of urine, and loss of bladder and bowel control. If all nerve impulses are blocked, paralysis and complete loss of sensation may result. Definitive care is determined by the cause of the compression. Treatment by a physician may include high doses of IV steroids to reduce inflammation, antibiotics, radiation, and other therapies. Surgery may be required to relieve the compression and prevent permanent nerve damage.

MANAGEMENT

Prehospital care of a patient with a CNS tumor may range from providing comfort and emotional support during patient transport to managing seizure activity and providing airway, ventilatory, and circulatory resuscitation. If the patient's condition permits, a focused history should be obtained and a neurological evaluation should be performed. Elements of the focused history for these patients should include the following:

- Past significant medical history (e.g., surgical removal of a tumor, radiation therapy)
- History and description of any headache
- Dizziness or loss of consciousness
- Seizure activity
- GI disturbances (vomiting, diarrhea)
- New onset of incoordination, difficulty walking or maintaining balance
- Behavioral or cognitive changes
- Weakness or paralysis
- Vision disturbances

Degenerative Neurological Diseases

There are many degenerative neurological diseases. The pathophysiology of many of these disorders is not fully understood. Some diseases may involve Schwann cells, the CSF, or axons of the CNS. Others may result from circulatory and immunological disorders and exposure to bacterial toxins and chemicals (see Chapters 28 and 57). The following specific neurological diseases are discussed in this chapter[21]:

- Dementia
- Alzheimer's disease
- Pick's disease
- Huntington's disease

- Creutzfeldt-Jakob disease
- Muscular dystrophy
- Multiple sclerosis
- Guillain-Barré syndrome
- Dystonia
- Parkinson's disease
- Cranial nerve disorders
- Bell's palsy
- Amyotrophic lateral sclerosis
- Peripheral neuropathy
- Spina bifida
- Polio

DEMENTIA

Dementia is a slow, progressive loss of awareness of time and place. It usually involves an inability to learn new things or recall recent events. Dementia often is a result of brain disease caused by strokes, genetic or viral factors, and Alzheimer's disease. Dementia generally is considered irreversible. It eventually results in full dependence on others because of progressive loss of cognitive functioning. During the course of the disease, patients often try to conceal their memory loss by **confabulation** (inventing stories to fill gaps in memory). Sudden outbursts or embarrassing conduct may be the first obvious signs of dementia. Some patients eventually regress to a "second childhood." At that point, they need full care for feeding, toileting, and physical activity. About 50% of nursing home residents have dementia. The disease affects about 20% of those over age 80 to some degree.[5] Prehospital care is primarily supportive.

NOTE

Any patient with altered mental status (e.g., confusion or lethargy) should be assessed for infections that may cause these symptoms. Infections that irritate and inflame the membranes of the CNS can cause neurological disorders, such as *encephalitis* and *meningitis*. These diseases are presented in Chapter 28.

ALZHEIMER'S DISEASE

Alzheimer's disease is a condition in which nerve cells in the cerebral cortex die and the brain substance shrinks. The disease is the single most common cause of dementia and is responsible for most cases in people over age 75. It is estimated that at least 5.3 million Americans are living with the disease.[22] Alzheimer's disease does not cause death directly; rather, these patients ultimately stop eating and become malnourished and immobilized. They then are prone to intercurrent infections (Box 25-9).

The cause of Alzheimer's disease is not known. Possible causes include abnormalities in glutamate metabolism, chronic infection, toxic poisoning by metals, reduction in brain chemicals (e.g., acetylcholine), and genetics. Early symptoms of Alzheimer's disease mainly are related to memory loss, especially the ability to make and recall new memories. As the disease progresses, agitation, violence, and impairment of abstract thinking occur. Judgment and cognitive disabilities begin to interfere with work and social relations. In the advanced stages of Alzheimer's disease, patients often become bedridden and totally unaware of their surroundings. Once the patient is bedridden, bed sores, feeding problems, and pneumonia shorten the person's life. Currently Alzheimer's disease has no cure. Treatment consists mainly of medications to help slow the progression of the disease and nursing and social care for the patient and relatives.

BOX 25-9 10 Signs of Alzheimer's Disease

1. Memory loss that disrupts daily life
2. Challenges in planning or solving problems
3. Difficulty completing familiar tasks at home, work, or leisure
4. Confusion with time or place
5. Difficulty understanding visual imagery or spatial relationships
6. New problems with words in speaking or writing
7. Misplacing things and losing the ability to retrace steps
8. Diminished or poor judgment
9. Withdrawal from work or social activities
10. Changes in mood or personality[22]

PICK'S DISEASE

Pick's disease is a rare neurodegenerative disease. It is one of the causes of frontotemporal dementia (FTD), a disease associated with the shrinking of the frontal and temporal anterior lobes of the brain. The disease is associated with changes in behavior or problems with language. These changes manifest as symptoms of behavior that can be either impulsive (disinhibited) or apathetic.[23] They include:

- Inappropriate social behavior
- Lack of social tact
- Lack of empathy
- Distractibility
- Loss of insight into the behaviors of oneself and others
- An increased interest in sex
- Changes in food preferences
- Agitation or, conversely, blunted emotions
- Neglect of personal hygiene
- Repetitive or compulsive behavior and decreased energy and motivation

Other features of the disease include symptoms of language disturbance, including difficulty making or understanding speech. Unlike Alzheimer's disease, spatial skills and memory in patients with Pick's disease remain intact. The disease has a strong genetic component; FTD often runs in families. No treatment is known to slow the progression of the disease, and the outcome is poor. Some patients are treated with behavior modification and

antidepressants. Most require institutionalized care. As in other forms of dementia, prehospital care for these patients is primarily supportive.

HUNTINGTON'S DISEASE

Huntington's disease (HD) (also known as *Huntington's chorea*) results from genetically programmed degeneration of neurons in the brain. This degeneration causes uncontrolled movements, loss of intellectual faculties, and emotional disturbance. HD is a rare, inherited disease that is passed from parent to child. Early symptoms of HD are mood swings, depression, irritability, memory loss, and inability to make decisions. As the disease progresses, concentration on intellectual and personal tasks becomes increasingly difficult. Patients may become unable to feed themselves or swallow food or water. The rate of disease progression and the age of onset vary from person to person. A number of medications are used to manage the symptoms of HD, but the course of the disease cannot be altered. Prehospital care is primarily supportive.

NOTE
Each child of a parent with HD has a 50% chance of inheriting the HD gene.[24] If a child does not inherit the HD gene, he or she will not develop the disease and cannot pass it to subsequent generations. A person who inherits the HD gene will develop the disease. Genetic counseling and testing are available for people who carry the gene.

CREUTZFELDT-JAKOB DISEASE

Creutzfeldt-Jakob disease (CJD) is a rare and fatal brain disorder. Worldwide, it affects about 1 in 1 million people per year. In the United States, about 200 cases occur per year.[25] CJD usually appears in later life and runs a rapid course. Typically, the onset of symptoms occurs at about age 60, and about 90% of patients die within 1 year.

NOTE
CJD may be categorized as *classic* or *variant*. Although both forms of the disease are fatal, classic CJD, described in this chapter, is not related to *bovine spongiform encephalopathy* (BSE, or "mad cow" disease). However, strong evidence links outbreaks in Europe of the disease in cattle to the variant form of CJD in humans.[26]

CJD is characterized by rapidly progressive dementia. Initially, patients with CJD have problems with muscular coordination. They often experience personality changes, involuntary movements, impaired memory, and poor judgment. Some patients develop blindness. As the illness progresses, these patients eventually lose the ability to move and speak; some may become comatose. Pneumonia and other infections often occur in these patients and can lead to death. No treatment exists to cure or control the disease. Prehospital care is primarily supportive.

MUSCULAR DYSTROPHY

Muscular dystrophy is an inherited muscle disorder. The disease is marked by a slow but progressive degeneration of muscle fibers. Different forms of the disease are classified by the age at which the symptoms appear, the rate at which the disease progresses, and the way in which it is inherited. *Duchenne's muscular dystrophy* is the most common type. It is caused by an absence of dystrophin, a protein that helps keep muscle cells intact. The disease affects about 1 in 3500 to 5000 male children.[27] It is inherited through a recessive sex-linked gene; therefore, only males are affected, and only females can pass on the disease.

Muscular dystrophy often is first diagnosed by the child's physician, who notices that the child is slow in learning to sit up and walk. The disease is confirmed through blood tests that reveal high levels of enzymes released from damaged muscle cells, through nerve conduction studies, and sometimes with muscle biopsy. Muscular dystrophy rarely is diagnosed before age 3. As the disease progresses, the child tends to walk with a waddle and has difficulty climbing stairs. Muscles (especially those in the calves) become bulky as wasted muscle is replaced by fat. By about age 12, affected children are no longer able to walk, and few survive their teenage years. Death usually results from pulmonary infections and heart failure.

CRITICAL THINKING
How can you determine a child's baseline level of functioning?

No effective treatment exists for muscular dystrophy. Parents or siblings of an affected child should receive genetic counseling. Some types of muscular dystrophy can be diagnosed before birth. This can be done through blood analysis and amniocentesis (testing of amniotic fluid).

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a progressive disease of the CNS in which scattered patches of myelin in the brain and spinal cord are destroyed. The cause of MS is unknown. However, it is thought to be an autoimmune disease in which the body's defense system begins to treat the myelin in the CNS as foreign, gradually destroying it *(demyelination),* causing scarring and nerve fiber damage.

MS is the most common acquired disease of the nervous system in young adults. To date, about 400,000 Americans have the disease. Each week, more than 200 people in the United States are diagnosed with MS.[28] The ratio of women to men affected is 3:2. The symptoms, which may be active briefly in early adult life and resume years later, vary

according to the parts of the brain and spinal cord affected. Symptoms range from numbness and tingling to paralysis and incontinence and may last several weeks to several months. Damage to the white matter in the brain may lead to fatigue, vertigo, clumsiness, unsteady gait, slurred speech, blurred or double vision, and facial numbness or pain. Some patients may have mild relapses and long symptom-free periods throughout life. Others may gradually become disabled from the first attack and are bedridden and incontinent in early middle life.

The disease usually is diagnosed by ruling out other diseases. Diagnostic tests that may help identify MS include lumbar puncture, CT scanning, and magnetic resonance imaging (MRI) studies. Patients are managed with medications (e.g., corticosteroids, antidepressants, immune system medications). These help control the symptoms of an acute episode and prevent exacerbation. The disease also is managed with physical therapy to help maintain mobility and independence. Currently no cure exists.

CRITICAL THINKING

Consider the patient who has been receiving long-term steroid therapy. This person is at risk for what conditions?

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is a rare autoimmune disorder that affects the body's peripheral nervous system. Initial symptoms of the syndrome include weakness or tingling sensations in the legs that may spread to the arms and upper body. These symptoms can increase in intensity until the muscles can no longer be used, causing total or near-total paralysis ("stocking and glove paralysis"). At this stage, the disorder is life-threatening. Patients often require mechanical ventilation to breathe. However, most patients recover from GBS, although some continue to have varying degrees of weakness.

GBS occurs a few days or weeks after the patient has had symptoms of a respiratory or GI viral infection.[29] Occasionally, surgery or vaccinations trigger the syndrome. The disorder can develop over the course of hours or days, or it may take up to 3 to 4 weeks. The syndrome is managed by supporting the patient's vital functions. Some patients are treated with plasmapheresis (the removal and replacement of plasma fluids) and high-dose immunoglobulin therapy.

DYSTONIA

The term **dystonia** refers to local or diffuse changes in muscle tone (usually abnormal muscle rigidity). These changes cause painful muscle spasms, unusually fixed postures, and strange movement patterns. Localized dystonia may result from *torticollis* (a painful neck spasm.) It also may result from *scoliosis* (an abnormal curvature of the spine). More generalized dystonia results from various neurological disorders. These include Parkinson's disease and stroke. It also may be a feature of schizophrenia or a side effect of some antipsychotic drugs (see Chapter 35). Dystonia sometimes is managed with medications such as benztropine or ***diphenhydramine.*** These help reverse the symptoms and prevent their recurrence.

PARKINSON'S DISEASE

Parkinson's disease is caused by degeneration of nerve cells in the basal ganglia in the brain or damage of unknown origin to those cells. The degeneration causes a lack of dopamine. This prevents the basal ganglia from modifying nerve pathways that control muscle contraction. The result is muscles that are overly tense. This causes tremor, joint rigidity, and slow movement. Parkinson's disease affects about 130 in 10,000 people, and 60,000 new cases are diagnosed in the United States each year.[30] Left untreated, the disease progresses over 10 to 15 years to severe weakness and incapacity. Parkinson's disease is the leading cause of neurological disability in people over age 60. Currently about 1 million people in the United States have the disease.

Parkinson's disease usually begins as a slight tremor in one hand, arm, or leg. In the early stages, the tremor is worse while the limb is at rest. In the later stages, the disease affects both sides of the body. It causes stiffness, weakness, and trembling of the muscles. Other symptoms include an unusual walking pattern (shuffling) that may break into uncontrollable, tiny running steps; constant trembling of the hands, sometimes accompanied by shaking of the head; a permanent rigid stoop; and an unblinking, fixed facial expression. Late in the disease, intellect may be affected. Speech becomes slow and hesitant. Depression is common.

At first Parkinson's disease is managed with counseling, exercise, and special aids in the home. As the disease progresses, management may include various combinations of drugs that either mimic or replace dopamine (e.g., levodopa). These drugs provide relief from specific symptoms. Other management measures may include brain surgery to reduce tremor and rigidity if medication therapy fails.

NOTE

Normal pressure hydrocephalus (NPH) is a syndrome that affects some older adults. It is caused by an abnormal increase in cerebrospinal fluid in the cavities of the brain. It may result from a subarachnoid hemorrhage, head trauma, infection, tumor, or complications of surgery. Often the cause is unknown. NPH can simulate Parkinson's disease, Alzheimer's disease, and other degenerative neurological diseases. Patients may present with a gait disorder, psychomotor slowing, incontinence, progressive dementia, and memory loss. NPH is diagnosed with a computed tomography (CT) scan or magnetic resonance imaging (MRI) studies or both. The disease is treated by surgical placement of a shunt in the brain to drain excess CSF.

CRANIAL NERVE DISORDERS

Cranial nerve disorders can affect the connections between cranial nerve centers in the brain. These disorders may lead to dysfunction of smell, vision, facial sensation or expression, taste, hearing, and balance, among others. Cranial nerve disorders discussed in this section include trigeminal neuralgia, acoustic neuroma, glossopharyngeal neuralgia, and hemifacial spasm. Because the cause of the cranial nerve disorders often is unclear, management sometimes is difficult. Treatment includes drugs to inhibit nerve impulses and sometimes surgery if the cause is a tumor or lesion. Prehospital care for patients with cranial nerve disorders is primarily supportive.

Trigeminal neuralgia (also known as central pain syndrome) refers to infection or disease of the trigeminal nerve (cranial nerve V). Patients with trigeminal neuralgia complain of paroxysmal episodes of excruciating pain (often described as recurrent bursts of an electric shock) that affect the cheek, lips, gums, or chin on one side of the face. The episode usually is very brief, lasting only a few seconds to minutes, but it may be so intense the person is unable to function during the attack. The pain of trigeminal neuralgia usually begins from a trigger point on the face. It can be brought on by touching, washing, shaving, eating, drinking, or talking. Trigeminal neuralgia is unusual in people under age 50 but may be associated with multiple sclerosis in younger people. Attacks occur in bouts that may last weeks at a time.

Acoustic neuroma is a noncancerous tumor that involves the vestibular portion of the acoustic nerve (cranial nerve VIII). Because of its position in the internal auditory canal, the tumor may also compress other cranial nerves. The tumor usually grows slowly. As it grows, it presses against the nerves that affect hearing and balance. Patients may be asymptomatic or may have mild symptoms that include loss of hearing on one side, tinnitus, and vertigo. Acoustic neuroma can be difficult to diagnose, because the symptoms are similar to those of middle ear infections.

Glossopharyngeal neuralgia is believed to be caused by irritation of the glossopharyngeal nerve (cranial nerve IX). Often the source of the irritation is never identified. Possible causes include pressure exerted by blood vessels on the glossopharyngeal nerve, lesions at the base of the skull, and tumors or infection of the throat and mouth. Symptoms include severe pain in the nose, ear, and throat. The discomfort often is triggered by coughing, chewing, laughing, or swallowing. Treatment is aimed at pain relief. Medications used to manage the disorder include analgesics, anticonvulsants, and antidepressants. In rare cases, surgery may be needed to correct the underlying cause of the pain.

Hemifacial spasm is a neuromuscular disorder characterized by frequent involuntary contractions of the muscles on one side of the face. It most often is caused by a blood vessel that presses on the facial nerve (cranial nerve VII), but it also can be caused by an injury or a tumor. The disorder occurs in both men and women, although it more frequently affects middle-aged or elderly women. The first symptom usually is an intermittent twitching of the eyelid muscle that can lead to forced closure of the eye. The spasm may then gradually spread to involve the muscles of the lower face, which may cause the mouth to be pulled to one side. Eventually the spasms involve all of the muscles on one side of the face almost continuously.

BELL'S PALSY

Bell's palsy (facial palsy) is a paralysis of the facial muscles. The paralysis is caused by inflammation of the facial nerve (cranial nerve VII) (Figure 25-16). It usually is one-sided and temporary. It often develops suddenly. Bell's palsy is the most common cause of facial paralysis; it affects 1 in 60 to 70 people in a lifetime.[31] The cause of the inflammation is unclear. However, it has been associated with many past or present infectious processes. These include Lyme disease, herpes viruses, mumps, and infection with the human immunodeficiency virus (HIV). Stroke should also be part of the paramedic's differential diagnosis.

CRITICAL THINKING

In the field, should you diagnose and release a patient who has Bell's palsy?

Bell's palsy usually causes the eyelid and corner of the mouth to droop on one side of the face. It sometimes is associated with numbness and pain. Depending on which branches of the nerve are affected, taste may be impaired, or sounds may seem oddly loud. Management may involve the use of antiviral and antiinflammatory drugs to reduce inflammation of the nerve, along with analgesics. Recovery usually is complete within 2 weeks to 2 months. A key

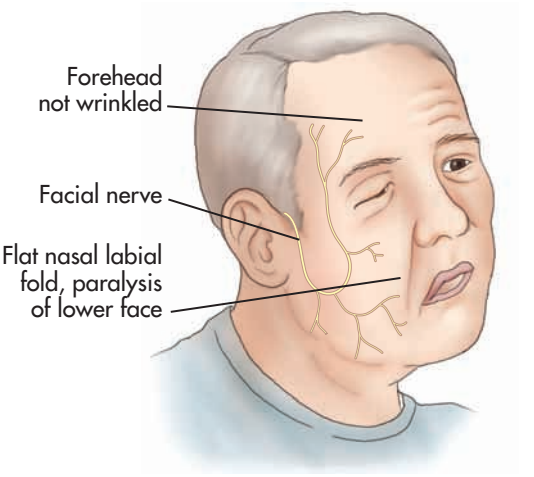

FIGURE 25-16 Bell's palsy. (McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children,* ed 5, St Louis, 2006, Mosby.)

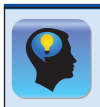
component of therapy is to protect the affected eye from corneal drying and injury, which may result because the paralysis prevents the eyelid from closing. These conditions are best prevented through the use of lubricating ointments and eye patches.

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS), also called *Lou Gehrig's disease,* is one of a group of rare disorders known as *motor neuron diseases.* In these disorders, the nerves that control muscular activity degenerate in the brain and spinal cord. ALS usually affects people over age 50. It is more common in men than in women. One or two cases of ALS are diagnosed each year per 100,000 people in the United States.[20] About 10% of ALS cases are familial.

Motor neuron diseases may involve deterioration of both upper and lower neuron tracts. When only muscles of the tongue, jaw, face, and larynx are involved, the term *progressive bulbar palsy* is used. When only corticospinal processes are affected, the term *primary lateral sclerosis* is used. When only lower motor neurons are affected, the term *progressive spinal muscular atrophy* is used. The term ALS is used for neuron signs that predominate in the extremities and trunk.

Patients with ALS often first notice weakness in the hands and arms. This is accompanied by involuntary quivering *(fasciculations).* The disease progresses to involve the muscles of all four extremities and those involved in respiration and swallowing. In the final stages of the disease, patients often are unable to speak, swallow, or move. However, awareness and intellect are maintained. Death usually occurs 2 to 4 years after the diagnosis. This is due to involvement of the respiratory muscles, aspiration pneumonia, and general inanition (starvation, failure to thrive). In some cases, life can be prolonged through the use of feeding tubes and ventilators. Care generally is aimed at providing emotional support and easing discomfort.



CRITICAL THINKING

Why is there a tendency to treat patients with amyotrophic lateral sclerosis (ALS) as if they have impaired intelligence?

PERIPHERAL NEUROPATHY

As the name implies, **peripheral neuropathy** refers to diseases and disorders that affect the peripheral nervous system. This includes the spinal nerve roots, cranial nerves, and peripheral nerves. Most neuropathies arise from damage to or irritation of either the axons or their myelin sheaths. This slows or fully blocks the passage of electrical signals. The various types of peripheral neuropathy are classified according to the site and distribution of damage. For example, damage to sensory nerve fibers may cause numbness and tingling, sensations of cold, or pain that often starts in the hands and feet and spreads toward the central body. Damage to motor nerve fibers may cause muscle weakness and muscle wasting. Damage to the nerves of the autonomic nervous system may result in blurred vision, impaired or absent sweating, fluctuations in blood pressure (and associated syncope), GI disorders, incontinence, and impotence.

Some peripheral neuropathies have no identifiable cause. Others may be related to specific causes, including the following:

- Diabetes
- Dietary deficiencies (especially of the B vitamins)
- Alcoholism
- Uremia
- Lead poisoning
- Drug intoxication
- Viral infection (e.g., Guillain-Barré syndrome)
- Rheumatoid arthritis
- Systemic lupus erythematosus
- Malignant tumors (e.g., lung cancer)
- Lymphomas
- Leukemias
- Inherited neuropathies (e.g., peroneal muscular atrophy)

When possible, management is aimed at the underlying cause (e.g., blood glucose control in a diabetic patient, improved nutrition). If management is successful and the cell bodies of the damaged nerves have not been destroyed, full recovery from the neuropathy is possible.

SPINA BIFIDA

Spina bifida is a congenital defect in which part of one or more vertebrae fails to develop completely. This leaves a portion of the spinal cord exposed. The condition can occur anywhere on the spine. However, it is most common in the lower back. Although the cause is unknown, spina bifida occurs in about 1 in 1000 births. An estimated 166,000 people in the United States are living with this birth defect.[32] It is more likely to occur with extremes of maternal age. A woman who has given birth to one child with spina bifida is 10 times more likely than the average woman to give birth to another affected child (indicating the need for genetic counseling).

Types of Spina Bifida. The severity of spina bifida depends on how much nerve tissue is exposed after the neural tube has closed. The four types of spina bifida are *spina bifida occulta, meningocele, myelomeningocele,* and *encephalocele.* Currently the condition has no cure. Treatment includes surgery, medications, and physical therapy. Most patients with spina bifida live into adulthood.

Spina bifida occulta is the most common and least serious form. There is little external evidence of the defect. Meningocele (Figure 25-17, *A*) is a type of spina bifida in which the nerve tissue of the spinal cord usually is intact and covered with a membranous sac of skin. Meningocele usually does not cause functional problems. However, it

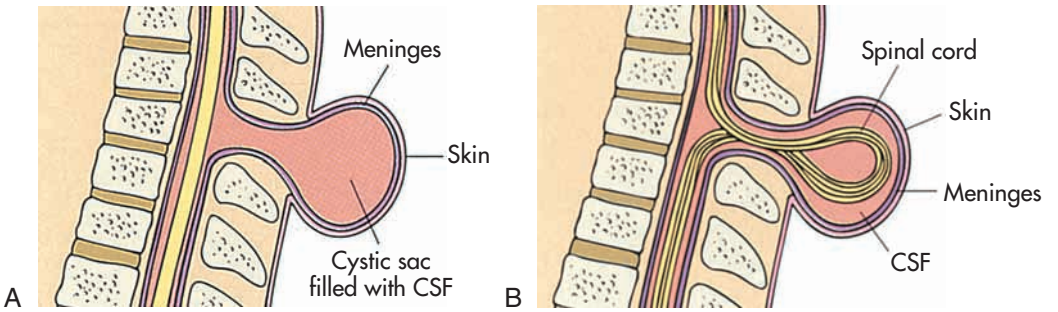


FIGURE 25-17 **A,** Meningocele. **B,** Myelomeningocele.

requires surgical repair early in life. Myelomeningocele (Figure 25-17, *B*) is the severest form of spina bifida. The child often is severely handicapped. This type of spina bifida is marked by a raw swelling over the spine and a malformed spinal cord that may or may not be contained in a membranous sac. The legs of these children often are deformed. Also, the condition causes partial or complete paralysis and loss of sensation in all areas below the level of the defect. Associated abnormalities of myelomeningocele include hydrocephalus (excess CSF in the skull) with brain damage, cerebral palsy, epilepsy, and developmental delay. In the fourth and very rare type of spina bifida, encephalocele, the protrusion occurs through the skull. Severe brain damage is common with this condition.

POLIO

Polio **(poliomyelitis)** is caused by the poliovirus. The virus attacks with variable severity. It may range from an infection that is not very apparent, to a febrile illness without neurological aftereffects, to aseptic meningitis, and finally to paralytic disease (including respiratory paralysis) and possibly death. The incidence of polio has declined in the United States, Canada, and Europe since the development of the Salk and Sabin vaccines in the 1950s. However, the disease may affect nonimmune adults and indigent children from other countries. It remains a serious risk for any unvaccinated individual traveling in southern Europe, Africa, or Asia. Polio vaccinations are given during infancy. In the United States, they usually are given in doses at 2, 14, and 18 months of age. An optional extra dose may be given at 6 months and a booster dose at 5 years.

CRITICAL THINKING
Ask your older friends or relatives about their memories of the polio epidemic. How did it affect their lives?

People infected with the poliovirus can pass large amounts of the virus in their feces. The virus then may be spread directly or indirectly to others by fingers-to-food transmission and by airborne transmission. Signs and symptoms of polio differ in the nonparalytic and paralytic forms. Fever, headache, sore throat, and malaise are common to both forms. However, the paralytic form of polio also is associated with generalized pain, weakness, muscle spasms, and paralysis of limbs and other muscles. If the infection spreads to the brainstem, the person may find it difficult or may be unable to swallow or breathe. A full recovery can be made from nonparalytic polio. Of those who become paralyzed, more than half eventually make a full recovery. Some patients may develop "postpolio deterioration." They may have new weakness and pain from recovered muscles. The disease is confirmed through CSF analysis, throat culture, or testing of fecal samples.

DIFFERENTIAL DIAGNOSIS OF NEUROLOGICAL DISORDERS

The key process in differentiating among the many neurological disorders is first to consider which disorders are most likely and most dangerous. Signs and symptoms of the various disorders often overlap, making a diagnosis difficult. Also, in many cases little correlation exists between a patient's pain and the seriousness of the condition.

The differential diagnosis begins with a thorough patient history and a detailed physical examination. This assessment, combined with personal experience, can help the paramedic identify signs and symptoms of the primary illness. To review, major neurological conditions include:

- Headache disorders (e.g., migraine, cluster headache, tension headache)
- Seizure disorders
- Neurodegenerative disorders (Alzheimer's disease, Parkinson's disease, Huntington's disease, ALS [Lou Gehrig's disease])
- Cerebrovascular disease (e.g., TIA and stroke)
- Cerebral palsy
- Infections of the brain (encephalitis), brain meninges (meningitis), and spinal cord
- Infections of the peripheral nervous system
- Neoplasms and tumors of the brain and its meninges (brain tumors), spinal cord tumors, and tumors of the peripheral nerves (neuromas)

- Movement disorders (e.g., Parkinson's disease, Huntington's disease)
- Demyelinating diseases of the CNS (e.g., MS) and of the peripheral nervous system (e.g., Guillain-Barré syndrome)
- Spinal cord disorders (tumors, infection, trauma, malformations)
- Disorders of the peripheral nerves, muscle (myopathy), and neuromuscular junctions
- Traumatic injuries to the brain, spinal cord, and peripheral nerves
- Altered mental status, encephalopathy, stupor, and coma
- Speech and language disorders

SUMMARY

- The body's ability to maintain a state of balance *(homeostasis)* results from the nervous system's regulatory and coordinating activities. The vertebral arteries and the internal carotid arteries supply blood to the brain.
- Neurological emergencies may be related to structural changes or damage, circulatory changes, or alterations in intracranial pressure that affect cerebral blood flow.
- Cerebral blood flow depends on the cerebral perfusion pressure. The CPP decreases when the mean arterial pressure drops or when the intracranial pressure rises (CPP = MAP – ICP).
- The primary survey begins by determining the patient's level of consciousness and by ensuring an open and patent airway. Key elements of the physical examination that may provide clues to the nature of the neurological emergency include the patient history, the history of the event, vital signs, and respiratory patterns.
- The neurological exam may include assessment of AVPU, the Glasgow Coma Scale score, posturing or paralysis, reflexes, pupil size and response, and extraocular movements.
- *Coma* is an abnormally deep state of unconsciousness. The patient cannot be aroused from this state by external stimuli. In general, two mechanisms produce coma: structural lesions and toxic/metabolic states.
- *Stroke* is a sudden interruption in blood flow to the brain that results in a neurological deficit. Strokes can be classified as ischemic strokes or hemorrhagic strokes. A stroke scale is used to assess for the presence of stroke. Rapid transport to a stroke resource center (if available) is indicated.
- A *seizure* is a brief alteration in behavior or consciousness. It is caused by abnormal electrical activity of one or more groups of neurons in the brain. In the prehospital setting, determining the cause of a seizure is not as important as other measures. These include managing the complications and recognizing whether the seizure is reversible with therapy (e.g., it is caused by hypoglycemia).
- The four fairly common types of headaches are tension headaches, migraines, cluster headaches, and sinus headaches.
- A CNS tumor, or *neoplasm,* is a mass in the cranial cavity or spinal cord. This mass can be either malignant or benign. Heredity may play a role in the development of brain tumors. They also are associated with several risk factors. These include exposure to radiation, tobacco use, dietary habits, some viruses, and the use of some medications.
- A *brain abscess* is a buildup of purulent material (pus) surrounded by a capsule within the brain. It develops from a bacterial infection. The infection often starts in the nasal cavity, middle ear, or mastoid bone.
- Dementia is a slow, progressive loss of awareness of time and place. Alzheimer's disease is the most common cause of dementia. Pick's disease is another type of dementia. It is associated with language disturbance.
- Huntington's disease causes degeneration of neurons in the brain. This causes uncontrolled movements and intellectual and emotional impairment.
- Creutzfeldt-Jakob disease is characterized by rapid progression of dementia.
- Muscular dystrophy is an inherited muscle disorder. The cause is unknown. The disease is marked by a slow but progressive degeneration of muscle fibers.
- Damage to the white matter of the brain in multiple sclerosis may lead to fatigue, vertigo, clumsiness, unsteady gait, slurred speech, blurred or double vision, and facial numbness or pain.
- Guillain-Barré syndrome is an autoimmune disorder. It causes muscle weakness, which progresses to paralysis that includes the muscles of respiration.
- The term *dystonia* refers to local or diffuse changes in muscle tone. These may cause painful muscle spasms, unusually fixed postures, and strange movement patterns.
- Parkinson's disease usually begins as a slight tremor in one hand, arm, or leg. In the later stages, the disease affects both sides of the body, causing stiffness, weakness, and trembling of the muscles.
- The term *central pain syndrome* refers to infection or disease of the trigeminal nerve. This causes intense pain of the face.
- Acoustic neuroma is a noncancerous tumor that affects the acoustic nerve (cranial nerve VII). It impairs balance and hearing.

- Glossopharyngeal neuralgia is an irritation of the glossopharyngeal nerve (cranial nerve IX) that causes pain in the ear, nose, and throat.
- Hemifacial spasm results in involuntary contractions of muscles on one side of the face.
- *Bell's palsy* is paralysis of the facial muscles. It is caused by inflammation of the facial nerve (cranial nerve VII). The condition usually is one-sided and temporary. It often develops suddenly.
- Amyotrophic lateral sclerosis is also called *Lou Gehrig's disease*. It is one of a group of rare nervous system disorders. In these disorders, the nerves that control muscular activity degenerate in the brain and spinal cord.
- Peripheral neuropathies usually arise from damage to or irritation of either the axons or their myelin sheaths. This slows or fully blocks the passage of electrical signals.
- *Spina bifida* is a congenital defect in which part of one or more vertebrae fail to develop completely. This leaves a portion of the spinal cord exposed.
- Polio is caused by a virus. The severity of the disease can range from unapparent infection, to a febrile illness without neurological aftereffects, to aseptic meningitis, and finally to paralytic disease and possibly death.

CHAPTER

26 Endocrinology

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe how hormones secreted from endocrine glands help the body maintain homeostasis.
2. Describe the anatomy and physiology of the pancreas and the ways its hormones maintain normal glucose metabolism.
3. Discuss pathophysiology as a basis for key signs and symptoms, patient assessment, and patient management for diabetes and diabetic emergencies of hypoglycemia, diabetic ketoacidosis, and hyperosmolar hyperglycemic nonketotic syndrome.
4. Discuss pathophysiology as a basis for key signs and symptoms, patient assessment, and patient management for disorders of the thyroid gland.
5. Discuss pathophysiology as a basis for key signs and symptoms, patient assessment, and management of emergencies related to Cushing's syndrome and Addison's disease.

KEY TERMS

acetate A byproduct of fatty acids in the liver.

Addison's disease A rare and potentially life-threatening disorder caused by a deficiency of the corticosteroid hormones normally produced by the adrenal cortex.

Cushing's syndrome A condition caused by an abnormally high circulating level of corticosteroid hormones produced naturally by the adrenal glands.

diabetes insipidus (DI) A metabolic disorder characterized by extreme polyuria and polydipsia that is caused by deficient production or secretion of antidiuretic hormone or inability of the kidney tubules to respond to antidiuretic hormone.

diabetes mellitus A complex disorder of carbohydrate, fat, and protein metabolism. It primarily results from a partial or complete lack of insulin secretion by the beta cells of the pancreas or from defects in the insulin receptors.

diabetic ketoacidosis An acute, life-threatening complication of uncontrolled diabetes characterized by hyperglycemia, hypovolemia, electrolyte imbalance, and a breakdown of free fatty acids, causing acidosis; also known as *diabetic coma*.

endocrine glands Glands that secrete chemicals and hormones directly into the blood rather than through a duct.

exocrine glands Glands that secrete chemicals and hormones into a duct.

gestational diabetes mellitus A disorder characterized by impaired ability to metabolize carbohydrates, usually caused by a deficiency of insulin; it occurs in pregnancy and disappears after delivery but in some cases returns years later.

glucagon A hormone produced by the alpha cells in the islets of Langerhans that stimulates the conversion of glycogen to glucose in the liver.

gluconeogenesis The formation of glycogen from fatty acids and proteins rather than carbohydrates.

glycogenolysis The breakdown of glycogen to glucose.

Graves' disease A type of excessive thyroid activity characterized by generalized enlargement of the gland (goiter) that leads to a swollen neck and often to protruding eyes (exophthalmos).

growth hormone (GH) A polypeptide hormone produced and secreted by the anterior pituitary gland; it acts as an insulin antagonist.

hormones Substances, usually a peptide or a steroid, produced by one tissue and conveyed by the bloodstream to another to effect physiological activity, such as growth or metabolism.

hormone receptors Receptors on target organs and body tissues that are able to respond to a particular hormone.

hyperglycemia A greater than normal amount of glucose in the blood.

hyperosmolar hyperglycemic nonketotic syndrome (HHNS) A diabetic state in which the level of ketone bodies is normal. It is caused by hyperosmolarity of extracellular fluid and results in dehydration of intracellular fluid.

hypoglycemia A lower than normal amount of glucose in the blood.

insulin A hormone secreted by the pancreatic islets.

ketogenesis The formation or production of ketone bodies.

ketone bodies The normal metabolic products of lipid and pyruvate within the liver; excessive production leads to their excretion in the urine.
myxedema A condition that results from a deficiency of thyroid hormone.
nonsteroid hormones Hormones synthesized chiefly from amino acids, such as insulin, parathyroid hormone, and others.
steroid hormones Hormones synthesized by endocrine cells from cholesterol; they include cortisol, aldosterone, estrogen, progesterone, and testosterone.
thyroid storm A life-threatening form of hyperthyroidism.
thyrotoxicosis Any toxic condition that results from thyroid hyperfunction.
type 1 diabetes Diabetes characterized by inadequate production of insulin by the pancreas. It may occur any time after birth and requires lifelong treatment with insulin.
type 2 diabetes Diabetes usually characterized by a decrease in the production of insulin by the pancreatic beta cells and diminished tissue sensitivity to insulin (insulin resistance).

The endocrine system and the nervous system allow the body to regulate many functions and to communicate among millions of cells. Paramedics encounter many patients with endocrine system disorders. These disorders can range from minor changes in functioning to life-threatening conditions.

(Courtesy Ray Kemp, St. Charles, Mo.)

ANATOMY AND PHYSIOLOGY OF THE ENDOCRINE SYSTEM

As described in Chapter 10, the endocrine system is composed of ductless glands and tissues that produce and secrete **hormones.** The major endocrine glands are the pituitary, thyroid, and parathyroid glands; the adrenal cortex and medulla; the pancreatic islets; and the ovaries and testes (Figure 26-1 and Table 26-1). Other specialized groups of cells that secrete hormones are found in the kidneys and the mucosa of the gastrointestinal (GI) tract.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 177-183.

Endocrine Gland Functions

Endocrine glands secrete hormones directly into the bloodstream and regulate various metabolic functions. The products of endocrine glands travel via the blood (or tissue fluids). They therefore are able to exert their effects at widespread sites, often distant from their source. The endocrine hormones are released in response to a change in the cellular environment; to maintain a normal level (i.e., homeostasis) of hormones or other substances; or to stimulate or inhibit organ functions. This integrated chemical and coordination system enables reproduction, growth and development, and the regulation of energy. Target organs and body tissues have **hormone receptors** and are able to respond to a particular hormone.

CRITICAL THINKING
How are hormones and their target organs like a lock and key?

HORMONE RECEPTORS

Most hormones can be categorized as proteins, polypeptides, derivatives of amino acids, or lipids. As shown in Table 26-1, each hormone may affect a specific organ or tissue or can have a general effect on the entire body. Hormones also may be classified as *steroid* or *nonsteroid*. **Steroid hormones** are synthesized by endocrine cells from cholesterol. They include cortisol, aldosterone, estrogen, progesterone, and testosterone. **Nonsteroid hormones** are synthesized chiefly from amino acids. These hormones include insulin, parathyroid hormone, and others.

Hormones affect only cells with appropriate receptors. They act on these cells to initiate specific cell functions or activities. Hormone receptor sites may be on the outside of

TABLE 26-1 Review of Endocrine Glands, Hormones, and Effects of Improper Function

Endocrine Gland	Location/Description	Hormones Produced	Gland/Hormone Function	Effects of Improper Function
Hypothalamus	Lower middle of the brain	Growth hormone–releasing hormone (GHRH) Thyrotropin-releasing hormone (TRH) Corticotropin-releasing hormone (CRH) Gonadotropin-releasing hormone (GnRH) Prolactin inhibitory factor (PIF; dopamine)	Communicates with both nervous and endocrine systems Stimulates (GHRH, TRH, CRH, GnRH) or inhibits (PIF) hormone production in the pituitary	Early puberty Thyroid diseases
		Oxytocin (OT)	Uterine contraction during labor	
		Antidiuretic hormone (ADH), also called arginine vasopressin (AVP)	Water balance	Diabetes insipidus
Pituitary	Inferior to hypothalamus, posterior to sinus cavity	Prolactin (PRL)	Milk production	Hypopituitarism Galactorrhea (milk production outside of pregnancy and normal breastfeeding because of high prolactin level)
		Growth hormone (GH)	Bone growth	Acromegaly or gigantism Growth hormone deficiency
		Adrenocorticotrophic hormone (ACTH)	Stimulates cortisol	Cushing's disease
		Thyroid-stimulating hormone (TSH)	Stimulates thyroid hormone	Hyperthyroidism/hypothyroidism
		Luteinizing hormone (LH), follicle-stimulating hormone (FSH)	Regulation of testosterone and estrogen, fertility	Loss of menstrual period Loss of sex drive Infertility
Thyroid	Butterfly-shaped gland that lies flat against trachea in the anterior neck	T4 (thyroxine) T3 (triiodothyronine)	Helps regulate rate of metabolism	Thyroid diseases (including hypothyroidism and hyperthyroidism)
		Calcitonin	Helps regulate bone status, blood calcium	
Parathyroid	Four tiny glands located posterior, adjacent to, or inferior to the thyroid	Parathyroid hormone (PTH)	Regulate blood calcium	Hyperparathyroidism Hypoparathyroidism
Adrenal	Two triangular glands, each located superior to a kidney	Epinephrine (adrenaline) Norepinephrine	Blood pressure regulation, stress reaction	Pheochromocytoma (adrenal tumor results in elevated levels of epinephrine and norepinephrine)
		Aldosterone	Salt, water balance	
		Cortisol	Stress reaction	Cushing's syndrome Addison's disease
Ovaries (females only)	Two glands located in the pelvis	Estrogen Progesterone	Female sex characteristics	Polycystic ovary syndrome
Testes (males only)	Two glands located in the scrotum	Testosterone	Male sex characteristics	Hypogonadism
Pancreas	Large, gourd-shaped gland located posterior to the stomach and between the spleen and duodenum	Insulin Glucagon Somatostatin	Glucose regulation	Diabetes mellitus Zollinger-Ellison syndrome
Pineal	Inferior and posterior to the thalamus	Melatonin	Not well understood; helps control sleep patterns, affects reproduction; involved in stress response

the cell membrane or in the interior of the cell. Cells with fewer receptor sites bind with less hormone than cells with many receptor sites (Figure 26-2). In addition, abnormalities in the presence or absence of specific hormone receptors can result in endocrine disorders.

Regulation of Hormone Secretion

All hormones operate with feedback systems. These systems are either positive or negative. The feedback systems help maintain the optimum internal environment. An example of positive feedback can be found in childbirth. The hormone *oxytocin* stimulates and enhances labor contractions. As the baby moves toward the birth canal, pressure receptors in the cervix send messages to the brain to secrete oxytocin. Oxytocin travels to the uterus through the bloodstream. It stimulates the muscles in the uterine wall to contract more strongly. The contractions intensify and

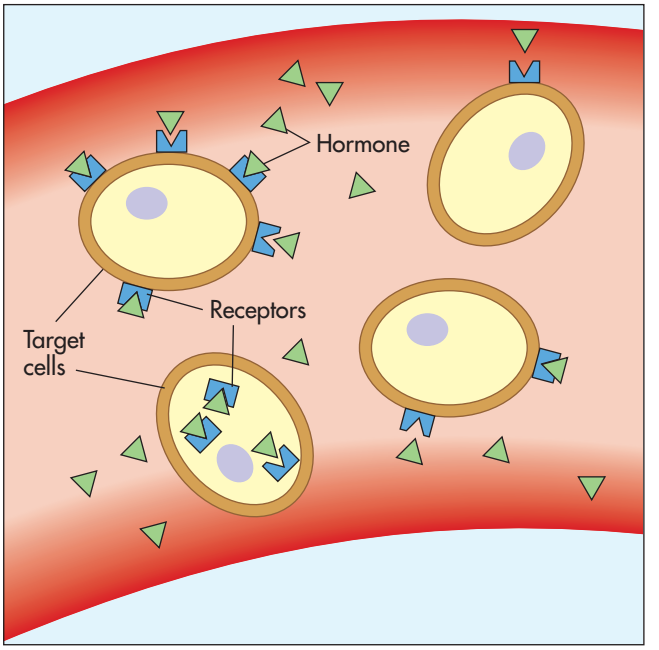

FIGURE 26-2 Target cell concept. Cells with fewer receptor sites bind with less hormone than cells with many receptor sites.

increase until the baby is delivered. When the stimulus to the pressure receptors ends, oxytocin secretion stops. Uterine contractions also stop.

Negative feedback (Figure 26-3) is the mechanism most commonly used to maintain homeostasis. For example, after a person eats a candy bar, the following occurs:

1. Glucose from the ingested lactose or sucrose is absorbed in the intestine. Consequently, the level of glucose in the blood rises.
2. The increase in the blood glucose concentration stimulates the pancreas to release insulin. Insulin facilitates the entry of glucose into the cells. As a result, the blood glucose level falls.
3. When the blood glucose level has dropped sufficiently, the endocrine cells in the pancreas stop producing and releasing insulin.

Another example is the hypothalamus receptors that monitor blood levels of thyroid hormones. Low blood levels of thyroid-stimulating hormone (TSH) cause the release of TSH-releasing hormone from the hypothalamus. This causes the release of TSH from the anterior pituitary. TSH travels to the thyroid. There, it promotes the production of thyroid hormones, which regulate the metabolic rate and body temperature.

NOTE

Negative feedback loops can be distinguished from positive feedback loops in a relatively simple way:

1. Negative feedback typically attempts to bring the system/body back toward its normal state (i.e., homeostasis).
2. Positive feedback tends to push the system/body away from normal.

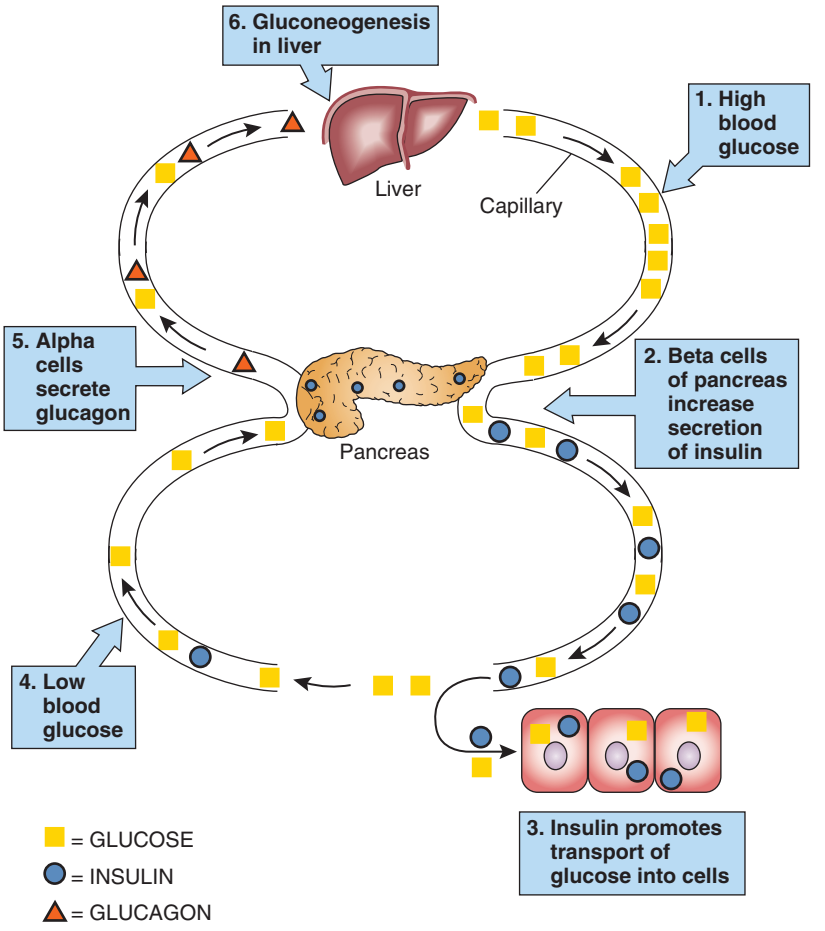

FIGURE 26-3 Negative feedback. (Gould BE: *Pathophysiology for the health professions,* ed 3, St Louis, 2006, Saunders.)

SPECIFIC DISORDERS OF THE ENDOCRINE SYSTEM

Disorders of the endocrine system arise from the effects of an imbalance in the production of one or more hormones. They also arise from the effects of a change in the body's ability to use the hormones produced. The clinical effects of endocrine gland disorders are determined by the degree of dysfunction. They also are determined by the age and gender of the affected person. The specific disorders of the endocrine system presented in this chapter are presented in Table 26-2.

TABLE 26-2 Specific Disorders of the Endocrine System

Gland	Disorder
Pancreas	Diabetes mellitus (types 1 and 2)
	Hyperosmolar hyperglycemic nonketotic syndrome (HHNS)
Thyroid	Hyperthyroidism
	Hypothyroidism
	Myxedema
	Thyroid storm
	Thyrotoxicosis
Adrenal	Addison's disease
	Cushing's syndrome

DISORDERS OF THE PANCREAS: DIABETES MELLITUS

Diabetes mellitus is a systemic disease of the endocrine system. It usually results from a dysfunction of the pancreas. It is a complex disorder of fat, carbohydrate, and protein metabolism that affects more than 24 million adults in the United States. It is estimated that another 57 million people have *prediabetes* (described later).[1] Diabetes mellitus is potentially lethal. It can put the patient at risk for several kinds of true medical emergencies.

Anatomy and Physiology of the Pancreas

The pancreas is important in the absorption and use of carbohydrates, fat, and protein. It is the chief regulator of glucose levels in the blood. The pancreas is located retroperitoneally, adjacent to the duodenum on the right and extending to the spleen on the left. As described in Chapter

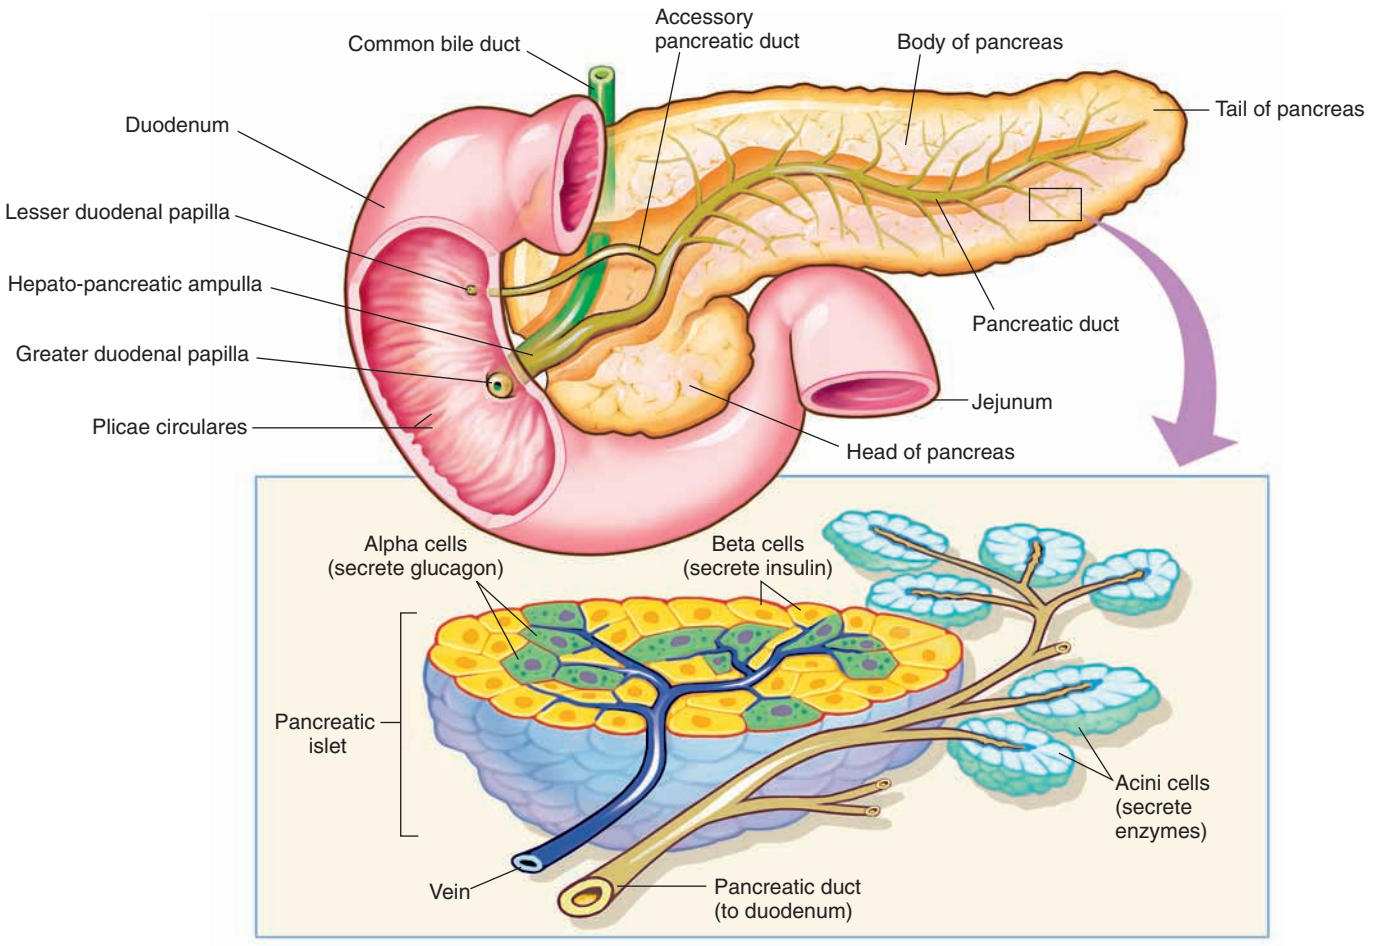

FIGURE 26-4 Two pancreatic islets (islets of Langerhans), or hormone-producing areas, are evident among the pancreatic cells that produce the pancreatic digestive juice. (Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 7, St Louis, 2010, Mosby.)

10, a healthy pancreas has exocrine and endocrine functions. To review, **exocrine glands** secrete substances through a duct onto the inner surface of an organ or the outer surface of the body. **Endocrine glands** secrete chemicals directly (not through a duct) into the bloodstream. The exocrine portion consists of *acini* (glands that produce pancreatic juice) and a duct system. The duct system carries the pancreatic fluids to the small intestine. The endocrine portion consists of pancreatic islets *(islets of Langerhans)* that produce hormones (Figure 26-4).

ISLETS OF LANGERHANS AND PANCREATIC HORMONES

About 500,000 to 1 million pancreatic islets are dispersed among the ducts and acini of the pancreas. Each islet is composed of beta cells, alpha cells, and delta cells. The beta cells produce and secrete insulin. The alpha cells produce and secrete glucagon. Delta cells produce and secrete the hormone somatostatin. This hormone inhibits the secretion of growth hormone and TSH. It also is thought to inhibit the secretion of insulin and glucagon. These properties of somatostatin act as a buffer to prevent rapid swings in blood glucose levels. Nerves from both divisions of the autonomic nervous system innervate the pancreatic islets, and each islet is surrounded by a well-developed capillary network.

CRITICAL THINKING

Consider that part of a patient's pancreas must be removed as a result of traumatic injury. Will the patient still be able to produce insulin and glucagon?

INSULIN

Insulin is a small protein. It is released by the beta cells when blood glucose levels rise. The main functions of insulin are to increase glucose transport into cells, increase glucose metabolism by cells, increase liver glycogen levels, and decrease the blood glucose concentration toward normal (Box 26-1). Many of the functions of insulin antagonize the effects of glucagon.

BOX 26-1 Primary Functions of Insulin

- Increase glucose transport into cells
- Increase glucose metabolism by cells
- Increase liver glycogen levels
- Decrease blood glucose concentration toward normal levels

GLUCAGON

Glucagon is a protein released by the alpha cells when blood glucose levels fall. Glucagon has two major effects. One effect is to increase blood glucose levels. It does this by stimulating the liver to release glucose stores from glycogen and other glucose storage sites. (This is called **glycogenolysis.**) The other effect is to stimulate **gluconeogenesis** (glucose formation) through the breakdown of fats and fatty acids, thereby maintaining a normal blood glucose level (Figure 26-5).

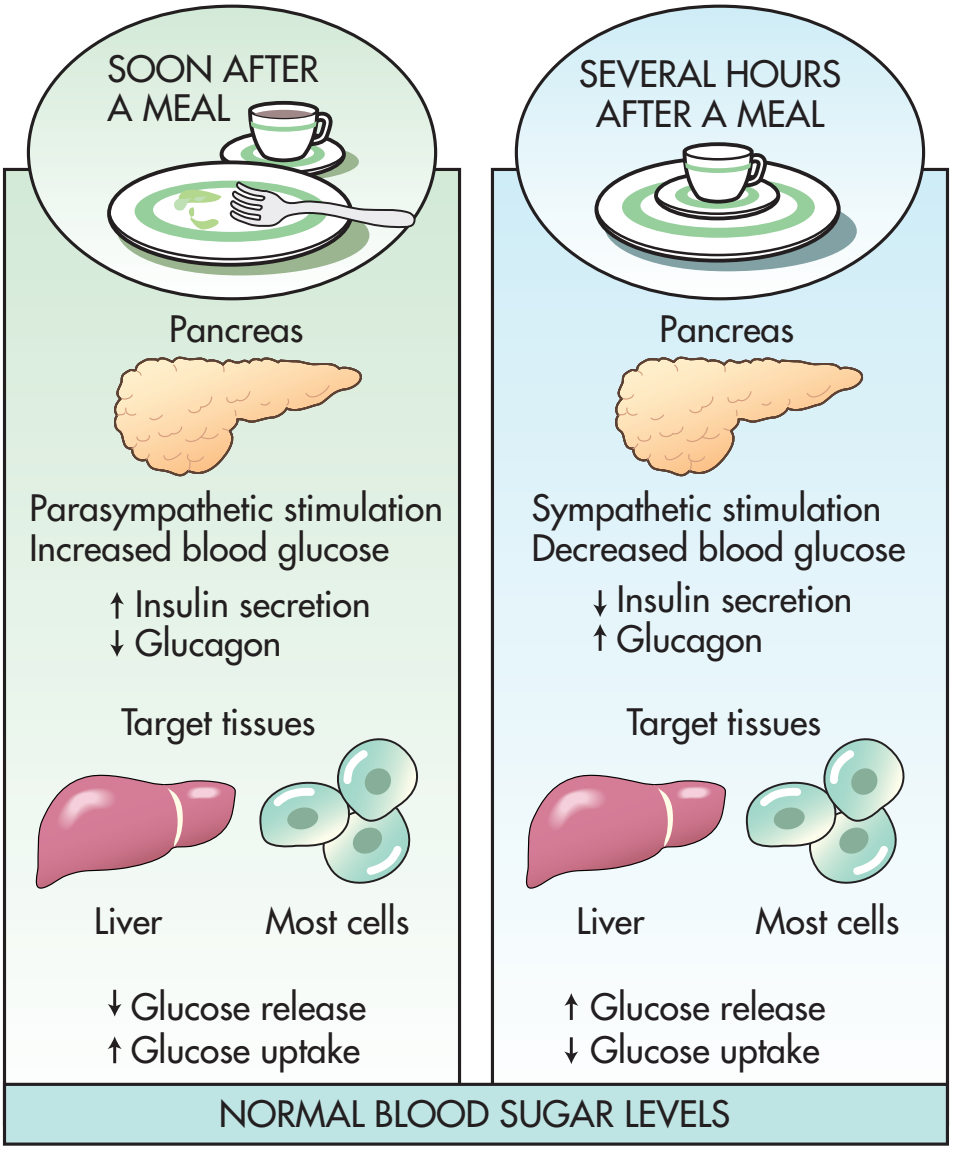

FIGURE 26-5 Regulation of insulin and glucagon secretion. Sympathetic stimulation and decreasing concentrations of glucose increase the secretion of glucagon, which acts primarily on liver cells to increase the rate of glycogen breakdown and the secretion of glucose from the liver. The release of glucose from the liver helps maintain blood glucose levels. Increasing blood glucose levels has an inhibitory effect on glucagon secretion. Increasing concentrations of glucose and amino acids stimulate the beta cells of the islets to secrete insulin. In addition, parasympathetic stimulation causes insulin secretion. Insulin acts on most tissues to increase the uptake of glucose and amino acids. As the blood levels of glucose and amino acids decrease, the rate of insulin secretion also decreases.

NOTE

Glycogenolysis and *gluconeogenesis* can be confusing terms. Glycogenolysis is the *breakdown* of glucose. Gluconeogenesis *generates* "new" glucose. (*Lysis* means to break or lyse; *neo* means new.)

GROWTH HORMONE

Growth hormone (GH) is a polypeptide hormone. It is produced and secreted by the anterior pituitary gland. GH secretion is triggered by many physiological stimuli. These include exercise, stress, sleep, and hypoglycemia. GH acts as an insulin antagonist. It decreases insulin's actions on cell membranes. This reduces the ability of muscles and adipose and liver cells to absorb glucose.

Regulation of Glucose Metabolism

Under normal conditions, the body maintains the serum glucose level in the blood at 60 to 120 mg/dL. (Normal fasting blood glucose is below 100 mg/dL.[1]) A knowledge of food intake and digestion is required to understand glucose metabolism.

DIETARY INTAKE

As described in Chapter 2, the three main organic components of food are carbohydrates, fats, and proteins. (Food also contains minerals and vitamins.) Carbohydrates are found in all sugary, starchy foods. They are a ready source of near-instant energy. They are the first food substances to enter the bloodstream after a meal is ingested. Carbohydrates yield the simple sugar glucose. If not "burned" for immediate energy, glucose is stored in the liver and muscles as glycogen for short-term energy needs, or it is stored in adipose tissue for intermediate and long-term needs.

LOOK AGAIN

See Chapter 2: Well-Being of the Paramedic, pp. 25-28.

PROCESS OF DIGESTION

Before food compounds can be used by body cells, they must be digested and absorbed into the bloodstream. Digestion begins in the mouth. It is accomplished by physical forces (chewing) and chemical (enzymatic) forces. This begins the process that reduces the food to soluble molecules and particles small enough to be absorbed. After food has been swallowed, it enters the stomach. There, various nutrients are absorbed into the circulatory system. These nutrients include glucose, salts, water, and some other substances (alcohol and certain other drugs). The remaining material (chyme) is shunted from the stomach into the intestine for further digestion.

The duodenum signals the release of hormones that mobilize the pancreas to contribute its molecule-splitting enzymes and the gallbladder to release bile salts. These enzymes and salts neutralize acids and help emulsify fats. Carbohydrates are absorbed as simple sugars. Fats are absorbed as fatty acids and glycerol. Proteins are absorbed as amino acids. These nutrients are then carried from the intestine to the liver by way of the portal vein. Water and remaining salts are absorbed from food residues in the colon. The liver synthesizes glycogen from the absorbed glucose, lipoproteins from the absorbed fatty acids, and many proteins required for health from absorbed amino acids.

Carbohydrate Metabolism. The secretion of insulin is controlled by chemical, neural, and hormonal means. An increased blood glucose concentration, parasympathetic stimulation, and GI hormones involved in the regulation of digestion cause the beta cells of the pancreas to release insulin after dietary intake of carbohydrates. Insulin travels through the blood to target tissues. There it combines with specific chemical receptors on the surface of the cell membrane to permit glucose to enter the cell (Table 26-3). This allows the cells to use glucose for energy. It also prevents the breakdown of alternative energy sources (proteins and fat cells). In addition, it promotes the uptake of glucose into the liver, where it is converted to glycogen for storage. This rapid uptake and storage of glucose normally prevents a large increase in blood glucose levels, even just after a normal meal.

CRITICAL THINKING

Why do individuals with diabetes eat carbohydrates instead of protein or fat when they sense that their glucose level is too low?

When the blood glucose level begins to fall, the liver releases glucose back into the circulating blood. Thus the liver removes excess glucose from the blood after a meal. Also, it returns it to the blood when it is needed between meals. Under normal circumstances, about 60% of the glucose in a meal is stored in the liver as glycogen and released later.

If the muscles are not exercised after a meal, much of the glucose transported into the muscle cells by insulin is stored as muscle glycogen. Muscle glycogen differs from liver glycogen. It cannot be reconverted into glucose and released into the circulation. The stored glycogen must be used by the muscle for energy.

The brain is quite different from other body tissues with regard to glucose uptake. Insulin has little or no effect on the uptake or use of glucose by the brain; the cells of the brain do not have adequate storage capacity. Also, because the brain normally uses only glucose for energy, it cannot depend on stored supplies of glycogen. Therefore, it is essential that the serum glucose be maintained at a level that provides adequate energy to these tissues. When the serum glucose level falls too low, signs and symptoms of hypoglycemia can develop quickly. These include progressive irritability, altered mental status, fainting, convulsions, and even coma.

TABLE 26-3 Effects of Insulin and Glucagon on Target Tissues

Target Tissue	Response to Insulin	Response to Glucagon
Skeletal muscle, cardiac muscle, cartilage, bone, fibroblasts, leukocytes, and mammary glands	Increased glucose uptake and glycogen synthesis; increased uptake of certain amino acids	Little effect
Liver	Increased glycogen synthesis; increased use of glucose for energy (glycolysis)	Rapid increase in the breakdown of glycogen to glucose (glycogenolysis) and release of glucose into the blood Increased formation of glucose (gluconeogenesis) from amino acids and, to some degree, from fats Increased metabolism of fatty acids, resulting in increased ketones in the blood
Adipose cells	Increased glucose uptake, glycogen synthesis, fat synthesis, and fatty acid uptake; increased glycolysis	High concentrations cause breakdown of fats (lipolysis); probably unimportant under most conditions
Nervous system	Little effect except to increase glucose uptake in the satiety center	No effect

From Seeley R: *Anatomy and physiology,* ed 2, St Louis, 1992, Mosby.

Fat Metabolism. Only a limited amount of glycogen can be stored in the liver and skeletal muscles. Therefore, one third of any glucose passing through the liver is converted to fatty acids. Under the influence of insulin, fatty acids are converted to triglycerides (storable fats.) They are stored in adipose tissue. In the absence of insulin, the stored fat is broken down. The plasma concentration of free fatty acids rapidly increases. A low level of insulin in the blood can result in high levels of triglycerides and cholesterol (in the form of lipoproteins) in the plasma. This is thought to contribute to the development of atherosclerosis in patients with serious diabetes.[1]

If needed (as in the absence of insulin), fatty acids in the liver can be metabolized and used for energy. A byproduct of the breakdown of fatty acids in the liver is **acetate.** Acetate is converted to acetoacetic acid and beta hydroxybutyric acid. These products are released into the circulating blood as **ketone bodies.** Ketone bodies may cause acidosis and coma (diabetic ketoacidosis) in a diabetic patient.

Protein Metabolism. Insulin causes the storage of proteins in addition to carbohydrates and fats. Through the actions of GH and insulin, amino acids are actively transported into the various cells of the body. Most amino acids are used as building blocks to form new proteins. (This is called *protein synthesis.*) However, some enter the metabolic cycle by being converted to glucose after initial breakdown in the liver.

In the absence of insulin, protein storage stops and protein breakdown (particularly in muscle) begins. This releases large amounts of amino acids into the circulation. The excess amino acids are used directly for energy or as substrates for gluconeogenesis. Degradation of the amino acids leads to increased excretion of urea in the urine. This "protein wasting" has serious effects in diabetes mellitus. It leads to extreme weakness and dysfunction of many organs.

GLUCAGON AND ITS FUNCTIONS

Glucagon has several functions that are the opposite of the functions of insulin. The most important is to increase the blood glucose concentration. Glucagon has two major effects on glucose metabolism. One is the breakdown of liver glycogen (glycogenolysis). The other is the generation of glucose (gluconeogenesis).

As the serum glucose level returns to normal (several hours after dietary intake), insulin secretion decreases with continued fasting. The blood sugar level then begins to drop. As a result, glucagon, cortisol, GH, and epinephrine (from sympathetic stimulation) are secreted. This initiates the release of glucose from glycogen and other glucose-storage sites. Glycogen is converted back to glucose and released into the blood. Uptake of glucose by most tissues helps maintain the blood glucose at levels necessary for normal function (Figure 26-6).

In summary, the four mechanisms for achieving adequate blood glucose regulation are as follows:

1. The liver functions as a blood glucose buffer system. It removes excess glucose from the blood and stores it as glycogen. It also returns glucose to the blood when the glucose concentration and insulin secretion decline.
2. Insulin and glucagon function as a negative feedback control system. They work to maintain normal serum

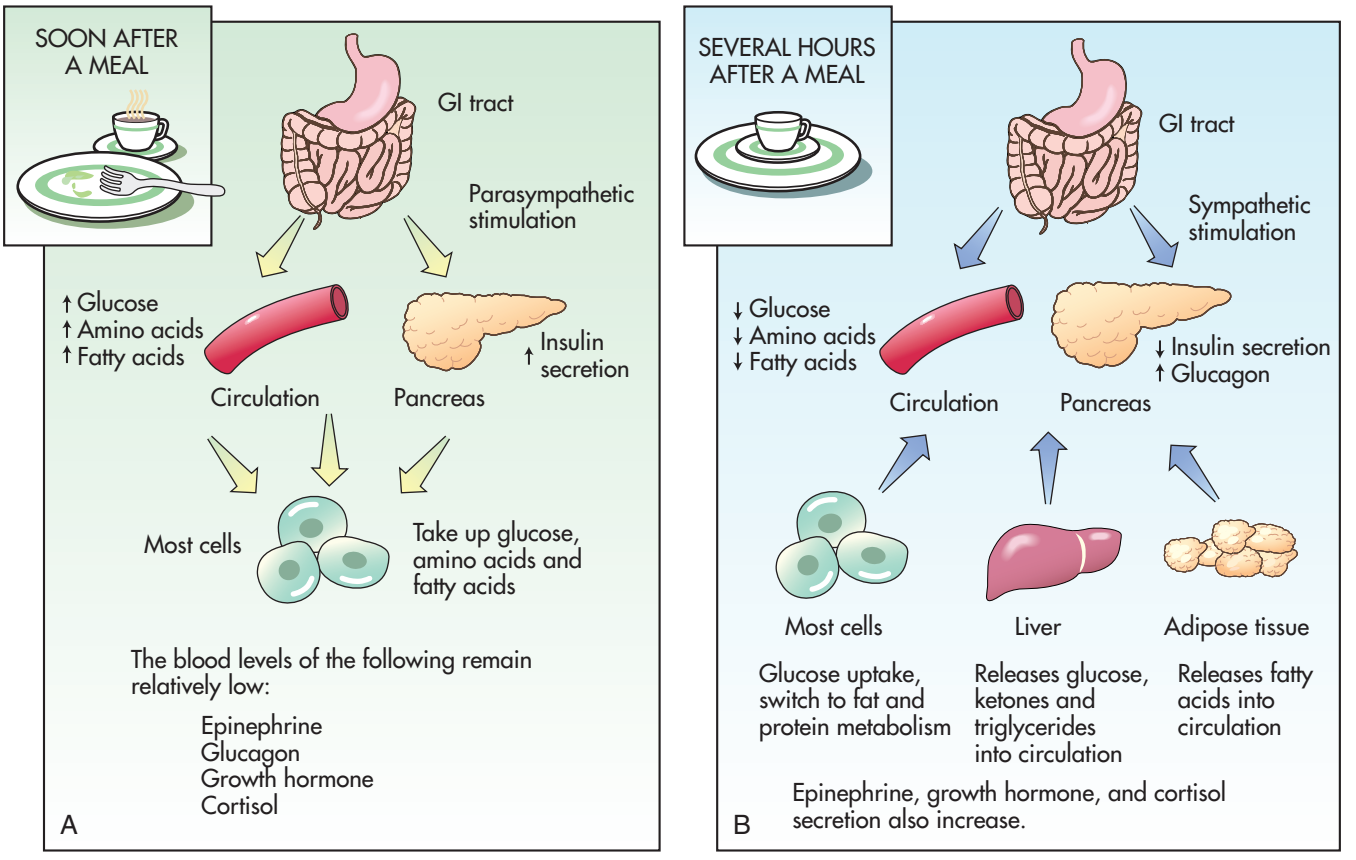

FIGURE 26-6 A, Soon after a meal, glucose, amino acids, and fatty acids enter the bloodstream from the intestinal tract. Glucose and amino acids stimulate insulin secretion. Cells take up the glucose and amino acids and use them in their metabolism. **B,** Several hours after a meal, absorption from the intestinal tract decreases, and the blood levels of glucose, amino acids, and fatty acids decrease. As a result, insulin secretion decreases, and glucagon, epinephrine, and growth hormone (GH) secretion increases. Cell uptake of glucose decreases, and the use of fats and proteins increases.

glucose concentrations. When the serum glucose level rises, insulin is secreted to lower it toward normal. On the other hand, when the serum glucose level falls, glucagon is secreted to raise the serum glucose level toward normal.

3. Low serum glucose levels stimulate the sympathetic nervous system to secrete epinephrine. Epinephrine and, to a lesser degree, norepinephrine have a glucagon-like effect that promotes liver glycogenolysis.
4. GH and cortisol play a role in less immediate regulation of serum glucose levels. They are secreted in response to more prolonged hypoglycemic episodes, such as a late overnight fast. They also increase the rate of glucose production. They tend to decrease the rate of glucose use.

CRITICAL THINKING
What signs and symptoms will a patient have in response to the release of epinephrine that occurs when the blood glucose level falls?

Pathophysiology of Diabetes Mellitus

Diabetes is the seventh leading cause of death in the United States.[2] The disease is characterized by a deficiency of insulin or by an inability of the body to respond to insulin. Diabetes often is associated with an increased intake of fluid *(polydipsia),* excretion of large amounts of urine that contains glucose *(polyuria, glucosuria),* and weight loss.

NOTE
Diabetes insipidus (DI) is a disorder marked by an abnormal increase in urine output, fluid intake, and often thirst. Diabetes insipidus (also called "water diabetes") is not the same as diabetes mellitus ("sugar diabetes"). The two diseases are completely unrelated, even though the symptoms of both include increased urination and thirst. DI has a variety of causes. The most common cause is a lack of vasopressin, which normally acts on the kidney to reduce urine output by increasing the concentration of the urine. Most patients with DI are aware of their disease. The paramedic should consider DI as a differential diagnosis in a patient who presents with increased urination and thirst.

Diabetes mellitus generally is classified as type 1 or type 2. Type 1 diabetes previously was called *insulin-dependent diabetes mellitus* (IDDM), or *juvenile diabetes.* Type 2 previously was called *non-insulin-dependent diabetes mellitus* (NIDDM), or *adult-onset diabetes.* A new classification system endorsed by the American Diabetes Association and the World Health Organization identifies four types of diabetes: type 1, type 2, gestational diabetes, and "other specific types," to address the continuum of **hyperglycemia** (elevated blood glucose) and insulin requirements.[1]

TYPE 1 DIABETES

Type 1 diabetes is characterized by inadequate production of insulin by the pancreas. It may occur any time after birth. However, it usually occurs in teenagers and young adults, and the incidence typically "peaks" at 12 years of age.[3] Heredity is a factor in type 1 diabetes. The disease appears to be an autoimmune phenomenon. It results from a genetic abnormality or susceptibility that causes the body to destroy its own insulin-producing cells. A person with a parent or sibling with type 1 diabetes has a 10% chance of developing the disease by age 50.[1] Type 1 diabetes requires lifelong treatment with ***insulin,*** exercise, and dietary regulation. The symptoms of type 1 diabetes usually appear suddenly. They include polyuria, polydipsia, dizziness, blurred vision, and rapid, unexplained weight loss. Only 5% to 10% of people with diabetes have this form of the disease.

TYPE 2 DIABETES

Type 2 diabetes usually is characterized by a decrease in the production of insulin by the pancreatic beta cells and diminished tissue sensitivity to insulin *(insulin resistance).* People who are insulin resistant have either too few insulin receptors or faulty insulin receptors. As a result, the circulating insulin cannot be properly used. Most people with type 2 diabetes are insulin resistant. The disease occurs most often in adults over age 40, in minorities, and in overweight individuals (Box 26-2). (Obesity predisposes a person to this form of diabetes. This is because larger amounts of insulin are needed for metabolic control in obese individuals than in people of normal weight.). Type 2 diabetes accounts for 90% to 95% of all diagnosed cases of diabetes.[4] Because of the increase in childhood obesity, a growing number of children and young adults are being diagnosed with type 2 diabetes.

NOTE

Prediabetes is a condition that is becoming common in the United States. People with prediabetes have blood glucose levels that are higher than normal but not high enough for a diagnosis of diabetes. This condition increases the risk the person will develop type 2 diabetes, heart disease, and stroke. The National Institutes of Health estimate that 79 million adults age 20 and older have prediabetes. People with prediabetes are likely to develop type 2 diabetes within 10 years unless steps are taken to prevent or delay diabetes. Preventive measures include weight loss, diet modification, and exercise.

BOX 26-2 Metabolic Syndrome

Many people with insulin resistance and high blood glucose levels have other conditions that increase their risk of developing type 2 diabetes and cardiovascular disease. These conditions include excess weight around the waist, high blood pressure, and abnormal blood levels of cholesterol and triglycerides. A person with several of these conditions is said to have *metabolic syndrome.* Metabolic syndrome is defined as the presence of any three of the following:

- Waist measurement of 40 inches or more for men or 35 inches or more for women
- Triglyceride level of 150 mg/dL or above or treatment with medication for elevated triglycerides
- High-density lipoprotein (HDL; "good" cholesterol) level below 40 mg/dL for men or below 50 mg/dL for women or treatment with medication for low HDL levels
- Blood pressure of 130/85 mm Hg or above or treatment with medication for elevated blood pressure
- Fasting blood glucose level of 100 mg/dL or above or treatment with medication for elevated blood glucose levels

Modified from Grundy SM, et al: Diagnosis and management of the metabolic syndrome: an American Heart Association/National Heart, Lung, and Blood Institute scientific statement, *Circulation* 112:2735-2752, 2005.

CRITICAL THINKING

Would patients with type 1 or type 2 diabetes have an increased risk of complications related to this disease?

Most patients with type 2 diabetes require oral hypoglycemic medications, exercise, and dietary regulation to control their illness. A small number of patients require ***insulin.*** Warning signs, if present, develop gradually. They include all of those associated with type 1 diabetes. Fatigue, changes in appetite, and tingling, numbness, and pain in the extremities also are indicators.

GESTATIONAL DIABETES MELLITUS

Gestational diabetes mellitus develops in some women during late pregnancy. This type of diabetes usually resolves with childbirth. However, some women go on to develop type 2 diabetes within 5 to 10 years. Gestational diabetes is addressed further in Chapter 46.

OTHER SPECIFIC TYPES OF DIABETES

Although less common than type 1 and type 2 diabetes, a number of other types of diabetes exist. A person may show characteristics of more than one type. Other types of diabetes include those caused by[5]:

- Genetic defects of the pancreatic beta cells
- Genetic defects in insulin action, resulting in an inability by the body to control blood glucose levels
- Diseases of the pancreas or conditions that damage the pancreas, such as pancreatitis and cystic fibrosis
- Excess amounts of certain hormones as a result of some medical conditions that work against

the action of insulin (e.g., cortisol in Cushing's syndrome)
- Medications that reduce the action of insulin (e.g., glucocorticoids) or chemicals that destroy beta cells
- Infections, such as congenital rubella and cytomegalovirus
- Rare immune-mediated disorders
- Genetic syndromes associated with diabetes, such as Down syndrome

Effects of Diabetes

Most of the effects of diabetes can be attributed to one of the following three effects of decreased insulin levels[6]:

1. Decreased use of glucose by the body cells, which results in an increase in the serum glucose level
2. Markedly increased mobilization of fats from the fat storage areas, causing abnormal fat metabolism, which may result in the short term in ketoacidosis and in the long term in severe atherosclerosis
3. Depletion of protein in body tissues and muscle wasting

LOSS OF GLUCOSE IN THE URINE

When the amount of glucose entering the kidneys rises above the kidneys' ability to reabsorb it, a significant portion of the glucose "spills" into the urine. The loss of glucose in the urine causes diuresis. This is because the osmotic effect of glucose prevents the kidneys from reabsorbing water (osmotic diuresis). The effect is dehydration. If left untreated, dehydration can lead to hypovolemic shock.

ACIDOSIS IN DIABETES

The shift from carbohydrate to fat metabolism results in the formation of ketone bodies *(ketoacids)*. Ketone bodies are acids, and their continuous production leads to a metabolic acidosis. Often the respiratory system at least partly compensates for this acidosis (indicated by Kussmaul respirations). The kidneys' ability to clear the acid is overwhelmed by the continuous production of ketone bodies. Profound acidosis eventually occurs. This acidosis, along with the usually severe dehydration that occurs as a result of the osmotic diuresis, can lead to death. Hyperkalemia, secondary to acidosis, also leads to cardiac dysrhythmias, some of which may be lethal. Treatment of this condition can be lifesaving.

Diabetes mellitus is a systemic disease with many long-term complications, including the following[5]:

- Blindness (5000 people with diabetes lose their sight each year)
- Kidney disease (10% of patients with diabetes develop some form of kidney disease, including end-stage kidney failure, which requires dialysis or a kidney transplant)
- Peripheral neuropathy, which results in nerve damage to the hands and feet and an increased incidence of foot infections
- Autonomic neuropathy, which damages the nerves controlling voluntary and involuntary functions and may affect sexual function, bladder and bowel control, and blood pressure
- Heart disease and stroke (People with diabetes are two to four times as likely to develop heart disease as those without the disease and are two to six times as likely to have a stroke.)
- High blood glucose and blood fat levels, which contribute to atherosclerosis
- Peripheral vascular disease (also secondary to atherosclerosis), which results in the need for amputations

DID YOU KNOW?

Diabetic Foot

About 20% of patients hospitalized with diabetes have foot problems.[7] These problems result from sensory neuropathy, ischemia, and infection. The loss of sensation leads to pressure necrosis from poorly fitting footwear. In addition, small wounds on the feet frequently go unnoticed by the patient, leading to foot ulcers and infection. The most common cause of foot injury is pressure on the plantar bony prominences.

Care should always be taken to assess the feet of any diabetic patient. Findings may include infected ulcerations, foreign bodies in the foot tissue, and bone abnormalities. Full-thickness ulcerations and cellulitis can be limb-threatening and can lead to sepsis. Patients with a *diabetic foot* should not be permitted to put weight or pressure on the affected area. Wounds should be dressed. Treatment by a physician may include debridement of devitalized tissue, advanced wound care, and antibiotic therapy. Some patients must be hospitalized.

Patients with diabetes also suffer from decreased immune function as a long-term complication of the disease. This places the diabetic patient at higher risk for increased morbidity and mortality from infectious diseases, such as influenza. These patients also are prone to infection-related complications from surgeries and other invasive procedures (e.g., intravenous [IV] therapy, bladder catheterization).

Management

The treatment of diabetes consists of drug therapy ***(insulin*** or oral hypoglycemic agents), dietary regulation, and exercise. These therapies allow patients to control their serum glucose levels. They also help restore normal metabolism. Pancreatic transplantation remains an experimental treatment for diabetes mellitus.

NOTE

The A1C test is a general measure of diabetes care. It indicates the amount of glucose attached to hemoglobin A proteins. The A1C test provides a patient with an average of the person's blood glucose levels for the past 2 to 3 months. The test often is done two to four times a year. The test result is reported as a percentage. For a person without diabetes, a typical A1C level is about 5%. The American Diabetes Association (ADA) recommends an A1C target of 7% or lower. The American Association of Clinical Endocrinologists recommends a level of 6.5% or lower.[8] Many diabetic patients know their A1C number.

INSULIN

As described in Chapter 13, genetically engineered human ***insulin*** is available in rapid-, intermediate-, and long-acting preparations. (***Insulin*** is administered by injection or nasal inhalation; it is a protein that would be digested if consumed orally.) A patient with insulin-dependent diabetes usually takes one or two doses of a long-acting ***insulin*** preparation each day. At meal times, these individuals also take a rapid-acting ***insulin*** (which lasts only a few hours).

LOOK AGAIN
See Chapter 13: Principles of Pharmacology and Emergency Medications, pp. 324-325.

An insulin infusion pump (Figure 26-7) is another means by which patients may self-administer ***insulin.*** The pump delivers a continuous "basal" level of ***insulin.*** The patient supplements the basal level with a bolus after eating. Patients calculate the amount of ***insulin*** to be taken based on their caloric intake. The glucose level must be monitored regularly to ensure adequate medication control. The medication balance is delicate. The dosage of ***insulin*** that appears correct at one time may be too much or too little at another time. The dosage depends on various factors, such as exercise or the presence of infection.

FIGURE 26-7 Insulin pump. **A,** Device and insertion site. **B,** Diabetic paramedic with an insulin pump.

ORAL HYPOGLYCEMIC AGENTS

Some oral hypoglycemic agents stimulate the release of insulin from the pancreas. These are effective only in patients who have functioning beta cells that produce some insulin (type 2 diabetes). Other agents help the body better utilize insulin or prevent the body from manufacturing glucose (Table 26-4). Oral hypoglycemic drugs can have important side effects. They require careful patient monitoring (e.g., periodic tests for liver and kidney function).

NOTE
Patients with type 2 diabetes who have an episode of hypoglycemia should be transported for evaluation by a physician. A patient who refuses transport should be advised of the associated risks and should be encouraged to call again for help if needed. In addition, these patients should not be left alone.

Diabetic Emergencies

Three life-threatening conditions may result from diabetes mellitus: hypoglycemia (insulin shock), hyperglycemia (diabetic ketoacidosis), and hyperosmolar hyperglycemic nonketotic syndrome (HHNS).

TABLE 26-4 Medications Used in the Treatment of Diabetes

Generic Name	Brand Name	Effect
Biguanides		
Metformin	Glucophage	Block the liver from making sugar
Sulfonylureas (Second-Generation)		
Glimepiride	Amaryl	Raise the amount of insulin in the body
Glipizide	Glucotrol	
Glyburide	Diabeta, Glynase, PresTab, Micronase	
Meglitinides		
Repaglinide	Prandin	Raise the amount of insulin in the body
Nateglinide	Starlix	
Thiazolidinediones		
Pioglitazone	Actos	Help the body use insulin better
Rosiglitazone	Avandia	
Alpha-Glucosidase Inhibitors		
Acarbose	Precose	Slow the digestion of sugar
Miglitol	Glyset

HYPOGLYCEMIA

Hypoglycemia is a syndrome related to blood glucose levels below 70 mg/dL.[8] Symptoms usually occur at levels below 60 mg/dL or at slightly higher blood glucose levels if the fall has been rapid. The condition also may occur in patients who are not diabetic. It usually is a result of an excessive response to glucose absorption, physical exertion, alcohol or drug effects, pregnancy and lactation, or decreased dietary intake. In patients with diabetes, hypoglycemic reactions usually are caused by the following:

- Too much ***insulin*** (or some types of oral hypoglycemic medication)
- Decreased dietary intake (a delayed or missed meal)
- Unusual or vigorous physical activity
- Administration of certain antibiotics (with oral hypoglycemic agents)

Less common causes and predisposing factors include the following:

- Chronic alcoholism (alcohol depletes liver glycogen stores)
- Adrenal gland dysfunction
- Liver disease (i.e., hepatic insufficiency or failure)
- Malnutrition
- Pancreatic tumor
- Cancer
- Hypothermia
- Sepsis
- Administration of beta blockers (e.g., ***propranolol***)
- Administration of salicylates (e.g., ***aspirin***) in ill infants or children
- Intentional overdose with ***insulin,*** oral hypoglycemic agents, or salicylates

NOTE

Relative hypoglycemia can occur when glucose levels fall rapidly below normal fasting levels for a particular person. This condition commonly is overlooked in diabetic patients who have elevated fasting levels. These patients may be symptomatic even with near-normal glucose readings. (This condition also is common in a newborn whose mother has diabetes.)

Signs and Symptoms. The signs and symptoms of hypoglycemia usually appear quickly, often within minutes. They are related to the release of epinephrine as the body tries to compensate for a drop in blood sugar. In the early stages, the patient may complain of extreme hunger. The patient may demonstrate one or more of the following signs and symptoms because of the decreased availability of glucose to the brain:

- Nervousness, trembling
- Irritability
- Psychotic (combative) behavior
- Weakness and incoordination
- Confusion
- Appearance of intoxication
- Weak, rapid pulse
- Cold, clammy skin
- Drowsiness
- Seizures
- Coma (in severe cases)
- Cardiac arrest

Hypoglycemia should be suspected in any diabetic patient who shows behavioral changes, confusion, abnormal neurological signs, or unconsciousness. This condition is a true emergency. It requires immediate administration of glucose to prevent permanent brain damage or death.

CRITICAL THINKING

Why might a call for a patient with diabetic ketoacidosis (DKA) be dispatched as a behavioral emergency?

DIABETIC KETOACIDOSIS

Diabetic ketoacidosis (DKA) results from an absence of or resistance to insulin (Box 26-3). The low insulin level prevents glucose from entering the cells. As a result, glucose accumulates in the blood. Consequently, the cells become starved for glucose and begin to use other sources of energy, principally fat. The metabolism of fat generates fatty acids and glycerol. The glycerol provides some energy to the cells, but the fatty acids are further metabolized to form ketoacids, resulting in acidosis.

As described in Chapter 11, acidosis increases the transport of potassium from the intracellular space into the intravascular space. The subsequent diuresis results in a high potassium concentration in the urine and a total body potassium deficit. In addition, the sodium concentration in the extracellular fluid usually decreases through osmotic dilution. The sodium is replaced by increased hydrogen ions, which adds greatly to the acidosis. As the blood sugar level rises, the patient undergoes massive osmotic diuresis. This, combined with vomiting, causes dehydration and shock. Although an overall loss of potassium occurs, the patient is still hyperkalemic. This can lead to cardiac dysrhythmias and cardiac abnormalities (e.g., peaked T waves,

BOX 26-3 Common Causes of Diabetic Ketoacidosis

- Inadequate insulin dose
- Failure to take insulin
- Infection
- Increased stress (trauma, surgery)
- Increased dietary intake
- Decreased metabolic rate
- Other, less common predisposing factors, including significant emotional stress, alcohol consumption (often associated with hypoglycemia), and pregnancy

a prolonged P-R interval, and widening of the QRS complex). Electrolyte imbalances may also cause altered neuromuscular activity, including seizures.

LOOK AGAIN
See Chapter 22: Cardiology, pp. 582-586.

NOTE
Patients may present with DKA without knowing that they are diabetic (i.e., their diabetes has not yet been diagnosed). This is especially true in children.[9]

Signs and Symptoms. The signs and symptoms of DKA usually are related to hypovolemia and acidosis. They usually are slow in onset (over 12 to 48 hours) and include the following:

- Diuresis
- Increased blood glucose level
- Warm, dry skin
- Dry mucous membranes
- Tachycardia, thready pulse
- Postural hypotension
- Weight loss
- Polyuria
- Polydipsia
- Polyphagia
- Acidosis
- Abdominal pain (usually generalized)
- Anorexia, nausea, vomiting
- Acetone breath odor (fruity odor)
- Kussmaul respirations (as the body attempts to reduce carbon dioxide levels)
- Diminished level of consciousness

Patients with DKA seldom are deeply comatose. Patients who are unresponsive should be assessed for another cause, such as head injury, stroke, or drug overdose.

NOTE
An elevation in blood glucose is common in the early phase of stroke. It is estimated that up to one third of acute stroke patients have either diagnosed or newly diagnosed diabetes. A significant proportion of these patients are likely to have *stress hyperglycemia,* mediated partly by the release of cortisol and norepinephrine. This form of hyperglycemia is associated with poor outcomes, such as a dependent state or intracerebral hemorrhage.[10] If a TIA or stroke is suspected in a patient over age 50, administration of a concentrated glucose solution may worsen cerebral damage. However, glucose should not be withheld if the patient is hypoglycemic. The paramedic should consult with medical direction.

CRITICAL THINKING
How can you distinguish Kussmaul respirations from hyperventilation?

HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC SYNDROME

Hyperosmolar hyperglycemic nonketotic syndrome (HHNS) is a condition of acute diabetic decompensation. It is a life-threatening emergency characterized by marked hyperglycemia, hyperosmolarity and dehydration, and decreased mental functioning that may lead to coma. It often occurs in older patients with type 2 diabetes or in patients with undiagnosed diabetes (Box 26-4). The syndrome is easily mistaken for DKA. It differs from DKA in that enough insulin may be present to prevent the metabolism of fats **(ketogenesis)** and the development of ketoacidosis. However, the amount of insulin may not be enough to prevent glucose use by peripheral tissues or to reduce gluconeogenesis by the liver.

HHNS develops from sustained hyperglycemia that produces a hyperosmolar state. This causes an osmotic diuresis that results in marked dehydration and electrolyte losses.[11] In HHNS, protein and fats are not used to create new supplies of glucose to the same degree as in DKA, and the ketotic cycle is either never started or does not occur until the glucose is extremely elevated.[12] These patients usually have blood glucose levels above 600 mg/dL. They also have less ketone formation. This results in less acidemia than in patients with DKA (Figure 26-8).

NOTE
HHNS can occur when a diabetic (or nondiabetic) patient is unable to drink sufficient fluids to offset urinary losses. This situation can result from stroke, Alzheimer's disease, and other diseases that can lead to dehydration. It also can occur as a result of drug use, trauma, burns, and dialysis.

HHNS tends to develop slowly, often over several days. It has a high mortality rate. Early signs and symptoms are mostly related to volume depletion. They include polyuria and polydipsia. Associated signs and symptoms may include orthostatic hypotension, dry mucous membranes, and tachycardia. CNS dysfunction may result in lethargy, confusion, and coma. Precipitating factors of HHNS include the following:

- Advanced age
- Preexisting cardiac or renal disease
- Inadequate insulin secretion or action (type 2 diabetes)
- Increased insulin requirements (stress, infection, trauma, burns, myocardial infarction)
- Medication use (thiazide and thiazide diuretics, glucocorticoids, ***phenytoin,*** sympathomimetics, ***propranolol,*** immunosuppressants)
- Supplemental parenteral and enteral feedings

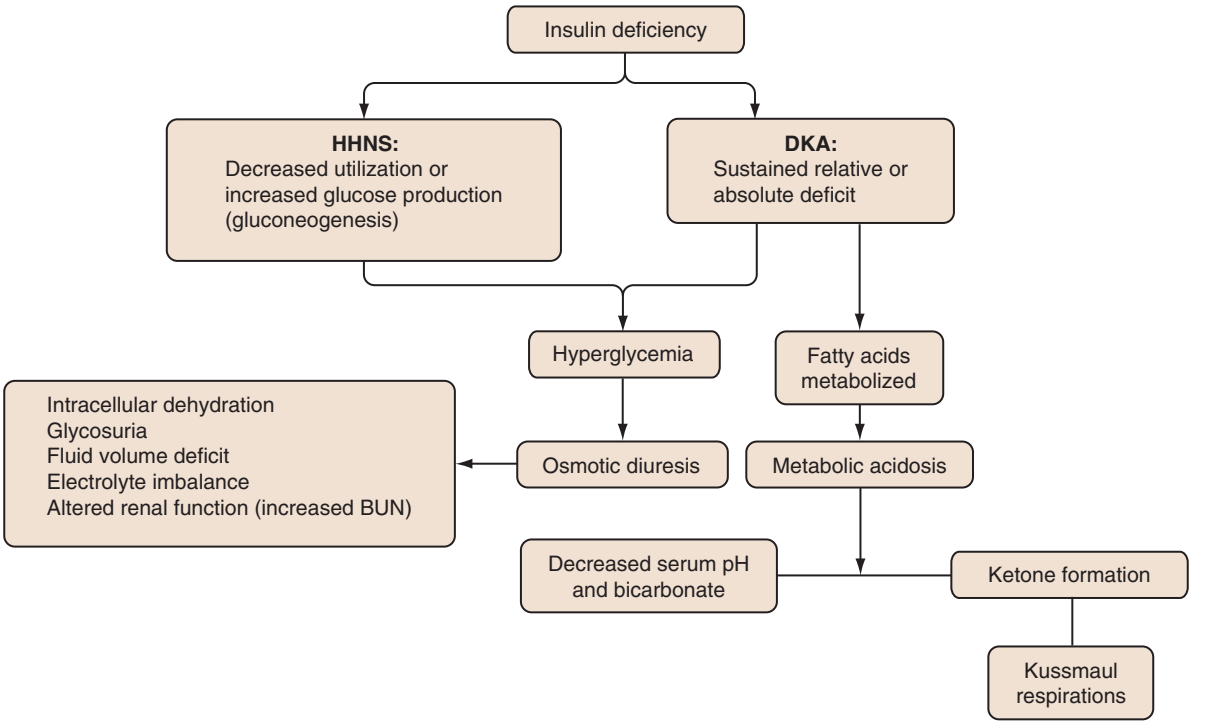

FIGURE 26-8 Pathophysiology of hyperosmolar hyperglycemic nonketotic syndrome (HHNS). (Sole ML: *Introduction to critical care nursing,* ed 5, St Louis, 2009, Saunders.)

ASSESSMENT OF THE DIABETIC PATIENT

A patient with a diabetic emergency may have a range of signs and symptoms. Many of these may mimic other, more commonly encountered conditions. Therefore, the paramedic must have a high degree of suspicion for illness related to diabetes.

In addition to the patient assessment, measures appropriate for any emergency patient encounter (primary assessment, physical examination, and treatment of life-threatening illness or injury), the paramedic should search for medical alert information, an insulin pump, insulin syringes, and diabetic medications (***insulin*** often is kept in the refrigerator). Important components of the patient history in the assessment of diabetic patients include the onset of symptoms, food intake, ***insulin*** or oral hypoglycemic use, alcohol or other drug consumption, predisposing factors (exercise, infection, illness, stress), and any associated symptoms.

FIGURE 26-9 Glucometer for measuring serum glucose levels.

MANAGEMENT OF THE CONSCIOUS DIABETIC PATIENT

If the diabetic patient is conscious and able to talk, a pertinent history should be obtained. The paramedic should do this while assessing the patient's airway, breathing, and circulation. If appropriate, the patient should be given glucose.

Protocols may include drawing a blood sample for laboratory testing before glucose is administered. Glucose testing in the field is done with a glucometer (Figure 26-9). Patients who have a glucose reading below 70 mg/dL (varies by protocol) *and* who have signs and symptoms consistent with hypoglycemia generally should be given glucose.[13] Some type I diabetic patients who have experienced a diabetic reaction may be treated at the scene and released. Others may need to be transported for evaluation by a physician. The paramedic should consult with medical direction or follow the established protocol. If a patient who received glucose refuses transport, before leaving the scene the paramedic should make sure the patient has been advised of the possibility of recurrent hypoglycemia.[14] In addition, paramedics should make sure the patient has a

"meal" available that is high in complex carbohydrates and protein. The meal should be consumed within 30 minutes of receiving the glucose, ideally before EMS leaves the scene.[15]

NOTE
A patient who may have taken an unintentional overdose of insulin always requires evaluation by a physician. These patients can develop delayed, profound, and protracted hypoglycemia. This is especially true with long-acting insulin preparations.[16]

The methods of glucose administration vary. If the patient is alert and able to swallow, sugar should first be administered orally. It can be given in the form of a candy bar, a glass of orange juice mixed with sugar, a nondiet soft drink, or by sublingual or buccal administration of a glucose gel preparation. An alternate method is to slowly administer ***50% dextrose*** (50%, 25%, or 10%) through a large, stable peripheral vein (Box 26-5). This dose may be repeated according to protocol (Box 26-6).

BOX 26-5 Cautions for Intravenous Administration of Glucose

- 50% Dextrose should not be administered to infants or young children or to patients with suspected stroke.
- Administration of 50% dextrose may lead to neurological complications in alcoholics and other patients with thiamine deficiency. Therefore, administration of thiamine before or during administration of dextrose should be considered for patients suspected of having a thiamine deficiency.
- IV dextrose may raise A1C levels.

BOX 26-6 Glucose Preparations

Concentrated dextrose in water is designed for intravenous administration. The preparation is available in several concentrations. High-concentration dextrose solution may infiltrate tissue, causing sloughing and necrosis of the vein.[17] Therefore, concentrated dextrose must be given through a large, stable vein. It may also be given by the intraosseous route (see the EDI). The concentrations used most often in prehospital care are:
- 50% dextrose in water (recommended for most adults)
- 25% dextrose in water (recommended for most children)
- 10% dextrose in water (recommended for most neonates)

SHOW ME THE EVIDENCE
In a randomized, controlled study, Welsh researchers evaluated the effectiveness of administering dextrose 10% in 5 g doses, compared with 50% dextrose given in 5 g doses, to treat hypoglycemia in the prehospital setting. The endpoint for treatment was a dose of 25 g or a Glasgow Coma Scale (GCS) score of 15. In both groups, patients recovered within a median time of 8 minutes. The group that received 10% dextrose required a significantly lower dose and had lower post-treatment blood glucose levels than the group that received 50% dextrose. An equal number of subjects from the two groups had a subsequent hypoglycemic event.

Moore C, Woollard M: Dextrose 10% or 50% in the treatment of hypoglycaemia out of hospital? A randomized controlled trial, *Emerg Med J* 22:512-515, 2005.

CRITICAL THINKING
What steps should you take before leaving the scene if the patient refuses transport after treatment with dextrose?

MANAGEMENT OF THE UNCONSCIOUS DIABETIC PATIENT

Prehospital management of any unconscious patient should be directed at airway management, administration of high-concentration oxygen, and ventilatory and

circulatory support. Depending on protocol, an IV line should be established for rehydration with lactated Ringer solution or a saline solution. The flow rate should be determined by the patient's blood pressure and heart rate. Before glucose is given, a blood sample should be drawn for laboratory analysis. If alcoholism or other drug abuse is suspected, the administration of ***thiamine*** or ***naloxone,*** or both, before glucose may be indicated.

NOTE
Administration of one dose of ***50% dextrose*** only minimally worsens DKA or HNNS. The drug also is lifesaving for patients who are hypoglycemic. In the rare event the blood glucose cannot be measured rapidly, ***50% dextrose*** should be given.[7]

If an IV line cannot be established, ***glucagon*** may be given by the subcutaneous route, intramuscular route, or intranasally via mucosal atomization (per protocol). Any of these methods can help raise the serum glucose level. They do so by stimulating the breakdown of liver glycogen. However, ***glucagon*** is not effective in any patient with decreased liver glycogen. Examples include chronic alcoholics; those with liver disease; those who are malnourished; and those on certain diets. Definitive treatment for patients with DKA or HHNS requires administration of ***insulin,*** fluid replacement, electrolyte monitoring, and in-hospital observation. While at the scene and during transport, the patient should be monitored closely for serious dysrhythmias, which can lead to cardiac arrest. They result from electrolyte abnormalities (hyperkalemia) and may require drug therapy ***(albuterol, calcium, sodium bicarbonate)*** (see Chapter 22). In addition, a patient with HHNS may require large amounts of IV fluid (1 to 1.5 L within the first hour) for rehydration while at the scene and during transport.

DIFFERENTIAL DIAGNOSIS

The signs and symptoms of diabetic emergencies can sometimes overlap, making the exact cause of the patient's condition difficult to identify. Although blood glucose monitoring is now a standard of care, Table 26-5 may help in making a differential diagnosis in difficult cases.

DISORDERS OF THE THYROID GLAND

Common disorders of the thyroid gland include hyperthyroidism and hypothyroidism. *Hyperthyroidism* is an excess of thyroid hormones in the blood, which may result in thyrotoxicosis. *Hypothyroidism* is an insufficiency of thyroid hormones in the blood, which may result in myxedema.

Thyrotoxicosis

Thyrotoxicosis is a mild form of hyperthyroidism. **Thyroid storm** is a life-threatening form of hyperthyroidism. Thyrotoxicosis is fairly common and develops over time. Thyroid storm is a rare condition that may occur spontaneously. It may be brought on by infection, stress, or a thyroidectomy. Most cases of hyperthyroidism occur as a consequence of toxic diffuse goiter (Graves' disease).[7] **Graves' disease** is a type of excessive thyroid activity characterized by generalized enlargement of the gland (goiter), which leads to a swollen neck and, often, protruding eyes (exophthalmos) (Figure 26-10). Graves' disease most often occurs in young women. It may arise as a result of an autoimmune process in which an antibody stimulates the thyroid cells.

ANATOMY AND PHYSIOLOGY OF THE THYROID GLAND

As described in Chapter 10, the thyroid gland is situated in the front of the neck just below the larynx. It consists of two lobes, one on each side of the trachea, which are joined by a narrower portion of tissue called the *isthmus* (Figure 26-11).

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 182-183.

Thyroid tissue is composed of two types of secretory cells: follicular cells and parafollicular cells (or C cells). Follicular cells make up most of the gland. They are arranged in the form of hollow, spherical follicles. They secrete the iodine-containing hormones thyroxine (T_4) and triiodothyronine (T_3). Parafollicular cells occur singly or in small groups in the spaces between the follicles. These cells secrete

DKA, Diabetic ketoacidosis; *HHNS*, hyperosmolar hyperglycemic nonketotic syndrome.

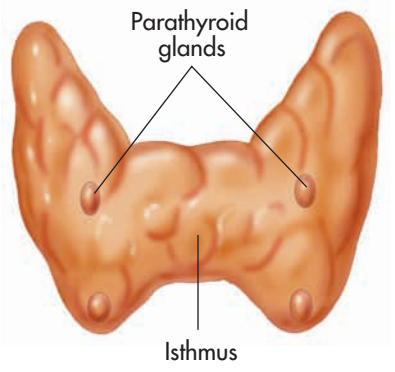

FIGURE 26-11 Thyroid gland.

the hormone calcitonin, which helps regulate the level of calcium in the body.

Thyroid hormones play a key role in controlling body metabolism. They are essential in children for normal physical growth and mental development. The secretion of T_3 and T_4 is controlled by a feedback system. This system involves the pituitary gland and the hypothalamus. (The secretion of calcitonin is regulated directly by the level of calcium in the blood, independent of the pituitary gland or hypothalamus.)

Disorders of the thyroid gland may result from defects in the gland itself or from disruption of the hypothalamic-pituitary hormonal control system (Box 26-7). The disease advances slowly. It may have nonspecific signs and symptoms over months to years. It also may culminate in an acute episode (thyroid storm). Nonspecific signs and symptoms of thyroid hyperfunction include fatigue, anxiety, palpitations, sweating, weight loss, diarrhea, and heat intolerance.

In acute episodes of thyroid storm, the signs and symptoms are those related to adrenergic hyperactivity. They may include the following:

- Severe tachycardia
- Heart failure
- Cardiac dysrhythmias
- Shock
- Hyperthermia
- Restlessness
- Agitation and paranoia

BOX 26-7 Causes of Thyroid Gland Disorders

- Congenital defects
- Genetic disorders
- Infection (thyroiditis)
- Tumors (benign or malignant)
- Autoimmune disorders
- Hormonal disorders during puberty or pregnancy
- Nutritional disorders

- Abdominal pain
- Delirium
- Coma

The paramedic should consider other causes of symptoms related to adrenergic hyperactivity, most notably hypoglycemia, use of cocaine and amphetamines, and withdrawal from alcohol and other drugs.

CRITICAL THINKING
What medical emergencies could produce signs and symptoms similar to those of thyroid storm?

MANAGEMENT

Mild hyperthyroidism requires no emergency therapy. It is best managed with physician follow-up. Thyroid storm, however, is a true emergency that requires immediate treatment. Emergency care efforts are directed at providing airway, ventilatory, and circulatory support and rapid transport to an appropriate medical facility. In-hospital care focuses on inhibiting hormone synthesis, blocking hormone release and the peripheral effects of thyroid hormone with antithyroid drugs, and providing general support of the patient's vital functions. Beta blockers also are given to control the heart rate, tremors, and anxiety. Table 26-6 lists the signs and symptoms of hyperthyroidism and hypothyroidism.

NOTE
All patients with disorders related to the thyroid gland should be closely monitored for cardiac dysrhythmias. Atrial fibrillation and supraventricular tachycardia are common in these patients. Efforts to control the heart rate may not be effective until the thyroid disorder has been treated.

Myxedema

Myxedema is a condition that results from hypothyroidism. It may be associated with inflammation of the thyroid gland (e.g., *Hashimoto thyroiditis*) or atrophy of the thyroid gland. It also may be a consequence of treatment for hyperthyroidism. Myxedema causes an accumulation of mucinous material in the skin. This results in thickening and coarsening of the skin and other body tissues (most notably the lips, nose, and throat) (Figure 26-12). The condition is most common in adults over age 40, especially women.

TABLE 26-6 Signs, Symptoms, and Medications Used in Hyperthyroidism and Hypothyroidism

Hyperthyroidism	Hypothyroidism
Exophthalmos	Facial edema
Goiter	Jugular venous distention (sometimes goiter)
Warm, flushed skin	Cool skin
Sensitivity to heat	Sensitivity to cold
Fever	Hypothermia
Agitation/psychosis	Coma
Hyperactivity	Weakness
Weight loss	Weight gain
Common Medications Used in Treatment	
Iodine	Levothyroxine (Synthroid)
Methimazole (Tapazole)	Liothyronine (Cytomel)
Propylthiouracil (Propacil)	Liotrix (Euthroid)

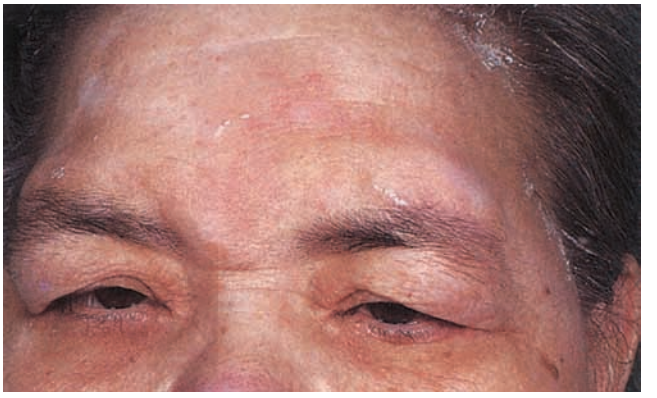

FIGURE 26-12 Myxedema. (Epstein O, et al: *Clinical examination,* ed 4, St Louis, 2008, Mosby.)

NOTE
Symptoms of hypothyroidism in children and adolescents differ from those in adults. In newborns, hypothyroidism causes *cretinism* (neonatal hypothyroidism). This condition is characterized by jaundice, poor appetite, constipation, a hoarse cry, outpouching of the navel (umbilical hernia), and slowed bone growth. If not diagnosed and treated within a few months of birth, hypothyroidism can lead to mental retardation. Hypothyroidism that begins in childhood *(juvenile hypothyroidism)* slows growth. This sometimes results in disproportionately short limbs. Tooth development also can be delayed.

Myxedema coma is a rare illness. In addition to myxedema, it is characterized by hypothermia and a reduced level of consciousness. Myxedema coma is a medical emergency that may be precipitated by the following factors:

- Exposure to cold
- Infection (usually pulmonary)
- Congestive heart failure
- Trauma
- Drugs (sedatives, hypnotics, anesthetics)
- Stroke
- Internal hemorrhage
- Hypoxia
- Hypercapnia
- Hyponatremia
- Hypoglycemia

MANAGEMENT

Prehospital care is directed at managing life-threatening conditions (airway, ventilatory, and circulatory compromise) and providing rapid transport to an appropriate medical facility for evaluation by a physician. En route, the patient's body temperature should be maintained and the ECG should be monitored closely for cardiac dysrhythmias. Once other causes of the coma have been ruled out and the patient's condition has been stabilized, treatment of myxedema can begin with oral administration of thyroxine. This treatment must be continued for life.

NOTE
The angioedema associated with thyroid disease often affects the patient's neck and throat. This may make for a difficult airway if intubation is required.

DISORDERS OF THE ADRENAL GLANDS

Two disorders of the adrenal gland are Cushing's syndrome and Addison's disease. Cushing's syndrome is caused by excessive activity of the adrenal cortex. Addison's disease is caused by inactivity of the adrenal cortex.

Anatomy and Physiology of the Adrenal Glands

As described in Chapter 10, the adrenal glands are triangular-shaped endocrine glands located on top of both kidneys (Figure 26-13). Each gland consists of a *medulla,* the center of the gland, which is surrounded by the *cortex*. The medulla is responsible for producing epinephrine and norepinephrine. The adrenal cortex produces other hormones necessary for fluid and electrolyte balance in the body (e.g., cortisone and aldosterone).

Cushing's Syndrome

Cushing's syndrome is a rare condition caused by an abnormally high circulating level of corticosteroid hormones. It mainly affects women 30 to 50 years of age. The syndrome may be produced directly by an adrenal gland tumor, which causes excessive secretion of corticosteroids. It also may be produced by administration of corticosteroid drugs, such as predinsone, dexamethasone, or methylprednisolone. These drugs are used to treat conditions such as rheumatoid arthritis, inflammatory bowel disease, and asthma. Finally, it may be produced by enlargement of both adrenal glands as a result of a pituitary tumor. The pituitary gland controls the activity of the adrenal gland by producing adrenocorticotropic hormone (ACTH). ACTH stimulates growth of the adrenal cortex.

People with Cushing's syndrome have a characteristic appearance (Figure 26-14). The face appears round ("moon face") and red (Figure 26-15). Also, the trunk tends to become obese from disturbances in fat metabolism. The limbs become wasted from muscle atrophy. Acne develops, and purple stretch marks may appear on the abdomen, thighs, and breasts. The skin often thins and bruises easily. Weakened bones are at increased risk of fracture. Other features of the disease include the following:

- Increased body and facial hair
- Hump on the back of neck ("buffalo hump")
- Supraclavicular fat pads
- Weight gain
- Hypertension
- Psychiatric disturbances (depression, paranoia)
- Insomnia
- Diabetes mellitus

CRITICAL THINKING
How do you think patients who suffer from Cushing's syndrome feel about their body image?

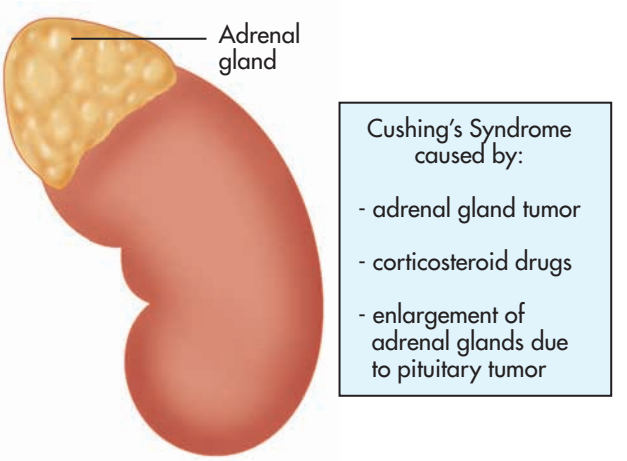

FIGURE 26-13 Adrenal gland.

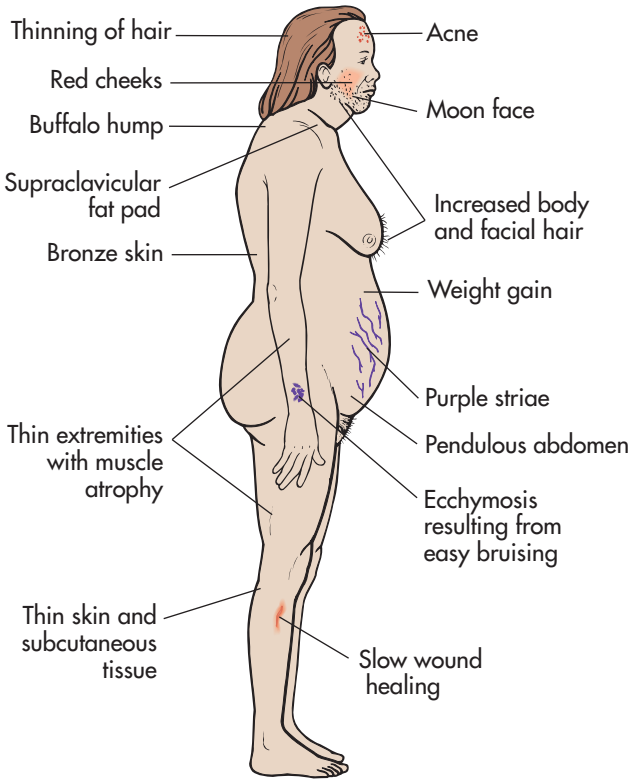

FIGURE 26-14 Cushing's syndrome. (Lewis SM, Collier IC, Heitkemper MM: *Medical-surgical nursing: assessment and management of clinical problems,* ed 7, St Louis, 2007, Mosby.)

MANAGEMENT

Prehospital care for patients with Cushing's syndrome is mainly supportive. The disease is diagnosed through measurement of hormone levels in the blood and urine and by radiological imaging (e.g., computed tomography [CT] scan). If the cause of the syndrome is overtreatment with corticosteroid drugs, the condition usually is reversible when the drug dosages are adjusted. If the cause is a tumor or overgrowth of the adrenal gland, the gland may require surgical removal. If the tumor is in the pituitary gland, the usual treatment involves surgery, radiation, and medication. Treatment usually is successful. Lifelong hormone replacement therapy is required.

Addison's Disease

Addison's disease is a rare disorder that can be life threatening. It is caused by a deficiency of the corticosteroid hormones cortisol and aldosterone. These hormones normally are produced by the adrenal cortex. The disorder can be caused by any disease process that destroys the adrenal cortices. Such disease processes may include adrenal hemorrhage or infarction, infections (tuberculosis, fungi, viruses), and autoimmune diseases. However, the most common cause of Addison's disease is shrinking of the adrenal tissue. When this occurs, production of corticosteroid hormones is inadequate to meet the body's metabolic requirements. Signs and symptoms associated with this disease include the following:

FIGURE 26-15 Moon-faced appearance in a patient with Cushing's syndrome. (Epstein O, et al: *Clinical examination,* ed 4, St Louis, 2008, Mosby.)

FIGURE 26-16 Hyperpigmentation in a patient with Addison's disease. (Forbes CD, Jackson WF: *Color atlas and textbook of clinical medicine,* ed 3, St Louis, 2003, Mosby.)

- Progressive weakness
- Progressive weight loss
- Progressive anorexia
- Skin hyperpigmentation (caused by increased hormone production by the pituitary gland, which stimulates melanin) (Figure 26-16)

- Hypotension
- Hyponatremia
- Hyperkalemia
- GI disturbances (nausea, vomiting, diarrhea)

Addison's disease usually has a slow onset and a chronic course. The symptoms develop gradually over months to years. However, acute episodes *(addisonian crisis)* may be brought on by emotional and physiological stress. Examples of such stressors include surgery, alcohol intoxication, hypothermia, myocardial infarction, severe illness, trauma, hypoglycemia, and infection. During these events, the adrenal glands cannot increase the production of the corticosteroid hormones to help the body cope with stress. As a result, blood glucose levels drop; the body loses the ability to regulate the content of sodium, potassium, and water in body fluids, causing dehydration and extreme muscle weakness; blood volume and blood pressure fall; and the body may not be able to maintain circulation efficiently. In these situations, airway, ventilatory, and circulatory support are required in the prehospital setting. The serum glucose level should be monitored closely. ECG findings as a result of hypokalemia may include peaked T waves, flattened P waves, and widening of the QRS complex. Some EMS services carry hydrocortisone (Solu-Cortef) to manage adrenal insufficiency.

NOTE

Many patients with Addison's disease carry injectable hydrocortisone in case of crisis. The paramedic may need to contact medical direction for an order to administer the drug to an unstable patient.

MANAGEMENT

In-hospital treatment involves maintaining the patient's vital functions and correcting the sodium deficiency and dehydration. After the life-threatening episode has been managed, treatment consists of administration of corticosteroids. The patient often is advised to increase the dosage of these drugs during times of emotional and physiological stress.

Table 26-7 presents a comparison of the signs and symptoms of Cushing's syndrome and Addison's disease.

TABLE 26-7 Signs, Symptoms and Medications Used in Adrenal Gland Disorders

Corticosteroid Excess (Cushing's Syndrome)	Adrenal Insufficiency (Addison's Disease)
Weight gain	Weight loss
Weakness	Weakness
Hump on back of neck	Hypotension
Slow healing	Gastrointestinal disorders
Increased body and facial hair	Skin hyperpigmentation
Common Medications Used in Treatment	
Aminoglutethimide (Cytadren)	Dexamethasone (Decadron)
Metyrapone (Metopirone)	Fludrocortisone (Florinef Acetate)

OTHER ENDOCRINE DISORDERS

The endocrine disorders presented in this chapter are the most common. However, there are many types of endocrine disorders and diseases. A discussion of each is beyond the scope of this textbook. The paramedic should remember that most endocrine disorders are related to hormone imbalance or nutritional deficiencies. After diagnosis, most patients require lifelong treatment.

SUMMARY

- The endocrine system consists of ductless glands and tissues. These glands and tissues produce and secrete hormones. Endocrine glands secrete their hormones directly into the bloodstream. They exert a regulatory effect on various metabolic functions. All hormones operate within feedback systems that are either positive or negative. These systems work to maintain the optimum internal environment.
- The pancreatic islets are composed of beta cells, alpha cells, and other cells. The beta cells secrete insulin. The alpha cells secrete glucagon. The function of the other cells is not completely clear. The chief functions of insulin are to increase glucose transport into cells, increase glucose metabolism by cells, increase the liver glycogen level, and decrease the blood glucose concentration toward normal. Glucagon has two major effects: (1) it increases blood glucose levels by stimulating the liver to release glucose stores from glycogen and other glucose storage sites (glycogenosis) and (2) it stimulates gluconeogenesis through the breakdown of fats and fatty acids, thereby maintaining a normal blood glucose level.
- Diabetes mellitus is characterized by a deficiency of insulin production or an inability of the body to respond to insulin. Diabetes generally is classified as type 1 or type 2. Patients with type 1 diabetes have inadequate insulin production. Treatment consists of insulin administration, exercise, and dietary regulation. Type 2 diabetes is caused by cellular resistance to insulin and, ultimately, decreased insulin

production. Most patients with type 2 diabetes require oral hypoglycemic medications, exercise, and dietary regulation to control the illness. Some require insulin administration.

- Hypoglycemia is a syndrome related to blood glucose levels below 70 mg/dL. A diabetic patient with behavioral changes or unconsciousness should be treated for hypoglycemia. This condition is a true emergency. It requires immediate administration of glucose to prevent permanent brain damage or death.
- Diabetic ketoacidosis results from an absence of or a resistance to insulin. The signs and symptoms of DKA are related to hypovolemia. They usually are slow in onset.
- Hyperosmolar hyperglycemic nonketotic syndrome is a life-threatening emergency. HHNS often occurs in older patients with type 2 diabetes. It also frequently occurs in individuals whose diabetes has not yet been diagnosed. The hyperglycemia produces a hyperosmolar state. This causes osmotic diuresis, dehydration, and electrolyte imbalances.
- Important components of the patient history in the assessment of diabetic patients include the onset of symptoms, food intake, insulin or oral hypoglycemic use, alcohol or other drug consumption, predisposing factors, and any associated symptoms.
- Any patient with a glucose reading below 70 mg/dL (varies by protocol) and signs and symptoms consistent with hypoglycemia generally should be given glucose.
- Thyrotoxicosis is any toxic condition that results from overactivity of the thyroid gland.
- Thyroid storm is a life-threatening condition resulting from an overactive thyroid gland. Thyroid hormones play a key role in controlling body metabolism. They are essential in children for normal physical growth and development.
- Myxedema is a condition that results from a thyroid hormone deficiency. Myxedema coma is a rare illness. In addition to myxedema, it is characterized by hypothermia and mental obtundation. It is a medical emergency.
- Cushing's syndrome is caused by an abnormally high circulating level of corticosteroid hormones. These are produced naturally by the adrenal glands.
- Addison's disease is a rare but life-threatening disorder. It is caused by a deficiency of the corticosteroid hormones cortisol and aldosterone. These are normally produced by the adrenal cortex.

CHAPTER

27 Immune System Disorders

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Outline the structure of the immune system.
2. Describe the antigen-antibody response.
3. Distinguish between natural and acquired immunity.
4. Differentiate between a normal immune response and an allergic reaction.
5. Distinguish between the four types of hypersensitivity reaction.
6. Describe the signs, symptoms, and management of local allergic reactions based on an understanding of the pathophysiology associated with this condition.
7. Identify allergens associated with anaphylaxis.
8. Describe the pathophysiology, signs and symptoms, and management of a nonsystemic allergic reaction.
9. Describe the pathophysiology, signs and symptoms, and management of anaphylaxis.
10. Define autoimmune disease.
11. Describe the pathophysiology, signs and symptoms, and prehospital considerations for patients who have collagen vascular diseases, such as systemic lupus erythematous and scleroderma.
12. Identify major complications associated with organ transplantation.
13. List infections associated with organ transplantation.
14. Outline characteristics of organ rejection.
15. Recognize side effects associated with antirejection medications.

KEY TERMS

acquired immunity Immunity that develops after exposure to specific antigens; also known as *adaptive immunity.*

allergens Substances that can produce hypersensitivity reactions in the body.

allergic reaction A hypersensitivity response to an allergen to which a person previously was exposed and to which the person has developed antibodies.

allografting The transplantation of cells, tissues, or organs between nonidentical (genetically unrelated) people.

anaphylactoid reaction An allergic reaction that is not mediated by an antigen-antibody reaction; it presents exactly like anaphylaxis but does not require previous exposure.

anaphylaxis An exaggerated, life-threatening hypersensitivity reaction to a previously encountered antigen.

angioedema A localized edematous reaction of the deep dermal or subcutaneous or submucosal tissues that appears as giant wheals.

antibodies Substances produced by the body that destroy or inactivate a specific substance (antigen) that has entered the body.

antigen-antibody reaction The binding of an antibody with an antigen of the type that stimulated the formation of the antibody; this makes the antigen more susceptible to ingestion and destruction by phagocytes or neutralization of an exotoxin.

antigens Substances (usually proteins) that cause the formation of an antibody and react specifically with that antibody.

autoimmune disease A condition that occurs when the immune system mistakenly attacks and destroys healthy body tissue.

B lymphocytes The lymphocytes responsible for antibody-mediated immunity.

basophils White blood cells that promote inflammation.

biphasic reaction An anaphylactic reaction that resolves and then recurs hours later without further exposure to the trigger.

cell-mediated immunity Immunity characterized by the formation of a population of lymphocytes that attack and destroy foreign material.

collagen vascular disease Abnormal immune system activity with inflammation in the connective tissues; it results in the accumulation of extra antibodies in the circulation.

degranulation A cellular process that releases antimicrobial substances from secretory vesicles (granules) found inside mast cells and basophils; it plays a role in allergic reactions.

eosinophils White blood cells that inhibit inflammation; they are thought to deactivate leukotrienes.

eosinophil chemotactic factor of anaphylaxis A group of active substances, including histamine and leukotrienes, that are released during an anaphylactic reaction.

erythema Redness of the skin, caused by hyperemia of the capillaries in the lower layers of the skin.
Fc receptors Proteins found on the surface of certain cells that contribute to the protective functions of the immune system. Fc receptors bind to antibodies that are attached to infected cells or invading pathogens.
histamine An amine released by mast cells and basophils that promotes inflammation.
humoral immunity One of the two forms of immunity that respond to antigens such as bacteria and foreign tissue.
IgA Immunoglobulin A; an antibody that plays a crucial role in mucosal immunity.
IgD Immunoglobulin D; an antibody present on the surface of most, but not all, B cells early in their development; IgD signals B cells to activate.
IgE Immunoglobulin E; an antibody that plays an important role in allergies; it is especially associated with type I anaphylactic reactions.
IgG Immunoglobulin G; the most abundant antibody; it is equally distributed in blood and tissue liquids.
IgM Immunoglobulin M; a basic antibody that produces B cells; the first antibody to appear in response to initial exposure to an antigen.
immune system A complex network of cells, tissues, and organs that work together to protect the body against "attacks" by foreign substances.
immunologic memory The body's ability to rapidly produce large numbers of specific immune cells after subsequent exposure to a previously encountered antigen.
immunology A broad branch of medical science that covers the study of the immune system.
immunosuppression Reduction in the activation or efficiency of the immune system; it often is caused with drugs or radiation to prevent the rejection of grafts or transplanted tissues or to control autoimmune disease.
isografting The transplantation of cells, tissues, or organs between identical twins.
leukotrienes A class of biologically active compounds that occur naturally in leukocytes and that produce allergic and inflammatory reactions.
lymphocyte A type of white blood cell formed in the lymphoid tissue.
macrophages Phagocytic cells in the immune system.
mast cells Specialized cells of the inflammatory response.
memory cells Cells that remember the same pathogen for faster antibody production with future exposures; they are produced by the division of B cells.
natural immunity Non-antigen-specific immunity that is present at birth; also known as *innate immunity* or *nonspecific immunity*.
organ transplant The replacement of a failing organ with a healthy one from a donor.
pathogen A disease-causing agent.
pathogenic microbes Microscopic pathogens that can cause infection, such as bacteria, parasites, fungi, and viruses.
phagocytosis The process of ingestion by cells of solid substances, such as other cells, bacteria, bits of necrosed tissue, and foreign particles.
pruritus A sensation that causes the desire or reflex to scratch.
Raynaud's phenomenon A condition in which cold temperatures or strong emotions cause blood vessel spasms that block blood flow to the fingers, toes, ears, and nose.
scleroderma A collagen vascular disease thought to arise when the immune system stimulates certain cells (fibroblasts) that cause increased production of collagen.
sensitization An acquired reaction in which specific antibodies develop in response to an antigen.
systemic lupus erythematosus (SLE) A chronic inflammatory disease that affects many systems of the body; it is characterized by severe vasculitis, renal involvement, and lesions of the skin and nervous system.
T lymphocytes The lymphocytes responsible for cell-mediated immunity.
thromboxanes Antagonistic prostaglandin derivatives that are synthesized and released by degranulating platelets, causing vasoconstriction and promoting the degranulation of other platelets.
urticaria A pruritic skin eruption characterized by transient wheals of various shapes and sizes that have well-defined margins and pale centers.
wheals Small areas of swelling of the skin that result from an allergic reaction.

__Immunology__ is a broad branch of medical science that covers the study of the immune system. A healthy immune system is the body's best defense against disease. However, sometimes the immune system goes awry, and the body begins to attack its own tissues and organs. People with immune system disorders are susceptible to a number of diseases, some of which can be life threatening. This chapter reviews the immune system and some of the more common immune disorders that may be encountered in the prehospital setting. These include allergic reaction and anaphylaxis, collagen vascular disease, and transplant disorders.[1]

SECTION ONE
Immune System and Allergic Reaction

OVERVIEW OF THE IMMUNE SYSTEM

As described in Chapter 11, the **immune system** is a complex network of cells, tissues, and organs. These cells, tissues, and organs work together to protect the body against "attacks" by foreign substances. Most of these substances are **pathogenic microbes,** or **pathogens.** Examples include bacteria, parasites, fungi, and viruses that can cause infection. The primary role of the immune system is to

(Courtesy Ray Kemp, St. Charles, Mo.)

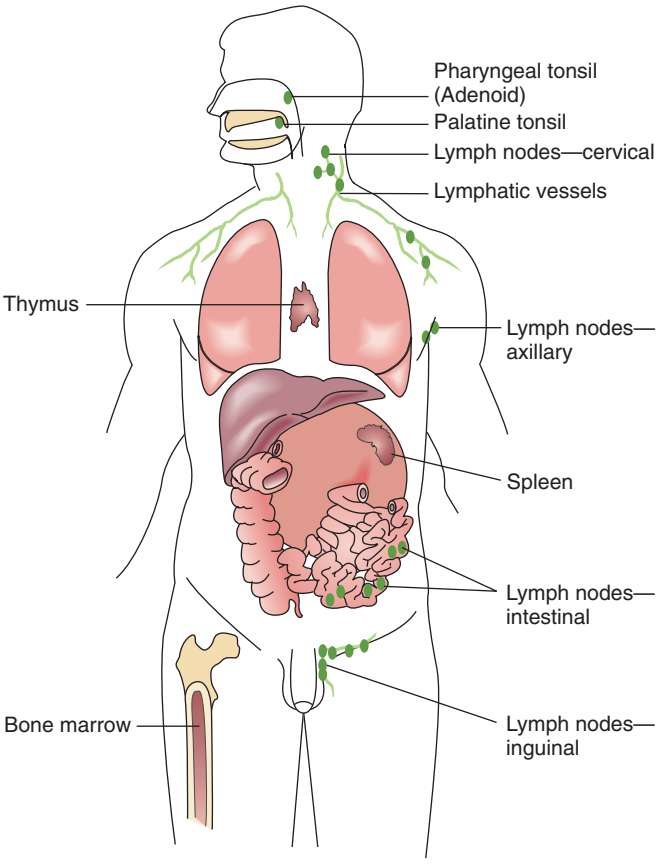

FIGURE 27-1 Structures of the immune system. (Gould BE: *Pathophysiology for the health professional*, ed 3, St Louis, 2006, Saunders.)

prevent these foreign substances from entering the body. If that fails, the immune system launches an attack so that these foreign bodies are found and destroyed.

LOOK AGAIN
See Chapter 11: Principles of Pathophysiology, pp. 242-248.

Immune System Structure

As described in Chapter 10, the organs of the immune system include the spleen, tonsils, adenoids, lymph nodes, and thymus (Figure 27-1). These organs are positioned throughout the body and are important outposts for lymphocytes, the key players in the immune system.

LYMPHOCYTES

The **lymphocyte** is the fundamental cellular unit of the immune system. About 25% of circulating white blood cells are lymphocytes. Lymphocytes are divided into two major classes: **B lymphocytes** *(B cells)* and **T lymphocytes** *(T cells)*. The roles of these two classes of lymphocytes are different and complementary.

B cells produce **antibodies.** Antibodies are proteins, not cells. In a sense, they are "magic bullets" that seek out specific invaders, or *antigens*. **Antigens** have *marker molecules* that identify them as foreign. When found, antibodies trigger a process that destroys them. The antibodies in blood and lymph make up the humoral immunity. **Humoral immunity** is the form of immunity that responds to antigens, such as bacteria and foreign tissue.

NOTE
The process by which leukocytes destroy and digest pathogens is called phagocytosis. Circulating macro phages are specialized white cells. They are responsible for clearing the area of dead cells and debris.

T cells also respond only to specific organisms. However, instead of producing antibodies, they perform other tasks. There are three varieties of T cells: (1) *killer T cells* attack the invading organism with chemicals; (2) *helper T cells* encourage B cells to produce antibodies; and (3) *suppressor T cells* help regulate the immune response to protect the body from its own defense. The work of T cells is called **cell-mediated immunity.** Cell-mediated immunity does not involve antibodies. Rather, this form of immunity activates lymphocytes that attack and destroy foreign material.

DID YOU KNOW?

Anatomy of an Antibody

As discussed in Chapter 11, there are five varieties of antibodies: immunoglobulin A (IgA), immunoglobulin D (IgD), immunoglobulin E (IgE), immunoglobulin G (IgG), and immunoglobulin M (IgM). IgA is found mainly in the body's mucous membranes, where it intercepts antigens in the nose and throat. IgE binds to certain antigens to cause allergic reactions. The exact function of IgD is largely unknown. It is thought to bind to basophils and mast cells, activating the cells to produce antimicrobial factors that participate in the respiratory immune defense.[2] The largest antibody is IgM**.** The most common antibody is IgG**.** Together, these two play the major role in attacking many bacteria and other antigens.

Each antibody consists of two chains of amino acids (the building blocks of protein). Each antibody has two long, thick amino chains that join to form a Y, and two smaller, thin chains along each branch of the Y (Figure 27-2). At the end of these four chains, the antibody binds with a specific antigen, similar to a lock and key. The *class* of immunoglobulin (e.g., IgG or IgM) enables the antibody to destroy antigens through an enzymatic chain reaction in the bloodstream.

Natural and Acquired Immunity

Once B cells and T cells have been activated by an antigen, some of these cells become **memory cells.** Many of the memory cells take up permanent residence in the lymph nodes, the gastrointestinal (GI) tract, and the spleen. Other memory cells travel through the lymphatic system and bloodstream. There they join with other lymphocytes and remain on guard for their chosen antigen. Memory cells ensure that the next time the body is exposed to the same antigen that produced the memory cell, the immune system is set into motion to destroy it. This memory is known as **immunologic memory.** The process by which this occurs is known as *immunity*. As described in Chapter 11, immunity can be either natural or acquired.

NATURAL IMMUNITY

Natural immunity is also known as *innate immunity* or *nonspecific immunity*. It is immunity that "naturally" exists. This type of immunity is not antigen-specific; it does not require previous exposure to an antigen. Natural immunity is present at birth because of antibodies the newborn receives from the mother. (The antibody IgG travels across the placenta and makes the newborn immune to the same microbes to which the mother is immune. Children who are nursed also receive IgA from breast milk to protect the infant's stomach.) Natural immunity also may have a heritable component. This type of immunity is quick to respond. It is the body's first line of defense against invading organisms.

Natural immunity can be *passive* or *active*. The natural immunity present at birth is passive. Passive immunity also can be conveyed through serum obtained from a person who is immune to a specific infectious agent *(artificially acquired passive immunity)*. For example, gamma globulin sometimes is given to travelers who visit countries where hepatitis is widespread. Passive immunity usually provides protection for only a few weeks. It also carries the risk of causing sensitivity reactions.

Active immunity can be triggered by infection and vaccination. For example, nondeliberate exposure to a person

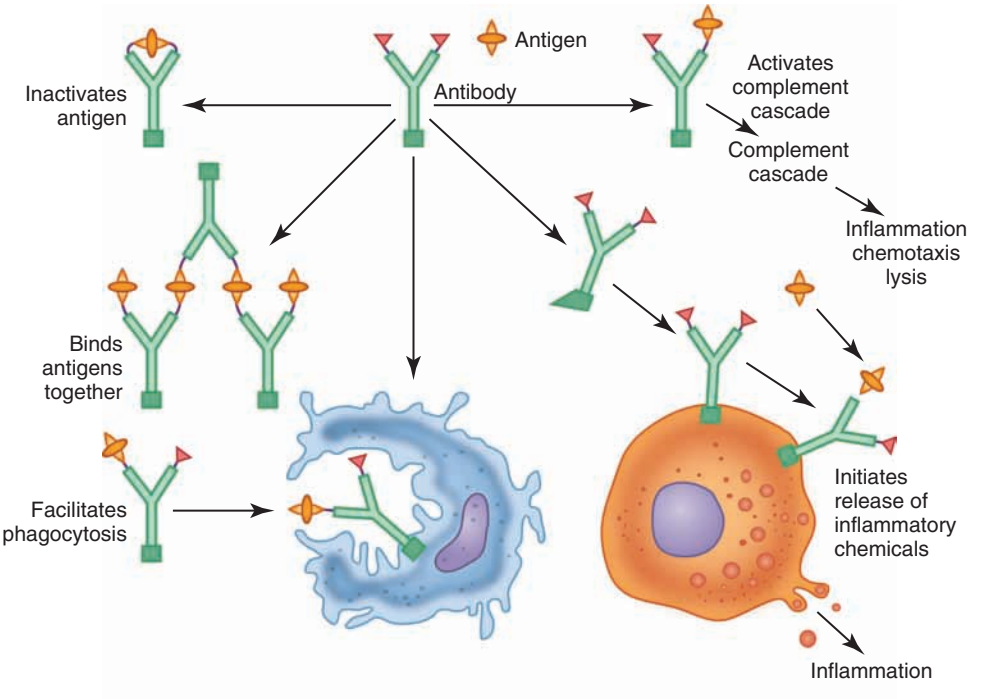

FIGURE 27-2 Antibodies act on antigens by inactivating and binding them together to facilitate phagocytosis and by initiating inflammation and activating the complement cascade.

with an illness can provide active immunity. The person exposed to the specific agent that caused the illness becomes immune to that specific disease. Vaccinations given with inactive (noninfectious) pathogens also provide active immunity. Like passive immunity, active immunity usually is short-lived.

NOTE
Natural immunity that is passive is achieved by the transfer of antibodies produced by one person *to another person.* Natural immunity that is active is the production of antibodies against a specific agent *by the immune system.* Natural immunity provides short-term protection for immediate threats. It does not change or prepare the immune system for future challenges.

ACQUIRED IMMUNITY

Acquired immunity is also known as *adaptive immunity*. It is immunity that develops after exposure to specific antigens. This type of immunity is "acquired" after the activation of B cells and T cells, which creates immunologic memory. Acquired immunity also may occur through immunization with a vaccine that contains a weak form of a specific antigen. Acquired immunity generally is a long-term immunity and often is considered permanent. It is slower to respond than natural immunity. However, immunologic memory significantly improves the rate of response to subsequent exposure to the same antigen. Acquired immunity acts as the body's second line of defense against invading organisms (Table 27-1). Like natural immunity, acquired immunity can be passive (acquired by the transfer of antibodies) or active (through immunization) (Figure 27-3).

NOTE
Acquired immunity is obtained deliberately. It changes and prepares the immune system to respond to future challenges.

IMMUNE RESPONSE

The first two lines of defense against infection (described previously) use the same mechanism to respond to all pathogens. However, the immune response is specific to individual pathogens (see Chapter 28). The immune system that makes up the immune response has four unique characteristics:

1. It has "self-nonself" recognition; therefore, it usually responds only to foreign antigens.
2. It produces antibodies that are antigen-specific. That is, new antibodies can be produced in response to new antigens.
3. The memory cells produced by some of the antibody-producing lymphocytes allow for a more rapid response to repeat invasions by the same antigen.
4. The immune system is self-regulated. It activates only when a pathogen invades. This ability prevents healthy tissues from being destroyed. When this function goes awry, allergic reactions and autoimmune disease can occur. The immune system also may require extrinsic regulation with drugs in patients with transplanted organs or severe autoimmune diseases.

CRITICAL THINKING
What major immune disorder causes life-threatening airway, breathing, and circulation problems?

ALLERGIC REACTIONS

Antigens can enter the body exogenously (from the outside) by injection, ingestion, inhalation, or absorption (see Chapter 34). As described previously, antigens stimulate the immune system to produce antibodies. Antibodies then help neutralize the antigens and remove them from the body. This normal **antigen-antibody reaction** protects the body from disease by activating the immune response.

The immune responses normally are protective. However, they can become oversensitive. They can become directed toward harmless antigens to which people often are exposed (e.g., ragweed and pollen). When this occurs, the response is termed *allergic.* Antigens or substances that cause an allergic response are called **allergens.** Common allergens include drugs, insects, foods, latex (Box 27-1), animals, pollens, and mold. The healthy body responds to an antigen challenge through immunity.

TABLE 27-1 Characteristics of Natural and Acquired Immunity

Natural Immunity	Acquired Immunity
Non–antigen-dependent	Antigen dependent
Immediate response	Requires time between exposure and response
Results in no immunologic memory	Results in immunologic memory

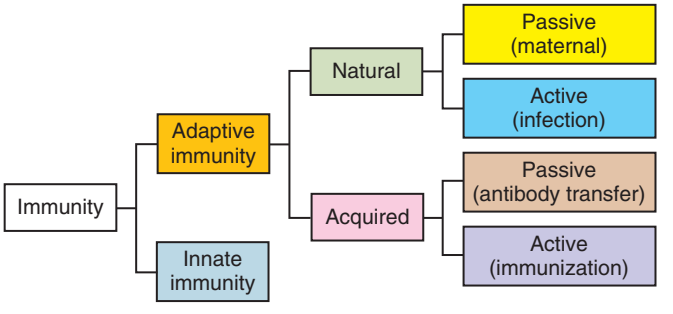

FIGURE 27-3 Passive or active immunity.

CRITICAL THINKING

Consider the list of antigens in Box 27-2. Based on this list, what are some likely locations to which you may be dispatched to care for a patient experiencing an anaphylactic reaction?

An **allergic reaction** (also known as a *hypersensitivity reaction*) is marked by an increased physiological response to an antigen after a previous exposure to the same antigen. This is known as **sensitization.** The allergic reaction starts when a circulating antibody combines with a specific foreign antigen, resulting in hypersensitivity reactions, or with antibodies bound to mast cells or basophils. To review, **mast cells** are cells found in several types of tissues. They contain granules that are rich in histamine and heparin. Mast cells are similar to **basophils,** a class of white blood cell that promotes inflammation through the release of chemical mediators (described later in the chapter). Mast cells and basophils and the release of these chemicals play an important role in allergic reactions (Figure 27-4).

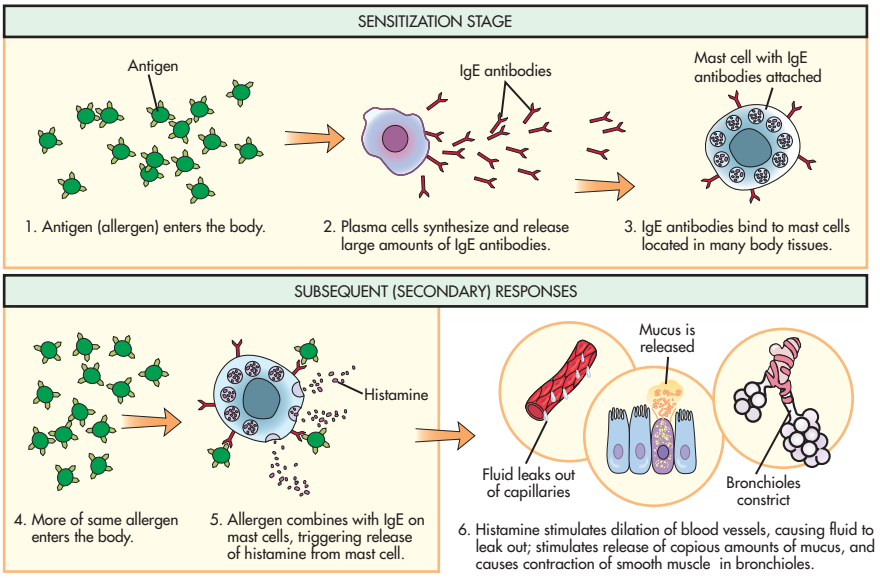

FIGURE 27-4 In an allergic reaction, antigen stimulates the production of massive amounts of immunoglobulin E, a type of antibody produced by plasma cells. IgE attaches to mast cells. This is the sensitization stage. When the antigen enters again, it binds to the IgE antibodies on the mast cells, triggering a massive release of histamine and other chemicals. Histamine in turn causes blood vessels to dilate and become leaky. This triggers the production of mucus in the respiratory tract. In some people the chemicals released by the mast cells also cause the small air-carrying ducts in the lungs to constrict, making breathing difficult.

BOX 27-1 Latex Allergies

Latex allergy is a significant concern, especially among health care workers. The first account of contact urticaria related to glove use was published in 1979. However, latex allergy was relatively unknown until after the acquired immunodeficiency syndrome (AIDS) epidemic in the mid-1980s and the resulting tremendous increase in glove use. The prevalence of sensitization to latex has been reported to range from 2.9% to 4.7% among health care workers and from 7% to 10% among operating room staff. (In addition to latex gloves, health care workers and latex-sensitive patients can be exposed to latex on medical instruments, surgical equipment, and other appliances.) Individuals considered at high risk for latex allergy include the following:

- Individuals who have had significant and early exposure to latex (e.g., patients with spina bifida or genitourinary anomalies and others who have had multiple surgeries and catheterizations)
- People with a genetic propensity to develop allergies
- Asthmatics
- Health care workers and law enforcement and fire service personnel who regularly use latex gloves
- Workers in some occupations (e.g., rubber manufacturing employees, hairdressers, food handlers, auto mechanics, tollbooth operators)

The symptoms of latex allergy can range from mild discomfort to life-threatening anaphylaxis. Most often the first manifestation of a latex allergy is urticaria, which typically is localized to the hands but may be widespread. A type I latex allergy can manifest in symptoms that include rash, lacrimation, rhinitis, wheezing, bronchospasm, laryngeal edema, hypotension, dysrhythmia and, in rare cases, respiratory or cardiac arrest.

Many health care facilities, EMS agencies, and other public service agencies have addressed this issue by developing "latex safe" environments and by using latex-free equipment for patients with latex allergy. For the health care provider, education, early recognition, prevention strategies, and implementation of safe and effective practices are essential. The National Institute for Occupational Safety and Health and many professional organizations have recommended that health care workers wear low-protein, powder-free gloves when latex gloves are necessary and synthetic gloves when the risk of exposure to blood-borne pathogens is low. Individuals not exposed to blood or body fluids (e.g., food handlers and maintenance workers) should avoid latex gloves altogether. All patients should be questioned about latex allergy; people with latex allergy should wear appropriate medical-alert identification. Sensitivity to latex should be documented on the patient care report, and this information should be conveyed to medical direction.

From Korniewicz D: Latex allergy: a current challenge. *Asepsis on the Web,* 1999. www.jnjmedical.com/asepsis/atex_allg.asp. Accessed September 22, 2004.

Allergic reactions can be mild, moderate, or severe, including anaphylaxis.[1] Mild and moderate reactions usually are localized, affecting the skin, upper and lower airways, and GI tract. They are not life threatening. Severe allergic reactions affect the same body systems but may be life threatening.

BOX 27-2 Agents That May Cause Allergies and Anaphylaxis

Drugs and Biological Agents
Antibiotics
Anticancer agents
Aspirin
Cephalosporins
Chemotherapeutics
Insulin
Local anesthetics
Muscle relaxants
Nonsteroidal antiinflammatory agents
Opiates
Vaccines

Insect Bites and Stings
Bees
Fire ants
Hornets
Wasps

Food
Cod, halibut, shellfish (e.g., shrimp)
Cottonseed
Egg white
Food additives
Mango
Milk
Peanuts, soybeans
Sesame and sunflower seeds
Strawberries
Tree-grown nuts

TYPES OF HYPERSENSITIVITY REACTIONS

As described in Chapter 11, hypersensitivity reactions are divided into four distinct types: *type I,* anaphylactic (IgE mediated) reactions; *type II,* cytotoxic (tissue specific) reactions; *type III,* immune complex–mediated reactions; and *type IV,* delayed (cell mediated) reactions (Table 27-2). A type I (anaphylactic) reaction is the most dramatic. It may lead to life-threatening anaphylaxis (described later). Box 27-2 presents examples of antigens that may cause hypersensitivity reactions. Patients who have a known sensitivity to these or other agents should avoid exposure.

LOOK AGAIN
See Chapter 11: Principles of Pathophysiology, pp. 246-247.

Localized Allergic Reaction

Contact with an allergen bridges adjacent antibodies. Each antibody binds with the invading organism at a different site. This changes the alignment of the antibodies on the surface of the mast cell. It causes the mast cell to burst and to release active chemical mediators into the surrounding fluid. Localized allergic reactions do not involve the entire body. In these cases, the sites of mast cell and basophil mediator release are limited. Common signs and symptoms of localized allergic reactions include the following:

- Conjunctivitis (inflammation of the conjunctiva of the eyes)
- Rhinitis (runny nose)
- Angioedema (swelling)
- Urticaria (hives)
- Pruritus (itching)

Localized allergic reactions are best managed with drugs that compete with histamine for receptor sites. This competition prevents histamine from performing its physiological actions (described later). Common antihistamines include over-the-counter oral and nasal decongestants and prescription and nonprescription ***diphenhydramine.*** Other

TABLE 27-2 Comparison of Hypersensitivity Types

Characteristics	Type I (Anaphylactic)	Type II (Cytotoxic)	Type III (Immune Complex)	Type IV (Delayed Type)
Antibody	IgE	IgG, IgM	IgG, IgM	None
Antigen	Exogenous	Cell surface	Viral (soluble)	Tissues and organs
Onset	Within minutes	Minutes to hours	3-8 hours	48-72 hours
Appearance	Wheal and flare	Lysis and necrosis	Erythema, edema, necrosis	Erythema and sclerosis
Cell type (histology)	Basophils and eosinophils	Antibody and complement	Complement and neutrophils	Monocytes and lymphocytes
Initiated by	Antibody	Antibody	Antibody	T cells
Examples	Urticaria, hay fever	Hemolytic anemia, glomerulonephritis	Lupus, serum sickness	Contact dermatitis, transplant rejection

medications that may be helpful for some local reactions include steroids and topical creams.

ANAPHYLAXIS

Anaphylaxis is an immediate, systemic, life-threatening allergic reaction. It is associated with major changes in the cardiovascular, respiratory, and cutaneous systems. Prompt recognition and appropriate drug therapy in the prehospital phase are vital to the patient's survival. *Anaphylaxis* comes from Greek terms. It means "against or opposite of protection." Anaphylaxis is the most extreme form of an allergic reaction, and it accounts for 500 to 1000 deaths a year in the United States.[3] It has a mortality rate of 3%. Rapid recognition and aggressive therapy are essential in treating this disorder.

Causative Agents

Almost any substance can cause anaphylaxis. The antigenic agents most frequently associated with anaphylaxis are penicillin (by ingestion or injection), venom from stinging insects, and food (especially nuts and shellfish). Regardless of the offending antigen, in sensitive individuals the risk of anaphylaxis increases with each exposure. To a lesser extent, the risk increases with the length of exposure or site of inoculation.

Pathophysiology of Anaphylaxis

As described previously, a person first must be exposed to a specific antigen to develop hypersensitivity. In the first exposure, the antigen enters the body by injection, ingestion, inhalation, or absorption. The antigen then activates the immune system. In susceptible individuals, large amounts of IgE antibody are produced. IgE antibodies leave the lymphatic system and bind to IgE-specific **Fc receptors** on the cell membranes of basophils that are circulating in the blood and to mast cells that are in tissues surrounding the blood vessels. The antibodies remain there and are inactive until the same antigen is introduced into the body a second time (Figure 27-5). With the next exposure to the specific antigen, the allergen cross-links at least two of the cell-bound IgE molecules. This results in **degranulation** (release of internal substances) of the mast cells and basophils and the onset of an anaphylaxis (Box 27-3).

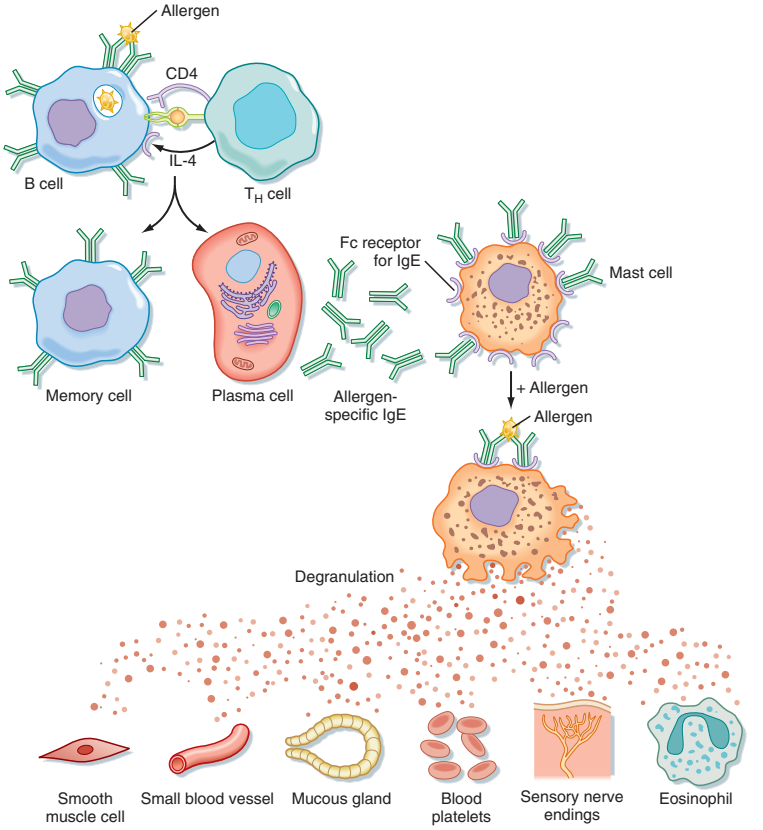

FIGURE 27-5 General mechanism underlying an allergic reaction. Exposure to an allergen activates B cells to form IgE-secreting plasma cells. The secreted IgE molecules bind to IgE-specific Fc receptors on mast cells and basophils. After a second exposure to the allergen, the bound IgE is cross-linked, which triggers the release of pharmacologically active mediators from mast cells and basophils. The mediators cause smooth muscle contraction, increased vascular permeability, and vasodilation. (Koeppen BM, Stanton BA: *Berne and Levy physiology,* ed 6, St Louis, 2010, Mosby.)

BOX 27-3 Anaphylaxis

Three conditions must be met for sensitization of an individual and generation of an anaphylactic response:

1. Antigen-induced stimulation of the immune system must occur, with specific IgE antibody formation.
2. A latent period must follow the initial antigenic exposure to allow sensitization of mast cells and basophils.
3. The person must subsequently be reexposed to the same specific antigen.

NOTE

Anaphylactoid reactions are allergic reactions that are not mediated by an antigen-antibody reaction. These reactions present exactly as does anaphylaxis, but they do not require previous exposure. For example, an anaphylactoid reaction can be caused by an IV medication that produces an excessive release of histamine in some patients. The distinction is not crucial with regard to treatment of an acute reaction; the two conditions are treated in the same way.[4]

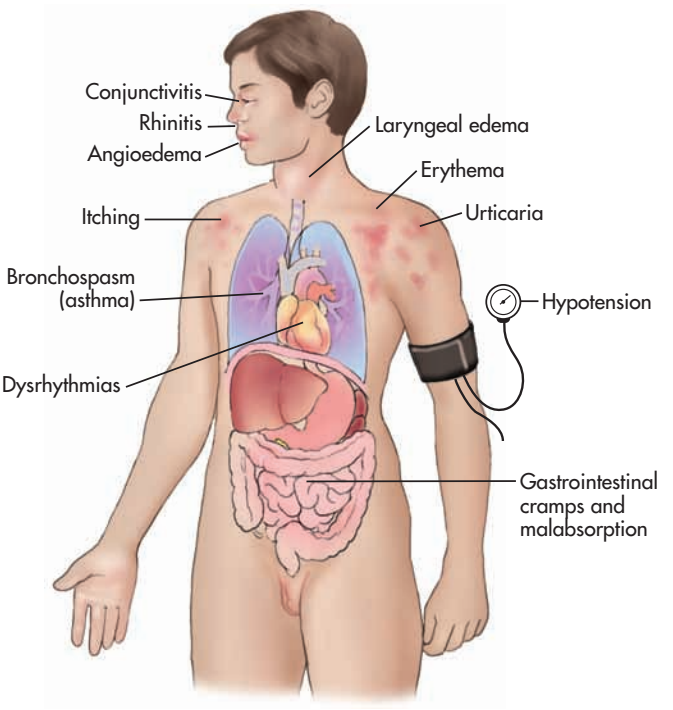

FIGURE 27-6 Manifestation of allergic reactions as a result of type I hypersensitivity includes itching, angioedema (swelling of the face, hands, feet, or genitals), edema of the larynx, urticaria (hives), bronchospasm, hypotension, dysrhythmias, and gastrointestinal cramping caused by inflammation of the gastrointestinal mucosa.

Degranulation of the target cell is associated with the release of pharmacologically active chemical mediators from inside the affected basophils and mast cells. These chemicals include histamine, leukotrienes**,** eosinophil chemotactic factor of anaphylaxis, neutrophils, heparin, kinins, prostaglandins, and **thromboxanes.** All of these chemicals mediate or trigger an internal systemic response.

Histamine is a protein released by mast cells and basophils. It promotes vascular permeability. It also causes dilation of capillaries and venules and contraction of smooth muscle in the GI tract and bronchial tree. An associated increase in gastric, nasal, and lacrimal secretions also occurs. This results in tearing and rhinorrhea. The increased capillary permeability allows plasma to leak into the interstitial space. This reduces the amount of intravascular volume available for the heart to pump. The profound bodywide vasodilation further reduces cardiac preload. This in turn decreases stroke volume and cardiac output. These responses lead to flushing, urticaria, angioedema, and hypotension (Figure 27-6). The onset of action of the histamine is rapid. However, the effects of histamine are short-lived, because they are quickly broken down by plasma enzymes. Figure 27-7 illustrates the pathophysiology of anaphylactic shock.

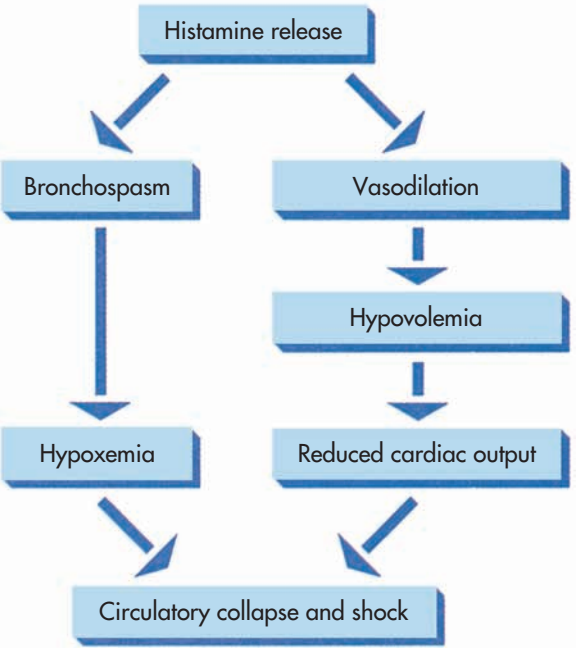

FIGURE 27-7 Pathophysiology of anaphylactic shock.

Leukotrienes are the most potent of the bronchoconstrictors, which cause wheezing. These chemical mediators also cause coronary vasoconstriction and increased vascular permeability. Leukotrienes formerly were known as *slow-reacting substances of anaphylaxis,* because their effects were delayed relative to histamine. However, the duration of action of these chemicals is much longer than that of histamine.

Eosinophil chemotactic factor of anaphylaxis is a group of active substances, including histamine and leukotrienes, that are released during an anaphylactic reaction.

The process of anaphylaxis attracts eosinophils to the site of allergic inflammation. **Eosinophils** are thought to contain an enzyme that can deactivate leukotrienes.

The remaining chemical mediators (heparin, neutrophils, thromboxanes, prostaglandins, and kinins) exert varying effects that may include fever, chills, bronchospasm, and pulmonary vasoconstriction. These complex chemical processes rapidly can lead to upper airway obstruction and bronchospasm, dysrhythmias, cardiac ischemia, circulatory collapse, and shock.

Assessment Findings

An accurate history and physical assessment are necessary to differentiate between severe allergic reactions and other conditions that may mimic anaphylaxis (Table 27-3). A flawed prehospital assessment in this group can have life-threatening consequences. Disease entities that may present similar signs and symptoms of anaphylaxis include the following:

- Severe asthma with respiratory failure
- Upper airway obstruction
- Toxic or septic shock
- Pulmonary edema (with or without myocardial infarction)
- Drug overdose
- Dystonic reaction to antipsychotics
- Scombroid poisoning
- Angiotensin-converting enzyme (ACE) inhibitor angioedema
- Hypovolemic shock

TABLE 27-3 Clinical Criteria for Diagnosing Anaphylaxis

Anaphylaxis is highly likely when any one of the following three criteria are fulfilled[5]:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized urticaria, pruritus or erythema, angioedema) *AND AT LEAST ONE OF THE FOLLOWING*
   a. Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, reduced peak expiratory flow [PEF], hypoxemia)
   b. Reduced blood pressure (BP) or associated symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure to *a likely allergen for that patient (minutes to several hours):*
   a. Involvement of the skin-mucosal tissue (e.g., generalized urticaria, pruritus, erythema, angioedema)
   b. Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)
   c. Reduced BP or associated symptoms (e.g., hypotonia [collapse], syncope, incontinence)
   d. Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced BP after exposure to *a known allergen for that patient (minutes to several hours):*
   a. Infants and children: Low systolic BP (age-specific) or greater than 30% decrease in systolic BP*
   b. Adults: Systolic BP of less than 90 mm Hg or greater than 30% decrease from that person's baseline

*Low systolic blood pressure for children is defined as less than 70 mm Hg from 1 month to 1 year; less than (70 mm Hg + [2 × Age]) from 1 to 10 years; and less than 90 mm Hg from 11 to 17 years.

RESPIRATORY EFFECTS

The initial signs of respiratory involvement associated with anaphylaxis may vary (Box 27-4). Signs may range from sneezing and coughing to complete airway obstruction

BOX 27-4 Signs and Symptoms of Anaphylaxis

Upper Airway
- Hoarseness or muffled voice
- Laryngeal or epiglottic edema
- Rhinorrhea
- Stridor

Lower Airway
- Accessory muscle use
- Bronchospasm
- Decreased breath sounds
- Increased mucus production
- Wheezing

Cardiovascular System
- Chest tightness
- Dysrhythmias
- Hypotension
- Tachycardia

Gastrointestinal System
- Abdominal cramps
- Diarrhea
- Nausea
- Vomiting

Neurological System
- Anxiety
- Coma
- Dizziness
- Headache
- Seizure
- Syncope
- Weakness

Cutaneous System
- Angioedema
- Edema
- Erythema
- Pallor
- Pruritus
- Tearing of the eyes
- Urticaria

(caused by laryngeal and epiglottic edema). The patient may complain of throat tightness and dyspnea. Stridor or voice changes also may be evident. Lower airway bronchospasm and associated hypersecretion of mucus caused by the actions of histamine, leukotrienes, and prostaglandins may produce wheezing and significant respiratory distress. Symptoms can develop with startling rapidity.

CARDIOVASCULAR EFFECTS

The cardiovascular manifestations of allergic reactions range from mild hypotension to vascular collapse and profound shock. Dysrhythmias (including severe bradycardia) are common. They may be related to the severe hypoxia and loss of circulating fluid volume that occurs. The patient may complain of chest pain if myocardial ischemia is present.

GASTROINTESTINAL EFFECTS

Nausea, vomiting, diarrhea, and severe abdominal cramping may occur in a patient having an anaphylactic reaction. The increased gastrointestinal activity is related to smooth muscle contraction, increased production of mucus, and outpouring of fluid from the gut wall into the intestinal lumen initiated by the chemical mediators.

NERVOUS SYSTEM EFFECTS

The nervous system responses are caused in large part by the impaired gas exchange and shock associated with anaphylaxis. At first the patient may be agitated and speak of a sense of impending doom. As hypoxia and shock worsen, brain functions deteriorate. This may result in confusion, weakness, headache, syncope, seizures, and coma.

CUTANEOUS EFFECTS

The most visible signs that distinguish anaphylaxis from other medical conditions relate to the skin. These signs are caused by the vasodilation induced by histamine release from the mast cells. Initially the patient may complain of warmth and **pruritus** (itching). Physical examination often reveals diffuse **erythema** (redness) and **urticaria** (hives). The hives are well-circumscribed wheals of 1 to 6 cm. Hives may be redder or more pallid than the surrounding skin. Often they are accompanied by severe pruritus (Figure 27-8). Significant swelling of the face, tongue, and deep tissues **(angioedema)** also may be present. This reflects involvement of deeper capillaries of the skin and mucous membranes. As hypoxia and shock continue, cyanosis may be evident.

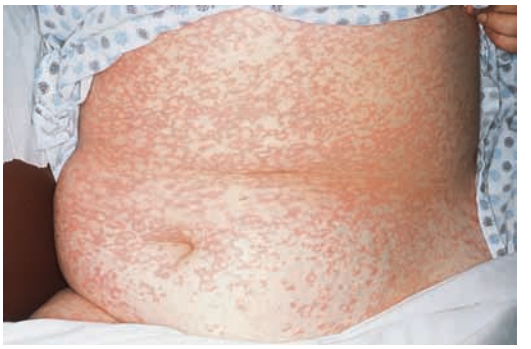

FIGURE 27-8 Urticaria as a result of an allergic reaction. (Courtesy Gary Quick, Oklahoma City, Okla.)

Primary Survey

As in any emergency, initial patient care is directed at providing adequate support for the airway, ventilation, and circulation. Drug therapy often is the definitive treatment in anaphylaxis. Therefore, drug therapy (described later) should be initiated as quickly as possible.

Airway assessment is critical, because most deaths from anaphylaxis are related directly to upper airway obstruction. A conscious patient should be evaluated for voice changes, stridor, or a barking cough. Complaints of tightness in the neck and dyspnea should alert the paramedic to impending airway obstruction. While drug therapy is underway, the airway of an unconscious patient should be assessed and secured. If air movement is blocked, an advanced airway should be placed. If laryngeal and epiglottic edema is severe, surgical or needle cricothyrotomy may be indicated to provide airway access (see Chapter 15). Early, elective intubation is indicated for patients with hoarseness, lingual edema, and posterior or oropharyngeal swelling. If respiratory function deteriorates, medical direction may recommend tracheal intubation (with sedation) without paralytic agents.[4]

The paramedic should monitor the patient closely for signs of respiratory distress, as indicated by pulse oximetry, capnography, skin color, accessory muscle use, wheezing, diminished breath sounds, and abnormal respiratory rates. Circulatory status also may deteriorate quickly. Therefore, the pulse quality, rate, and location should be assessed frequently.

History

A history may be difficult to obtain. However, ruling out other medical emergencies that may mimic anaphylaxis can be critical. The patient should be questioned about the chief complaint and the rapidity of the onset of symptoms. The signs and symptoms of anaphylaxis usually appear within 1 to 30 minutes of introduction of the antigen.[2] The onset of a reaction can be delayed if the exposure is by the oral route.

Important medical history includes previous exposure and response to the suspected antigen. In addition, the

NOTE

Angioedema is a localized swelling of the deep dermis or subcutaneous or submucosal tissues. It appears in the form of giant **wheals** (swelling under the skin). Patients with angioedema are at high risk for rapid deterioration.

paramedic should identify the method of exposure to the antigen. Injection of an antigen often produces the most rapid and severe response. Other significant history includes chronic or concurrent illness and medication use. Preexisting cardiac disease or bronchial asthma should alert the paramedic to anticipate severe complications as a result of the allergic reaction. Certain drugs, such as beta-blocking agents, may diminish the patient's response to ***epinephrine*** and may necessitate the administration of other medications. The paramedic also should determine whether the patient has an emergency ***epinephrine*** drug kit (e.g., EpiPen [Box 27-5]) and whether the medication was administered before the paramedic crew arrived. Some patients with a history of allergic reaction may have taken an oral antihistamine (e.g., ***diphenhydramine***), or they may have used aerosolized ***epinephrine*** (e.g., Primatene Mist or Medihaler Epi). The paramedic should try to determine whether the patient has taken these drugs, if possible. However, appropriate intervention should not be delayed.

SHOW ME THE EVIDENCE

Safdar and colleagues reviewed the literature to evaluate the use of subcutaneous epinephrine in patients with either asthma or anaphylaxis. They sought to determine its effects on older adults who did not have known cardiovascular disease. The researchers found three cases that reported adverse effects related to epinephrine administration. They noted that none of the literature included controlled studies. They concluded that insufficient evidence was available to prohibit the use of epinephrine to treat asthma or anaphylaxis in older adults with no known cardiovascular disease.

Safdar BD, Cone DC, Pham KT: Subcutaneous epinephrine in the prehospital setting, *Prehosp Emerg Care* 5:200-207, 2001.

Physical Examination

Vital signs should be assessed often. In severe reactions, most patients initially are tachycardiac, tachypneic, and hypotensive if deterioration to cardiac arrest has not occurred. The paramedic should inspect the patient's face and neck for angioedema, urticaria, tearing, and rhinorrhea and should note the presence of erythema or urticaria in other body regions. Along with vital signs, the paramedic should assess airway and lung sounds often to evaluate the patient's clinical progress. Such assessment also helps the paramedic monitor the effectiveness of interventions. Cardiac monitoring should be instituted as soon as possible to aid evaluation of the patient.

Key Interventions to Prevent Arrest

Organ involvement in anaphylaxis varies. This makes a standardized approach to patient management difficult. The following key interventions commonly are used to manage anaphylaxis.[3,4]

BOX 27-5 EpiPen

EpiPen is an autoinjector prescribed for people with a history of severe allergic reactions or anaphylaxis. Each EpiPen contains a single dose of 0.3 mg of epinephrine. This dose is appropriate for people who weigh 66 pounds (29.7 kg) or more. EpiPen Junior contains 0.15 mg of epinephrine. This dose is appropriate for children who weigh 33 to 66 pounds (14.9 to 29.7 kg). The drug is administered by pushing the autoinjector into the anterior-lateral thigh and holding it in place for 10 seconds. (The EpiPen self-injects through clothing.) The EpiPen is packaged in single and 2-Pak cartons (in case a second dose of the drug is needed to manage an allergic reaction).

1. Place the patient in a position of comfort. Elevate the legs until replacement fluids improve the blood pressure.
2. Administer high-concentration oxygen. Early recognition of the potential for a difficult airway in anaphylaxis is paramount in patients who develop hoarseness, lingual edema, stridor, or oropharyngeal swelling. Planning for advanced airway management, including a surgical airway, is recommended.
3. Give ***epinephrine*** to all patients with clinical signs of shock, airway swelling, or difficulty breathing. ***Epinephrine*** may be given by the IM route (see the Emergency Drug Index). ***IV epinephrine*** should be considered immediately if life-threatening signs and symptoms are present.
4. Initiate IV therapy with normal saline solution if hypotension is present and does not respond rapidly to ***epinephrine.*** Repeated 1000 mL IV boluses (up to 4 L) to maintain a systolic pressure above 90 mmHg rapid infusion of 1 to 2 L (up to 4 L) may be needed initially.
5. Position the patient recumbent and elevate the legs unless precluded by vomiting or shortness of breath. Transport the patient for evaluation by a physician. Most patients are observed carefully in the hospital for up to 24 hours. Many patients do not respond promptly to therapy, and symptoms may recur in some patients **(biphasic reaction)** (Box 27-6).

NOTE

Complications of IV administration of ***epinephrine*** are significant and include the development of uncontrolled systolic hypertension, vomiting, seizures, dysrhythmias, and myocardial ischemia. This route should be used only in patients with a critical life-threatening condition. Intravenous administration of ***epinephrine*** rarely is performed in conscious patients. Intravenous administration is performed with extreme caution in rare circumstances and only with authorization from medical direction. *Epinephrine 1:1000 should never be given as an IV bolus*. The paramedic should follow the specific administration guidelines in the Emergency Drug Index.

BOX 27-6 Biphasic Reactions

As many as 25% of those who have an anaphylactic reaction experience a recurrence in the hours after the beginning of the reaction and will require further medical treatment.[6] This delayed reaction is called *biphasic,* meaning in two phases. The second phase usually occurs after an asymptomatic period of 1 to 8 hours, but a delay of up to 24 hours is possible. Epinephrine again is the treatment of choice, and the drug should be administered immediately. Post-treatment observation of these patients is necessary, and they should remain within ready access of emergency care for the next 48 hours.[7]

CRITICAL THINKING

How does ***epinephrine*** reverse the signs and symptoms of anaphylaxis?

OTHER DRUG THERAPY

Additional drug therapy may be helpful. However, ***epinephrine*** is the only drug that can reverse the life-threatening complications of anaphylaxis immediately. It is the drug of choice, because its beta stimulation produces bronchodilation; its alpha stimulation produces vasoconstriction; and it reduces the release of chemical mediators from mast cells. Pharmacological agents that may be used with ***epinephrine*** include antihistamine to antagonize the effects of histamine, beta agonists to improve alveolar ventilation, corticosteroids to prevent a delayed reaction, ***glucagon*** (for patients unresponsive to ***epinephrine,*** especially those taking antidysrhythmics [beta blockers]), and perhaps vasopressors to manage protracted hypotension (H2 antagonists such as cimetidine or ranitidine may be given in cases of hypotension that are unresponsive to ***epinephrine***). Other drugs that may be useful in managing anaphylaxis include ***albuterol*** for bronchodilation, ***diphenhydramine*** to counter the effects of histamine, and ***methylprednisolone*** to reduce inflammation (Box 27-7). (See the EDI.)

NOTE

Beta blockers may increase the incidence and severity of anaphylaxis and can produce a paradoxical response to ***epinephrine.***[4] For patients taking beta blockers, ***glucagon*** may be effective.

Key Interventions During Arrest

Cardiac arrest from anaphylaxis may be associated with profound vasodilation, intravascular collapse, tissue hypoxia, and asystole. Special considerations for resuscitation of these patients are described next.[3,4]

AIRWAY, OXYGENATION, AND VENTILATION

Swelling of the airway can make bag-mask ventilation and endotracheal intubation difficult or ineffective in patients with anaphylaxis. In addition, the landmarks for needle cricothyrotomy may not be visible because of severe swelling in the soft tissues of the neck. Fiberoptic intubation and digital intubation are alternative methods to consider in these situations (see Chapter 15). Smaller than normal endotracheal tubes may be needed because of associated edema.

BOX 27-7 Additional Drug Therapy for Anaphylaxis

Antihistamines
- Diphenhydramine
- Hydroxyzine
- Promethazine
- Cimetidine
- Ranitidine
- Famotidine

Corticosteroids
- Methylprednisolone
- Hydrocortisone
- Dexamethasone

Beta Agonists
- Albuterol
- Levalbuterol

Anticholinergic Bronchodilator
- Ipratropium

Antiarrhythmics
- Amiodarone
- Lidocaine and others

Vasopressors
- Dopamine
- Norepinephrine
- Vasopressin

Glucagon

SUPPORT OF CIRCULATION

Cardiac arrest from anaphylaxis requires rapid, aggressive volume replacement (2 to 4 L) to support circulation and the use of vasopressor drugs to support blood pressure. ***Epinephrine*** (including immediate use of EpiPen, if available) is the drug of choice for the treatment of vasodilation and hypotension in cardiac arrest (see the EDI). Alternative vasoactive drugs (***vasopressin***, ***norepinephrine***, methoxamine, and metaraminol) may be considered in cardiac arrest secondary to anaphylaxis that does not respond to epinephrine.[3]

Asystole or pulseless electrical activity with a heart rate less than 60 beats/minute are the most common arrest rhythms in anaphylaxis (see Chapter 22). Cardiac arrest from anaphylaxis may respond to prolonged periods of cardiopulmonary resuscitation. This may be the case especially when the patient is young and has a healthy heart and cardiovascular system.

SECTION TWO
Collagen Vascular Disease

Collagen vascular disease is also known as *connective tissue disease*. Collagen is the principal structural protein of most body tissues. Many connective tissue diseases feature abnormal immune system activity with inflammation in the tissues. This is a result of an immune system that is directed against one's own body tissues **(autoimmune disease).** Collagen vascular disease may have both genetic and environmental causes. The immune system disorder results in the accumulation of extra antibodies in the circulation. Two "classic" collagen vascular diseases described in this chapter are systemic lupus and scleroderma,[1] (Other autoimmune diseases, such as rheumatoid arthritis, are discussed in Chapter 33.) Some patients have a combination of these diseases; this is known as *mixed connective tissue disease*.[9]

NOTE
Physician care for patients with collagen vascular disease often is multidisciplinary because of the nature of the disease and the affected organs and body systems. Specialists involved in this care may include rheumatologists, clinical immunologists, dermatologists, neurologists, nephrologists, cardiologists, psychologists, social workers, and others. Prehospital care is primarily supportive. When possible, these patients should be transported to their primary hospital for their specialized care.

SYSTEMIC LUPUS

Systemic lupus is a term that refers to one of many disorders of the immune system. **Systemic lupus erythematosus (SLE)** is the form of the disease most people refer to as "lupus." SLE usually first affects people between 15 and 45 years of age. However, it also can occur in childhood or later in life.

NOTE
Lupus primarily is a disease of young women, beginning mainly between the ages of 15 and 40 years. Women are six to 10 times more likely to have lupus than are men. Lupus can run in families, but the risk that a child or a brother or sister of a patient will also have lupus is still quite low. Lupus occurs in both siblings in approximately 25% to 50% of identical twins and 5% of fraternal twins.[10]

As in all autoimmune diseases, the immune system produces antibodies against the body's healthy cells and tissues. With lupus, these antibodies, called *autoantibodies,* contribute to the inflammation of various parts of the body and can damage organs and tissues. The most common type of autoantibody that develops in people with lupus is called an *antinuclear antibody* (ANA). It is so named because it reacts with parts of the cell's nucleus. Lupus can affect many parts of the body, including the joints, skin, kidneys, heart, lungs, blood vessels, and brain. These patients frequently develop inflammatory heart disease (pericarditis). They also may experience early-onset arthrosclerosis as a complication of the disease.

People with SLE can have many different symptoms (Box 27-8).[11] Some of the most common symptoms are extreme fatigue, painful or swollen joints (arthritis), unexplained fever, skin rashes, and kidney problems. A common finding in a patient with SLE is a characteristic reddish skin rash, called the *butterfly* or *malar rash*. This rash may appear across the nose and cheeks (Figure 27-9). Systemic effects of lupus may include the following[12]:

- GI ulceration or hemorrhage, abdominal pain, pancreatitis, cholecystitis, bowel infarction
- Renal failure

BOX 27-8 Signs and Symptoms of Lupus

- Painful or swollen joints and muscle pain
- Unexplained fever
- Red rash, most commonly on the face
- Chest pain on deep breathing
- Unusual loss of hair
- Pale or purple fingers or toes from cold or stress (Raynaud's phenomenon)
- Sensitivity to the sun
- Swelling (edema) in legs or around eyes
- Mouth ulcers
- Swollen glands
- Extreme fatigue

FIGURE 27-9 Systemic lupus erythematosus (SLE) flare. The classic butterfly rash occurs in 10% to 50% of patients with acute cutaneous lupus erythematosus. The rash appears over the nose and cheeks. (Christensen BL, Kockrow EO: *Adult health nursing*, ed 6, St Louis, 2010, Mosby.)

- Anemia and clotting abnormalities
- Pericarditis
- Pleurisy or pleural effusions
- Skin rash
- Behavioral changes, seizures, headaches, stroke

Management

The symptoms of SLE may be mild or serious. The goal of treatment is to prevent flareups, organ damage, and complications. Physician care may include nonsteroidal antiinflammatory drugs and corticosteroids to decrease inflammation, and antimalarials to treat fatigue, joint pain, skin rashes, and lung inflammation. Other therapies may include hormones, dietary modification, and nutritional supplements. Currently no cure is available for the disease.

SCLERODERMA

Scleroderma is derived from the Greek words *sklerosis*, meaning hardness, and *derma,* meaning skin. Scleroderma literally means hard skin. The disease is thought to result when the immune system stimulates certain cells (fibroblasts) that cause increased production of collagen. The excess collagen collects in the skin and internal organs, interfering with their function. Blood vessels and joints also can be affected. The disease is more common in women than in men. Because scleroderma can be difficult to diagnose, only rough estimates of its prevalence are available. The number of people in the United States with systemic sclerosis is estimated at 40,000 to 165,000.[13]

Scleroderma can be either localized or systemic, and both groups have subgroups. The localized forms of the disease are limited to the skin and related tissues and may involve underlying muscle. Internal organs are not affected. Localized scleroderma does not progress to systemic forms. Localized conditions often subside, but skin changes and damage from the event can be permanent (Figure 27-10). Two types of the localized condition are recognized: morphea and linear scleroderma.[14]

FIGURE 27-10 Scleroderma (acrosclerosis). Note the inflammation and shiny skin. (McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children,* ed 6, St Louis, 2009, Mosby.)

- *Morphea* is marked by local patches of hardened skin. Red patches of skin develop white centers with purplish borders. Lesions remain active for weeks to several years. Spontaneous softening that leaves a darkened area of skin often occurs. In localized morphea, one or a few patches are seen. In generalized morphea, the patches may grow over large areas of the body. Morphea can occur at any site. Occasionally the lesions can be extensive and gradually evolve into generalized morphea, in which the patches extend over most or all of the body surface.
- *Linear scleroderma* is characterized by a single line or band of thickened, discolored skin. The line usually runs down an arm or leg but sometimes runs down the forehead. When the band runs down the forehead, it may be called *en coup de sabre* ("sword stroke" in French).

Systemic scleroderma *(systemic sclerosis)* affects the skin, blood vessels, and major organs. Two types of systemic disease are recognized: limited and diffuse.

- ***Limited systemic sclerosis.*** In this form of scleroderma, skin thickening generally is limited to the fingers, forearms, legs, face, and neck. *Raynaud's phenomenon* may be present for years before any other symptoms develop. People with this form are less likely to develop severe organ involvement than are people with diffuse disease.
- ***Diffuse systemic sclerosis.*** In this form of scleroderma, skin thickening may occur anywhere on the body, including the trunk. Only a short period elapses between the onset of Raynaud's phenomenon and significant organ involvement. Damage typically occurs over the first 3 to 5 years, after which most patients enter a stable phase that varies in length. Organ involvement may lead to diseases and dysfunction of the esophagus, GI tract, kidneys, heart, and lungs.

NOTE

In a person with Raynaud's phenomenon, cold temperatures or emotional distress can cause the arteries feeding the hands or feet (or both) to constrict. This constriction causes the hands and feet to feel cold, turn white, and then turn blue. Once the vessels reopen (usually within 10 to 15 minutes), the hands turn red or mottled. More than 90% of individuals with scleroderma have Raynaud's phenomenon. It often is the first symptom of the disease. It also is found in patients with SLE.

CRITICAL THINKING

How might Raynaud's phenomenon affect your assessment of a patient who is hypoxic?

Management

No treatment for the complicated process that causes scleroderma has proved effective.[14] Therapies are aimed at preventing or reducing organ damage to prolong life.

Treatment decisions are made on a symptom-by-symptom and an organ-by-organ basis.

Patients with systemic scleroderma can suffer serious organ failure as a result of their disease. Thickening of vessels can lead to significant hypertension and pulmonary, cardiovascular, and renal failure. As a result, these patients can present with hypertensive crisis, renal failure, and heart failure. Drug therapy that may be needed to manage these disorders includes nitrates and calcium channel blockers to lower blood pressure, and angiotensin-converting enzyme (ACE) inhibitors to reverse renal crisis. Prehospital care may include both basic and advanced life support.

SECTION THREE
Transplant Complications

Every 10 minutes, a new name is added to the National Transplant Waiting List.[15] Many of these people are waiting for a solid organ transplant. These organs include the kidneys, liver, pancreas, heart, and lungs. In 2010, 28,663 Americans received an organ transplant.[16] Therefore, the likelihood of EMS personnel caring for a patient who has had an organ transplant is great. Common complications in patients who have received an organ transplant are related to **immunosuppression.** These include infection, rejection, and drug toxicity.[1]

NOTE

Two major complications associated with solid organ transplantation are infection and malignancy. These are the result of the lifelong immunosuppressive therapy that must be endured by transplant recipients to maintain function. The organisms most commonly associated with post-transplantation infection are the result of reactivation of latent infection carried by the donor organ or the recipient. They also may be due to new exposures in the community or in the hospital.[17]

INFECTION

Infection is the most common life-threatening complication of long-term immunosuppressive therapy in patients who have received an **organ transplant.**[18] Infection after transplantation of a solid organ can have many causes (Table 27-4), including:

- Community-acquired bacterial and viral diseases
- Opportunistic infections
- Infections due to *P. carinii* (also called *P. jirovecii*), *Nocardia asteroides*, *Aspergillus spp.*, *Cryptococcus neoformans*, CMV, VZV, influenza, respiratory syncytial virus (RSV), *Rhodococcus equi,* and *Legionella spp.*

After a patient has been infected, the inflammatory responses associated with the invasion of microbes are impaired by immunosuppressive therapy. As a result, the signs and symptoms of infection that normally would be

TABLE 27-4 Possible Causes of Infection After Organ Transplantation

- *Month 1 (early post-transplantation):* The immune system usually is most suppressed in the first month after transplantation. Most infections during this time period are due to surgical or hospital-acquired infections. These may include infections caused by bacteria or *Candida* organisms. Infections may present as a urinary tract infection, wound infection, pneumonia, or a bloodstream infection. Herpes simplex virus (HSV) may reactivate (e.g., as cold sores). Many transplant recipients are prescribed medications to prevent the reactivation of HSV.
- *Months 2 to 6:* During this period, transplant recipients are at risk for unusual or opportunistic infections, such as *Pneumocystis carinii* pneumonia (PCP) or tuberculosis. During this phase, the transplant recipient also is at highest risk for reactivation of certain viruses, including cytomegalovirus, varicella zoster virus, Epstein-Barr virus, and the hepatitis viruses (see Chapter 28).
  - Cytomegalovirus (CMV): CMV infection occurs in 44% to 85% of patients who have received a kidney, heart, or liver transplant. Symptomatic CMV disease occurs in 8% to 29% of kidney and liver transplant recipients. CMV disease can occur if a transplant recipient without a history of CMV receives an organ transplant from a donor with a history of CMV (primary infection). CMV disease also can reactivate after transplantation in a recipient who has a history of a previous CMV infection. CMV disease can present in a variety of ways, such as a flulike illness with fever, muscle aches, and fatigue, or as hepatitis. CMV is both preventable and treatable with antiviral medications such as ganciclovir, valganciclovir, and foscarnet.
  - Varicella zoster virus (VZV): VZV is the virus that causes chickenpox. Ninety percent of adult transplant recipients were exposed to VZV during childhood, and they are at risk for reactivation of VZV in a form called *shingles.* Shingles is a painful, blister-like rash.
  - Epstein-Barr virus (EBV): EBV is the virus that causes mononucleosis, or "mono." Transplant recipients who are not immune to EBV may get mononucleosis. Symptoms include fever, fatigue, muscle aches, and pains. EBV also may reactivate and cause post-transplantation lymphoproliferative disease (PTLD) in 1% to 2% of kidney and liver transplants, respectively. Symptoms are varied and can include fever, sore throat, abdominal pain, jaundice, or kidney and liver dysfunction. Treatment depends on the level of disease.
  - Hepatitis B and hepatitis C viruses (HBV and HCV): Viral hepatitis can recur in transplant recipients who receive their transplants because of chronic hepatitis. Hepatitis B recurs in 5% to 10% of patients; hepatitis C recurs in 80% to 90% of recipients.
- *After 6 months (late post-transplantation):* Most transplant recipients do well 6 months after transplantation. They are at risk for community-acquired infections, such as urinary tract infections, influenza, and pneumococcal (bacterial) pneumonia.[19]

evident are masked. Consequently, infections often are advanced or have spread by the time of the patient complaint or clinical presentation. Established infection is difficult to treat in immunocompromised transplant recipients.[20] Significant antimicrobial toxicities are common, often as a result of diminished renal or hepatic function and drug interactions (described later).

NOTE
Paramedics should observe strict aseptic technique when caring for transplant recipients to avoid introducing infection. Vascular access should be avoided unless the need is clear.

CRITICAL THINKING
Which signs and symptoms of infection may be masked by immunosuppressive treatment?

DID YOU KNOW?
Post-Transplantation Infection
Infections in transplant recipients usually are categorized according to three phases that follow transplantation (early post-transplantation [month 1], months 2 to 6, and late post-transplantation [after 6 months]). Certain infections are more likely to occur during a specific phase.

REJECTION

Tissues or cells from another person (except an identical twin) carry nonself markers and may be recognized by the body as foreign. This is the reason some tissue transplants *(grafts)* are rejected. Most solid organ transplants are donated by nonidentical (genetically unrelated) people. This is known as **allografting.** If the transplanted tissue is donated by an identical twin, it is termed is **isografting.** Because allografts are more common than isografts, organ rejection is a major complication of solid organ transplant recipients. Rejection can be classified as *hyperacute, acute,* or *chronic* (Box 27-9).

NOTE
Rejection rates for transplant recipients have improved with advances in antirejection drugs. In the 1960s, 70% to 80% of patients experienced at least one rejection episode, and the 1-year survival rate for transplanted organs was about 65%. Newer drugs have reduced the rejection rate to 10% to 15%, and the 1-year survival rate for transplanted organs now is about 95%.[21]

Signs and symptoms of transplant rejection vary, depending on the transplanted organ and the recipient's general health. General signs and symptoms include the following:

- Pain at the site of the transplant
- General malaise
- Irritability (in children)
- Flulike symptoms
- Fever
- Weight changes
- Swelling and edema
- Change in the heart rate or blood pressure

BOX 27-9 Classes of Rejection

Hyperacute rejection is a complement-mediated response in recipients with preexisting antibodies to the donor (e.g., ABO blood type antibodies). Hyperacute rejection occurs within minutes. The transplant must be removed immediately to prevent a severe systemic inflammatory response.

Acute rejection usually begins 1 week after transplantation. The risk of acute rejection is highest in the first 3 months after transplantation. Acute rejection occurs to some degree in all transplant recipients (except those between identical twins). This type of rejection can be successfully managed if recognized quickly.

Chronic rejection refers to cases of transplant rejection in which the rejection is due to a poorly understood chronic inflammatory and immune response against the transplanted tissue.

DRUG TOXICITY

Many drugs are necessary to manage a patient who has received a solid organ transplant. Most of the medications are required for life to ensure the patient's survival and the success of the graft. The primary goals of drug therapy are to prevent organ rejection and infection. A major complication of the drug therapy is drug toxicity and adverse effects (see Chapter 13).

TYPES OF DRUGS USED IN TRANSPLANT RECIPIENTS

Oral immunosuppressant drugs commonly used in the United States include interleukin-2 (IL-2), receptor antagonist such as daclizumab (Zenapax) and basiliximab (Simulect), and OKT3 (monoclonal antibody). Other drugs include tacrolimus (Prograf), mycophenolate mofetil (CellCept), sirolimus (Rapamune), prednisone, cyclosporine (Neoral, Sandimmune, Gengraf), and azathioprine (Imuran). Medications to help prevent infections include antivirals such as acyclovir (Zovirax) or valganciclovir (Valcyte) to fight viruses, and antifungals such as fluconazole (Diflucan), nystatin (Mycostatin, Nilstat), or itraconazole (Sporanox) to fight fungal infections. Antibiotics such as sulfamethoxazole/trimethoprim (Bactrim, Septra) are used to treat bacterial infections. Three drugs commonly associated with drug toxicity and adverse drug interactions in transplant recipients are cyclosporine, azathioprine, and corticosteroids (Table 27-5).[1]

NOTE

Other medications and some foods may interact with post-transplantation medications. Complications can arise from the following:

- Some prescription medicines, such as erythromycin, clarithromycin (Biaxin), ***diltiazem*** (Cardizem, Tiazac), and ***verapamil*** (Calan, Verelan)
- Over-the-counter products, such as cimetidine (Tagamet) or herbal products or natural remedies, including St. John's wort, echinacea, black cohosh, and others.
- Eating grapefruit or drinking grapefruit juice, which can alter drug metabolism

MANAGEMENT OF PATIENTS WITH TRANSPLANT DISORDERS

Prehospital care for a patient who has received a solid organ transplant may vary from providing only comfort measures to supporting vital functions. These patients often have a long and complex medical history. Most require rapid transport for evaluation by a physician and specialty care.

TABLE 27-5 Drugs That Can Cause Toxicity in Transplant Recipients[22]

Drug	Adverse Effects
Cyclosporine	Hyperkalemia, hypomagnesemia, nausea, vomiting, diarrhea, hypertrichosis, hirsutism, gingival hyperplasia, hyperlipidemia, glucose intolerance, infection, malignancy, hyperuricemia. Multiple drug interactions are possible, primarily with agents affecting the cytochrome.
Azathioprine	Leukopenia, thrombocytopenia, gastrointestinal difficulties, hepatitis, cholestasis, alopecia. Azathioprine is compatible with cyclosporine and tacrolimus.
Corticosteroids	Cushing's disease, bone disease (osteoporosis, avascular necrosis), cataracts, glucose intolerance, infections, hyperlipidemia, growth retardation.

SUMMARY

- The immune system is designed to prevent foreign substances from entering the body. If that fails, this system should launch an attack to find and destroy these foreign substances.
- Organs of the immune system include the spleen, tonsils, adenoids, lymph nodes, and thymus.
- Lymphocytes are the primary units of the immune system. There are B lymphocytes and T lymphocytes. B lymphocytes produce antibodies. This is called *humoral immunity*. T lymphocytes provide immune protection with three types of cells. Killer T cells attack invading organisms; helper T cells encourage B-cell antibody production; and suppressor T cells regulate the immune response so that it does not attack the body. T cells provide cell-mediated immunity.
- Natural immunity is present at birth. It is not antigen-specific. Acquired immunity develops after exposure to specific antigens.
- Local allergic reactions do not produce life-threatening signs and are treated with antihistamine (e.g., diphenhydramine).
- Anaphylaxis is an immediate, systemic, and life-threatening reaction.
- Antigens are substances that trigger antibody formation.
- Antibodies bind to the antigen that produced them. Antibodies help neutralize the antigen and remove it from the body.
- An allergic reaction is an increased physiological response to an antigen after a previous exposure to the same antigen.
- Localized allergic reactions do not affect the entire body. They affect the skin, nasal passages, or eyes, not the lungs or cardiovascular system. They are treated with antihistamines (e.g., diphenhydramine).
- Anaphylaxis is a form of type I hypersensitivity reaction. It is the most extreme form of allergic reaction. Rapid recognition and aggressive therapy are needed for patient survival.
- Almost any substance can cause anaphylaxis. The risk of anaphylaxis increases with the frequency of exposure.
- Chemical substances released by basophils and mast cells cause signs and symptoms of anaphylaxis. These chemicals include histamine, leukotrienes, and other substances.
- Symptoms of anaphylaxis may include a sudden onset of hives, angioedema, and pruritus; sneezing and coughing; airway obstruction; wheezing; hypotension or vascular collapse; chest pain; nausea, vomiting, or diarrhea; and weakness, headache, syncope, seizures, or coma.
- The paramedic should determine whether the patient has used an epinephrine autoinjector or taken diphenhydramine before arrival of the paramedic crew.
- Treatment of anaphylaxis includes administration of epinephrine and, if the patient is hypotensive, 1 to 2 L of normal saline. Additional interventions may include antihistamines, inhaled beta agonists, corticosteroids, glucagon, and vasopressors.
- Autoimmune disease occurs when the body's immune system attacks normal body cells, causing harm.

Continued

- Collagen vascular disease is also called *connective tissue disease*.
- Systemic lupus erythematosus, or lupus, is a disease of young women that can damage many organs. It often causes a butterfly rash on the nose and cheeks. Severe damage to the GI organs, kidneys, lungs, and central nervous system are possible.
- Scleroderma means hard skin. It is caused by increased collagen production. Systemic scleroderma may cause Raynaud's phenomenon and dysfunction of the esophagus, GI tract, kidneys, heart, and lungs.
- Solid organ transplants include the kidneys, liver, pancreas, heart, and lungs.
- Infection, rejection, and drug toxicity are the key complications seen after organ transplant.
- Infections may include community-acquired bacterial or viral diseases, opportunistic infections, and others. Normal signs and symptoms of infection may be masked by the immunosuppressive therapy.
- When the body recognizes the transplanted tissue as "nonself," it begins to reject it. Rejection may be hyperacute (occurring within minutes), acute (occurring within 1 week), or chronic (occurring after 1 week).
- Immunosuppressive drugs have many side effects. Three drug groups known to cause many adverse effects are cyclosporines, azathioprines, and corticosteroids.

CHAPTER

28 Infectious and Communicable Diseases

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Identify general public health principles related to infectious disease.
2. Describe the chain of elements necessary for an infectious disease to occur.
3. Explain how internal and external barriers affect susceptibility to infection.
4. Differentiate the four stages of infectious disease: the latent period, the incubation period, the communicability period, and the disease period.
5. Describe the mode of transmission, pathophysiology, prehospital considerations, and personal protective measures to be taken for the human immunodeficiency virus (HIV), hepatitis, tuberculosis, meningococcal meningitis, and pneumonia.
6. Describe the mode of transmission, pathophysiology, signs and symptoms, and prehospital considerations for patients who have rabies or tetanus.
7. List the signs, symptoms, and possible secondary complications of selected childhood viral diseases.
8. List the signs, symptoms, and possible secondary complications of influenza, severe acute respiratory syndrome (SARS), and mononucleosis.
9. Describe the mode of transmission, pathophysiology, prehospital considerations, and personal protective measures for sexually transmitted diseases.
10. Identify the signs, symptoms, and prehospital considerations for scabies and lice.
11. Outline the reporting process for exposure to infectious or communicable diseases.
12. Discuss the paramedic's role in preventing disease transmission.

KEY TERMS

asplenia Congenital absence or surgical removal of the spleen.

bacterial endocarditis Inflammation of the endocardium and one or more heart valves; also known as *infective endocarditis.*

bacterial meningitis A life-threatening illness that results from bacterial infection of the meninges.

body lice Tiny parasites that concentrate around the waist, shoulders, axillae, and neck.

C. diff colitis Inflammation of the colon caused by the bacterium *Clostridium difficile*.

chemotactic factors Biochemical mediators that are important in activating the inflammatory response.

chickenpox An acute, highly contagious viral disease caused by a herpes virus, varicella-zoster virus; it occurs primarily in young children and is characterized by crops of pruritic vesicular eruptions on the skin; also known as *varicella.*

Chlamydia A genus of microorganisms that live as intracellular parasites; a common cause of sexually transmitted diseases and a frequent cause of sterility.

Clostridium difficile A bacterium that normally is present in small numbers in the intestines.

communicability period A stage of infection that begins when the latent period ends and continues as long as the agent is present and can spread to other hosts.

communicable disease An infectious disease that can be transmitted from one person to another.

complement system A group of proteins that coat bacteria and help to kill them directly or assist in having them taken up by neutrophils in the blood or by macrophages in the tissues.

congenital rubella syndrome A serious disease that affects about 25% of infants born to women infected with rubella during the first trimester of pregnancy; it is associated with multiple congenital anomalies, mental retardation, and an increased risk of death from congenital heart disease and sepsis during the first 6 months of life.

designated officer (DO) A person who serves as a liaison between the public safety agency and community health agencies involved in monitoring and responding to communicable diseases.

disease period A stage of infection that follows the incubation period; the duration of this stage varies with the disease.

exposure incident Any specific contact of the eyes, the mouth, other mucous membranes, or nonintact skin, or any parenteral contact, with blood, blood products, bloody body fluids, or other potentially infectious materials.

external barriers The surface of the body that is exposed to the environment. This includes the skin and the mucous membranes of the digestive, respiratory, and genitourinary (GU) tracts; the body's first line of defense against infection.

gonorrhea A sexually transmitted disease that results from contact with the causative organism *Neisseria gonorrhoeae.*

hantavirus A cause of several different forms of hemorrhagic fever with renal syndrome.

head lice Tiny parasites that concentrate around the scalp (sometimes including the eyebrows and eyelashes).

hepatitis An inflammatory condition of the liver characterized by jaundice, hepatomegaly, anorexia, abdominal and gastric discomfort, abnormal liver function, clay-colored stools, and dark urine. Viruses responsible for hepatitis are *hepatitis A virus, hepatitis B virus, hepatitis C virus*, *hepatitis D virus*, and *hepatitis E virus*.

hepatitis A Viral hepatitis.

hepatitis B Serum hepatitis.

hepatitis C Non-A/non-B hepatitis.

herpes simplex virus 1 An infection caused by the herpes simplex virus; it tends to occur in the facial area, particularly around the mouth and nose.

herpes simplex virus type 2 An infection caused by the herpes simplex virus; it usually is limited to the genital region.

host The human or animal exposed to an infectious agent.

host susceptibility Factors of the host that contribute to prevention or continuation of infection.

human immunodeficiency virus The viral agent responsible for acquired immunodeficiency syndrome.

incubation period The stage of infection during which an organism reproduces; it begins with invasion of the agent and ends when the disease process begins.

indigenous flora Agents found on various sites of the body that could produce disease if allowed access to the interior of the body.

infectious disease Any illness caused by a specific microorganism.

influenza A highly contagious infection of the respiratory tract transmitted by airborne droplet infection. Researchers have identified three main types of the virus (types A, B, and C).

internal barriers Protection against germs provided by the inflammatory response and the immune response; the body's second line of defense against infection.

latent period A stage of infection that begins when a pathogenic agent invades the body and ends when the agent can be shed or communicated.

latent TB infection Tuberculosis that is not symptomatic or infectious; must be treated to prevent active TB disease.

meningococcal meningitis Inflammation of the membranes that surround the spinal cord and brain; can be caused by a variety of different bacteria, viruses, and other microorganisms; also known as *spinal meningitis*.

mode of transmission The way in which diseases are transmitted; may be direct or indirect contact.

mononucleosis A viral infection causing fever, sore throat, and swollen lymph glands, especially in the neck.

mumps An acute viral disease characterized by swelling of the parotid glands.

opportunistic infections Infections that take advantage of weakness in the immune defenses.

pandemic An infectious disease outbreak that infects large numbers of people in a large geographical region and may occur worldwide.

pathogen A disease-causing agent.

pertussis An acute, highly contagious respiratory disease characterized by paroxysmal coughing that ends in a loud, whooping inspiration; also known as whooping cough.

pneumonia An acute inflammation of the lungs, usually caused by inhaled pneumococci of the species *Streptococcus pneumoniae.*

portal of entry The means by which the pathogenic agent enters a new host.

portal of exit The method by which a pathogenic agent leaves one host to invade another.

pubic lice Tiny parasites that concentrate in the pubic area.

rabies An acute, usually fatal viral disease of the central nervous system of animals; it is transmitted from animals to human beings by infected blood, tissue, or, most commonly, saliva.

resistance The immune status of the host; the ability to ward off infection.

reservoir Any person, animal, plant, soil, or substance in which an infectious agent normally lives and multiplies; typically harbors the infectious agent without injury to itself and serves as a source from which other individuals can be infected.

reticuloendothelial system Part of the immune system composed of immune cells in the spleen, lymph nodes, liver, bone marrow, lungs, and intestines; stores mature B and T cells until the immune system is activated.

rubella A contagious viral disease characterized by fever, symptoms of mild upper respiratory tract infection, lymph node enlargement, and a diffuse, fine, red maculopapular rash; it is spread by droplet infection; also known as *German measles.*

rubeola An acute, highly contagious viral disease involving the respiratory tract; it is characterized by a spreading, maculopapular, cutaneous rash and occurs primarily in young children who have not been immunized; also known as *red measles.*

scabies A contagious parasitic skin infection characterized by superficial burrows and intense pruritus; caused by the mite *Sarcoptes scabiei.*

sexually transmitted disease Refers to a group of infections that are passed from one person to another through sexual contact.

shingles An acute infection caused by reactivation of the latent varicella-zoster virus; it is characterized by painful vesicular eruptions that follow the underlying route of cranial or spinal nerves inflamed by the virus; also known as *herpes zoster*.

syphilis A sexually transmitted disease characterized by distinct stages of effects over a period of years; any organ system may be involved.

tabes dorsalis An abnormal condition characterized by the slow degeneration of all or part of the body and the progressive loss of peripheral reflexes.

TB disease Active tuberculosis.

tetanus An acute, potentially fatal infection of the central nervous system caused by the tetanus bacillus *Clostridium tetani;* characterized by muscle spasms and convulsions.

transmitted nonspecific urethritis A sexually transmitted disease characterized by inflammation or infection of the urethra in which the cause is not defined; also known as nongonococcal urethritis.

tuberculosis A chronic granulomatous infection caused by *Mycobacterium tuberculosis;* it usually affects the lungs and generally is transmitted by inhalation or ingestion of infected droplets.

universal precautions Infection control practices in health care that are observed with every patient and procedure and that prevent exposure to blood-borne pathogens.

viral meningitis A syndrome generally associated with an existing systemic viral disease (e.g., enteroviral infection, herpes virus infection, mumps, and, less commonly, influenza); also known as *aseptic meningitis*.

virulence The relative strength of a pathogen.

Emergencies that involve infectious and communicable diseases are common in the prehospital setting. They can pose a significant health risk to emergency medical services (EMS) personnel. This chapter addresses the duties of the paramedic and EMS agencies in ensuring personal protection. It also presents the causes of infectious and communicable diseases, as well as special aspects of providing care for these conditions.

(Courtesy Ray Kemp, St. Charles, Mo.)

PUBLIC HEALTH PRINCIPLES RELATED TO INFECTIOUS DISEASES

An **infectious disease** is any illness caused by a specific germ. A **communicable disease** is an infectious disease that can be passed from one person to another. Infectious (communicable) diseases affect entire populations of people. These populations or groups of people are defined by location, age, socioeconomic status, and the relationships between the groups. Groups display varying susceptibilities to infection and varying degrees of susceptibility. In addition to demographics, other factors can affect the life cycle of an infectious agent within a population. These include:

- International travel
- Age distributions
- Population settling and migration dictated by religion
- Genetic factors
- The effectiveness of treatment once the infection has been established (Box 28-1)

When a disease outbreak occurs, local, state, private, and federal health agencies and other organizations become involved in prevention and management. Local agencies usually are the first line of defense in disease surveillance and outbreak. As described in Chapter 3, these include municipal, city, and county agencies such as health departments, fire departments, and EMS agencies.

LOOK AGAIN
See Chapter 3: Injury Prevention and Public Health, pp. 54-57.

State agencies often are involved in the regulation and enforcement of federal guidelines. They frequently are required by statute or public law to meet or exceed federal guidelines and recommendations for prevention and management of disease outbreaks.

The private sector is composed of regional and national health care providers, local and national health

BOX 28-1 The Emergence of AIDS: An Outbreak of Disease

The presence of the human immunodeficiency virus (HIV) may have been detected as early as 1959 in Zaire. However, the virus did not become epidemic until 20 to 30 years later. The outbreak may have resulted from the migration of poor and young sexually active people from rural areas to urban centers in developing countries. This group often returned to rural areas or moved internationally because of civil wars, tourism, business travel, and the drug trade.

Acquired immunodeficiency syndrome (AIDS) was first identified in the United States in 1981. Young, previously healthy homosexual men in New York and California were found to have an unusual clustering of rare diseases (most notably Kaposi sarcoma, *Pneumocystis carinii* pneumonia, and unexplained persistent lymphadenopathy). A review of laboratory tests from that time for antibodies to HIV suggests that the virus entered the U.S. population in the late 1970s. Yet, at the end of 2008, an estimated 1,178,350 persons in the United States were living with HIV. And about 235,670 of those people do not know they are infected.[1] In 2008, an estimated 33.4 million people worldwide are living with HIV infection or AIDS. Since the epidemic began in 1981, more than 25 million people have died of AIDS.[2]

maintenance organizations, laboratories (hospital and private), infection control and disease specialists, and others. These groups influence protocols and guidelines for tracking diseases and responding to outbreaks.

Federal and national organizations include Congress, which plays an integral role in national health policy by passing public laws and drafting the federal budget; the U.S. Department of Labor's Occupational Safety and Health Administration (OSHA); and agencies under the U.S. Department of Health and Human Services, such as the Centers for Disease Control and Prevention (CDC) and the National Institute for Occupational Safety and Health (NIOSH). Other federal and national organizations involved in the prevention and management of disease outbreaks include the U.S. Department of Defense, the Federal Emergency Management Agency (FEMA), the National Fire Protection Association (NFPA), the U.S. Fire Protection Administration (USFPA), and the International Association of Firefighters (IAFF).

Local public health agencies can also play an important role during a disease outbreak in a community. These agencies can provide education to public service agencies, vaccine distribution through immunization clinics, and outbreak surveillance and tracking of infectious agents.

CRITICAL THINKING

Have you had an outbreak of a communicable disease in your region? How was it controlled?

Agency Responsibility in Infectious Agent Exposure

National concerns regarding communicable disease and infection control have resulted in public law, guidelines, standards, and recommendations to protect health care personnel and emergency responders from infectious diseases. The components of a health care agency's exposure control plan should include the following[3]:

- Health maintenance and surveillance
- Appointment of a **designated officer (DO)** to serve as a liaison between the agency and community health agencies involved in monitoring and responding to communicable diseases
- Identification of job classifications and, in some cases, specific tasks when exposure to blood-borne pathogens is possible
- A schedule detailing when and how the provisions of blood-borne pathogen standards will be implemented
- Personal protective equipment (PPE)
- Body substance isolation (BSI)
- Procedures for evaluating exposure and postexposure counseling
- Notifying and working with local health authorities and state and federal agencies regarding exposures
- Personal, building, vehicle, and equipment disinfection and storage
- Education of employees regarding disinfection agents
- After-action analysis of the agency's response
- Correct disposal of needles and sharps in appropriate containers
- Correct handling of linens and supplies that become contaminated with body fluids during patient care
- Identification of agency and/or contracted personnel for counseling, authorization of acute medical care, and documentation

SHOW ME THE EVIDENCE

These authors reviewed existing literature to determine the incidence of blood-borne pathogens in firefighters and emergency medical technicians. Studies from St. Louis, Florida, Portland, New York City, Chicago, Baltimore, Atlanta, Fulton and Dade Counties, and Tucson were evaluated. Although there were problems with study design, they concluded that, even though the populations that EMS and firefighters encounter have a higher prevalence of HIV, HBV, and HCV than the general population, the emergency responders did not. The authors propose that this may be related to employment-related drug screening in this industry. Studies indicate that between 0% and 0.8% of first responders state they have ever injected drugs. They did find that paramedics have a higher incidence of needle-stick injury and mucous membrane and skin exposure than EMTs. Further, EMTs have a higher rate of blood-borne exposures than firefighters who are not EMTs or paramedics.

From Boal WL, Hales T, Ross C: Blood-borne pathogens among firefighters and emergency medical technicians, *PEC* 9(2):236-247, 2005.

GUIDELINES, RECOMMENDATIONS, STANDARDS, AND LAWS

To protect health care workers against the spread of infection, OSHA requires that personal protective equipment be made available to all employees considered at high risk for exposure to infectious diseases. It also requires that all employees be offered preexposure prophylaxis against hepatitis B through inoculation with hepatitis vaccines.[4] The CDC and NFPA have established similar guidelines, recommendations, and standards regarding the protection of health care workers and emergency personnel from communicable disease. This includes regular testing for tuberculosis. It also includes vaccination for measles in individuals who do not have immunity (Box 28-2).

DID YOU KNOW?

Ryan White Act

The *Ryan White Comprehensive AIDS Resources Emergency Act* (PL 101-381), passed in 1990, requires notification of emergency responders if they have been exposed to infectious diseases. It also requires that employers name a DO to direct communications between the hospital and emergency service in case of an exposure. Notification must be made within 48 hours of determination of the presence of the disease.

In December 2006, the *Ryan White Treatment Modernization Act of 2006* (PL 109-415) was signed into law. The portion of the law in the original *Act* that covered notification of disease exposure to first responders was stricken from the legislation, but was recently restored.[5] In addition, many states have laws in place that require emergency responders to be notified if they have been exposed to infectious disease.

The CDC has classified infectious disease into two types: airborne and blood-borne. An example of an airborne disease is infectious tuberculosis. Examples of blood-borne diseases spread by pathogens are the hepatitis B and C viruses and HIV. The CDC also lists less common communicable diseases. These include diphtheria, hemorrhagic fevers, meningococcal disease, plague, and rabies.

Currently, medical facilities are not required to test patients for any infectious disease. If paramedics have a significant exposure to blood or body fluids, they may submit a written notice to the DO. The DO, in turn, must submit a written request for a determination to the medical facility that treated the patient. The medical facility must try to identify the source patient and review any signs and symptoms shown by the patient that may correspond to the CDC list of infectious diseases. After determining whether a paramedic may have been exposed to an infectious disease, the medical facility must notify the DO within 48 hours of receiving the request. If it is a significant exposure and the source patient is known, the medical facility will usually ask for patient consent to test for HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV) infection. In addition, the paramedic will be counseled about the need for postexposure prophylaxis (PEP) based on the patient's risk factors as well as the need for safe sex until follow-up results are known. If the patient refuses to be tested or the source patient is unknown, follow-up monitoring for the paramedic is arranged. Follow-up monitoring for the development of HIV, HBV, and HCV is important because PEP is most effective if started immediately.

BOX 28-2 Recommended Immunizations for Emergency Medical Services Personnel*

- Hepatitis B†
- Diphtheria
- Pertussis
- Influenza
- Measles
- Mumps
- Rubella
- Tetanus
- Polio

*Testing for tuberculosis (TB) may be required at the time of initial employment and annually thereafter. Additional vaccinations are recommended for EMS personnel involved in disaster services, military employment, or international work.

†This vaccination is required by the federal Occupational Safety and Health Administration.

NOTE

Immediate testing will only reveal infection from a previous exposure—not from the exposure that prompted the immediate testing. A paramedic who tests positive for an infectious disease through an immediate test has had a previous exposure to the disease. Conversely, a paramedic who tests negative for an infectious disease through an immediate test may still have been infected from the exposure that prompted the test.

CRITICAL THINKING

What rights do you think paramedics had to obtain infectious disease information before the Ryan White law was passed?

Personal Responsibilities in Infectious Agent Exposure

Paramedics should familiarize themselves with the laws, regulations, and national standards regarding infectious disease. They should take personal protective measures against exposure to these pathogens. At times all paramedics will provide patient care to a person with an infectious disease. They must be aware of the potential consequences of the disease for public health and through contact with family members and friends. Table 28-1 and Box 28-3

TABLE 28-1 Personal Equipment for Protection Against Transmission of Human Immunodeficiency Virus (HIV) and Hepatitis B Virus

Activity	Disposable Gloves	Gown	Mask	Protective Eyewear
Bleeding control (spurting blood)	Yes	Yes	Yes	Yes
Bleeding control (minimal blood)	Yes	No	No	No
Emergency childbirth	Yes	Yes	Yes*	Yes*
Intravenous therapy	Yes	No	No	No
Endotracheal intubation	Yes	No	Yes*	Yes*
Oral or nasal suctioning	Yes	No	No	No
Administration of an injection	No	No	No	No

Modified from Centers for Disease Control and Prevention: Recommendations for preventing transmission of human immunodeficiency virus and hepatitis B virus to patients during exposure-prone invasive procedures, *MMWR* 40(RR08):1-9, 1991.
*If splashing is likely.

provide an overview of CDC guidelines. These are designed to help prevent the spread of infectious disease to public safety and emergency response workers. Paramedics should follow local protocol regarding similar or additional precautions for personal protection and should be aware of their individual responsibilities, including the following:

- A proactive attitude toward infection control
- Maintenance of personal hygiene (esthetics of patient care)
- Attention to wounds and maintenance of the skin (the external barrier to infection)
- Effective hand washing after every patient contact using warm water and antiseptic cleanser or waterless antiseptic cleanser when portable water is unavailable
- Washing or disposing of work garments before entering the home
- Handling uniforms in accordance with the agency's definition of PPE
- Proper handling and laundering of work clothes soiled with body fluids, with consideration for bathing and showering after the work shift and before returning home
- Preparing food and eating in appropriate areas
- Maintenance of general physiological and psychological health to prevent stress, which can compromise the immune system of a healthy individual
- Use of needleless or safe needle devices if available
- Proper disposal of needles and sharps in appropriate containers
- Proper disposal of body fluid–tinged linens and supplies
- Awareness and avoidance of tendencies to wipe the face and/or rub the eyes, nose, or mouth with gloved hands
- Knowledge of general classifications of exposure to determine the extent of infection control measures applied to the health care worker

UNIVERSAL PRECAUTIONS

As described in Chapter 14, the CDC published the *Recommendations for Prevention of HIV Transmission Guidelines in Health-Care Settings* (1987). This document recommended that **universal precautions** (universal blood and body fluid precautions) be used for all patients, regardless of their blood-borne infection status.[6] Since then, the U.S. Food and Drug Administration (FDA) and the CDC have worked together to further identify the body fluids to which universal precautions apply (Box 28-4).

LOOK AGAIN
See Chapter 14: Venous Access and Medication Administration, pp. 380-381.

DECONTAMINATION METHODS AND PROCEDURES

Guidelines for cleaning, disinfecting, and sterilizing patient care equipment have been established by the CDC, OSHA, the Environmental Protection Agency (EPA), USFA, and other agencies and organizations. These guidelines are part of an EMS agency's protocols and standard operating procedures. The following is a brief description of these decontamination methods and procedures.[7]

Sterilization destroys all forms of microbial life. It is used for instruments that penetrate the skin or come in contact with normally sterile parts of the body (e.g., scalpels and needles). Methods that may be used for sterilization include steam under pressure (autoclave), gas (ethylene oxide), dry heat, and immersion in an EPA-approved chemical sterilant.

High-level disinfection destroys all forms of microbial life *except* high numbers of bacterial spores. It is used for reusable instruments that have contact with mucous membranes (e.g., laryngoscope blades, endotracheal tubes). Methods that may be used for high-level disinfection include hot water pressurization and exposure to an EPA-registered chemical sterilant.

Intermediate-level disinfection destroys *Mycobacterium tuberculosis,* most viruses, vegetative bacteria, and most fungi, but not bacterial spores. It is used for surfaces that come in contact with intact skin (e.g., stethoscopes, blood pressure

BOX 28-3 Guidelines for Prevention of Transmission of Human Immunodeficiency Virus (HIV) and Hepatitis B Virus to Health Care and Public Safety Workers

These general principles have been developed from existing principles of occupational safety and health. They have been developed in conjunction with data from studies of health care workers in hospitals. The basic premise is that workers must be protected from exposure to blood and other potentially infectious body fluids in the course of their work. However, data concerning the risks these worker groups face are lacking. This complicates the development of control principles. Thus the guidelines here are based on principles of prudent public health practice.

Fire and emergency medical services personnel provide medical care in the prehospital setting. The following guidelines can help rescue personnel make decisions on the use of personal protective equipment and resuscitation equipment. They also are meant to help them make decisions regarding documentation, disinfection, and disposal procedures.

Personal Protective Equipment

The proper personal protective equipment should be made available by the employer. This reduces the risk of exposure. For many situations, the rescuer's chance of being exposed to blood and other body fluids to which universal precautions apply can be determined in advance. If the chance of exposure is high, the worker should put on protective attire before beginning patient care. (Examples of high-risk situations include cardiopulmonary resuscitation, intravenous line insertion, trauma, and childbirth.) (This list is not intended to be all-inclusive.) Important pieces of protective gear include the following:

1. *Gloves.* Disposable gloves should be a standard part of emergency response equipment. All personnel should put them on before giving any care that involves exposure to blood or other body fluids to which universal precautions apply. Extra pairs should always be available. No single type or thickness of glove offers the best protection in all situations. Considerations in the choice of disposable gloves should include dexterity, durability, fit, and the task to be performed. When large amounts of blood are likely, the gloves must fit tightly at the wrist. This prevents contamination of the hands around the cuff. For care of several trauma victims, gloves should be changed between patients if the situation allows.

   More extensive personal protective measures are indicated when broken glass and sharp edges are likely to be encountered. Such a situation might include extricating a person from a motor vehicle crash. Structural firefighting gloves that meet the requirements of the federal Occupational Safety and Health Administration for firefighter gloves* should be worn in any situation in which sharp or rough surfaces are likely to be encountered.

   While wearing gloves, paramedics should avoid handling personal items (e.g., combs, pens) that could become soiled or contaminated. Gloves that have become contaminated with blood or other body fluids should be removed as soon as possible. In doing so, paramedics should take care to avoid skin contact with the exterior surface of the gloves. Contaminated gloves should be placed and transported in bags that prevent leakage. They should be disposed of properly or, in the case of reusable gloves, cleaned and disinfected as required.
2. *Mask, eyewear, and gowns.* Masks, eyewear, and gowns should be kept on all emergency vehicles that respond or may respond to medical emergencies or victim rescues. This barrier equipment should be used in accordance with the level of exposure encountered. Minor cuts or small amounts of blood do not merit the same degree of barrier use as that needed for victims with massive blood loss. Management of the patient who is not bleeding and who has no body fluids present should not routinely require the use of barrier precautions. Masks and eyewear (e.g., safety glasses) should be worn together or a face shield should be used by all personnel for any situation that is likely to involve splashes of blood or other body fluids to which universal precautions apply. Gowns or aprons should be worn to protect clothing from blood splashes. If large splashes or amounts of blood are present or anticipated, nonpermeable gowns or aprons should be worn. An extra change of work clothing should be available at all times.
3. *Resuscitation equipment.* No transmission of hepatitis B virus or HIV infection during mouth-to-mouth resuscitation has been documented. However, because of the risk of transmission of other infectious diseases through saliva, disposable airway equipment or resuscitation bags should be used. Diseases that can be spread in saliva include herpes simplex infection and *Neisseria meningitidis.* Theoretically, a risk exists of HIV and hepatitis B virus transmission during artificial ventilation of trauma victims. Disposable resuscitation equipment and devices should be used once and then discarded. If reusable, this equipment should be thoroughly cleaned and disinfected after each use according to the manufacturer's recommendations.

Mechanical respiratory assist devices (e.g., bag-valve-masks, oxygen demand-valve resuscitators) should be available on all emergency vehicles. They also should be available to all emergency response personnel who respond to medical emergencies or victim rescues.

Pocket mouth-to-mask resuscitation masks are designed to prevent personnel from coming in contact with victims' blood and blood-contaminated saliva, respiratory secretions, and vomitus. These should be provided to all personnel who provide or may provide emergency treatment.

Modified from U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, National Institute of Occupational Safety and Health: *Guidelines for prevention of transmission of human immunodeficiency virus and hepatitis B virus to health-care and public-safety workers,* Washington, DC, 1989, Author.

*Standards are presented in 29 Code of Federal Register (CFR) 1910.156 and in National Fire Protection Association Standard 1973, Gloves for Structural Fire Fighters.

BOX 28-4 Clarification of Use of Universal Precautions*

Body Fluids to Which Universal Precautions Apply

- Blood and other body fluids containing visible blood
- Semen and vaginal secretions
- Human tissue
- Human fluids (cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, amniotic fluid)

Body Fluids to Which Universal Precautions Do Not Apply (in the Absence of Blood)

- Feces
- Nasal secretions
- Sputum
- Sweat
- Tears
- Urine
- Vomitus

Precautions for Other Body Fluids in Special Settings

- Human breast milk in mothers infected with hepatitis B virus (HBV) (e.g., milk banking procedures)
- Saliva in some individuals infected with HBV or human immunodeficiency virus (HIV) (e.g., human bites [remote], dental procedures)

Modified from Centers for Disease Control and Prevention: Perspectives in disease prevention and health promotion update: universal precautions for prevention of transmission of human immunodeficiency virus, hepatitis B virus, and other bloodborne pathogens in health-care settings, *MMWR Morb Mortal Wkly Rep* 37(24):377, 1988.
*Established by the Centers for Disease Control and Prevention and the U.S. Food and Drug Administration.

BOX 28-5 Types of T Cells

Sensitized T cells develop into distinct groups. Each group has a specific set of functions that coordinate the activity of other components of the immune system.

- *Killer T cells* (like B cells) are sensitized and stimulated to multiply by the presence of antigens on abnormal body cells. Unlike B cells, killer T cells do not produce antibodies.
- *Helper T cells* "turn on" the activities of killer (cytotoxic) cells. They also control other aspects of the immune response.
- *Suppressor T cells* "turn off" the action of the helper and killer T cells. This prevents them from causing harmful immune reactions.
- *Inflammatory T cells* stimulate allergic reactions, anaphylaxis, and autoimmune reactions.

cuffs, splints). It also is used for surfaces that have been visibly contaminated with blood or body fluids. (Surfaces must be cleaned of visible material before disinfection.) Methods that may be used for intermediate-level disinfection include use of EPA-registered "hospital disinfectant" chemical germicides that claim to be tuberculocidal on the label, hard surface germicides, and solutions containing at least 550 parts per million (ppm) free available chlorine (1:100 dilution of common household bleach: approximately ¼ cup of bleach per 1 gallon of water).

Low-level disinfection destroys some viruses, most bacteria, and some fungi, but not *M. tuberculosis* or bacterial spores. It is used for routine housekeeping. It also is used to clean up soiling when no blood is visible. Methods that may be used for low-level disinfection include use of EPA-registered "hospital disinfectants." (The label carries no claim of tuberculocidal activity.)

Environmental disinfection cleans soiled surfaces in the environment, such as floors, ambulance seats, and counter tops. Such surfaces should be disinfected with cleaners or disinfectant agents.

As described in Chapter 27, the body's immune response to an invading pathogen depends partly on the size of the pathogen. It also depends on the pathogen's ability to stimulate production of an antibody. Often, peripheral phagocytic cells encounter a pathogen first. However, circulating B and T cells also are scouting for pathogens (Box 28-5). Complex interactions occur among neutrophils, macrophages, and B and T cells. These cells assist each other in processing antigens that allow them to recognize and destroy the invading pathogens.

LOOK AGAIN
See Chapter 27: Immune System Disorders, pp. 826-828.

The B cell's role is to produce antibody (humoral immunity). This antibody coats the pathogen and facilitates phagocytosis. Antibody can also fix *complement*. The **complement system** is a group of proteins that coat bacteria and help to kill them directly. Or the proteins can have the bacteria taken up by neutrophils in the blood or by macrophages in the tissues. T cells not only process antigen for the B cells, but also include a subpopulation of "killer cells." These cells play a major role in cell-mediated immunity (Figure 28-1).

Both the humoral and cell-mediated types of immunity take time to work. Both require previous exposure to mobilize specialized white cells. In time, these white cells differentiate between antibodies. They then organize an attack on the foreign material. By comparison, the complement system recognizes and kills invaders on first sight. It does not take time to mobilize specialized responses.

Reticuloendothelial System. The **reticuloendothelial system** (RES), described in Chapter 11, works with the lymphatic system to dispose of debris that results from the immune system attack on invading organisms. The RES is composed of immune cells in the spleen, lymph nodes,

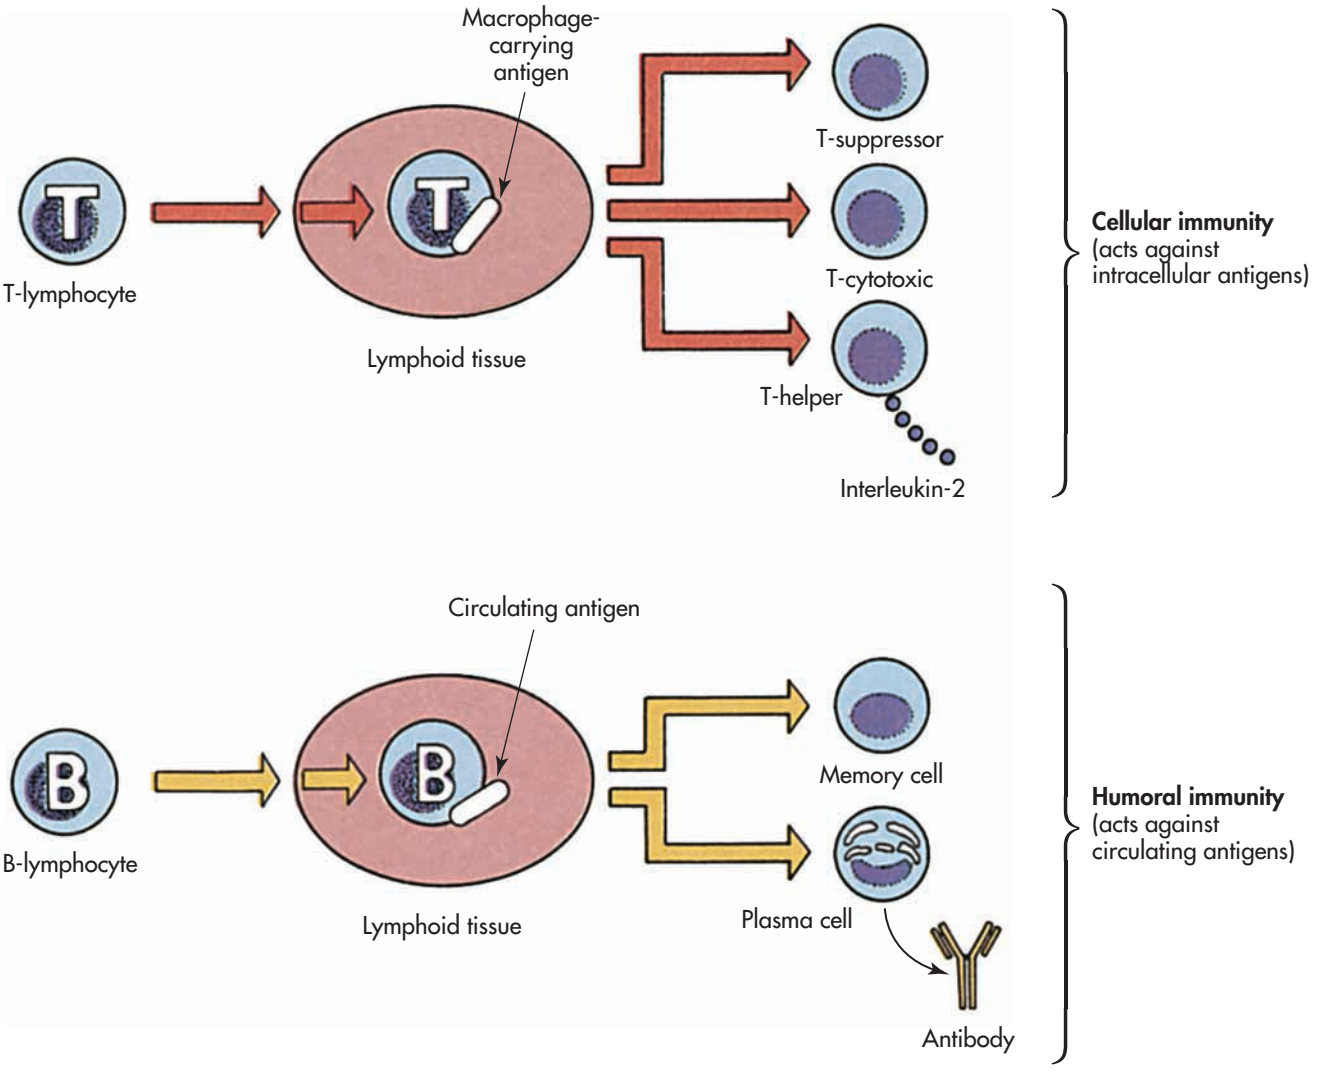

FIGURE 28-1 Cellular and humoral immunity. Cellular immunity results from activation of T cells through contact with intracellular organisms. Activated T cells differentiate and proliferate. Humoral (antibody-mediated) immunity results from the activation of B cells. (From Grimes D: *Infectious diseases,* St Louis, 1991, Mosby.)

liver, bone marrow, lungs, and intestines. These structures store mature B and T cells until the immune system is activated.

LOOK AGAIN
See Chapter 11: General Principles of Pathophysiology, pp. 234-237.

PATHOPHYSIOLOGY OF INFECTIOUS DISEASE

Infectious and communicable diseases are the second leading cause of death worldwide (after heart disease), and the third most common cause of death in the United States.[8] The development and/or manifestations of clinical disease depend on several factors, including the **virulence** (degree of pathogenicity) of the infectious agent, the number of infectious agents (dose), the **resistance** (immune status) of the **host** (the human or animal who is exposed to the infectious agent), and the correct mode of entry.[9] These factors all rely on an intact chain of elements to produce an infectious disease (Figure 28-2). The elements of the chain include the following[10]:

- The pathogenic agent
- A reservoir
- A portal of exit from the reservoir
- An environment conducive to transmission of the pathogenic agent
- A portal of entry into the new host
- Susceptibility of the new host to the infectious disease

Even if all these elements are present, exposure does not necessarily mean that a person will become infected.

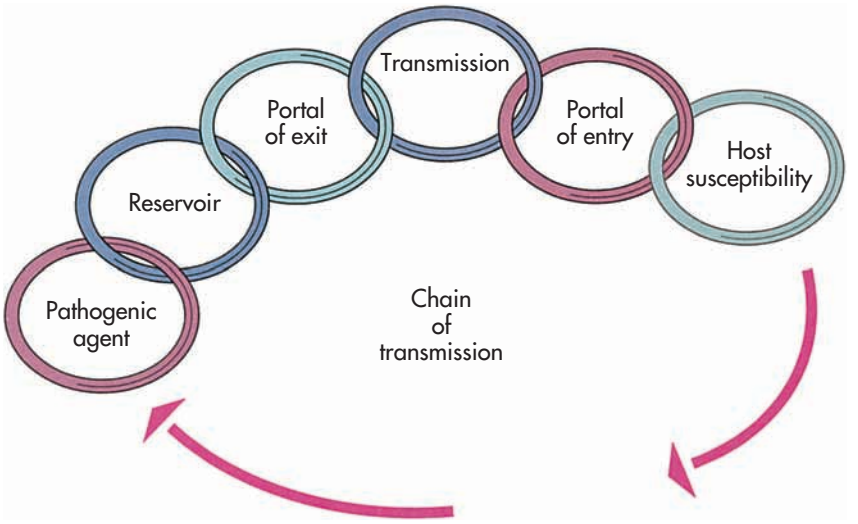

FIGURE 28-2 Chain of transmission for infection. The chain must be intact for an infection to be transmitted to another host. Transmission can be controlled by breaking any link in the chain.

NOTE
According to the World Health Organization, five diseases cause 90% of all infectious disease deaths worldwide. In order of prevalence, they are acute respiratory tract infections (including pneumonia and influenza), AIDS, diarrheal diseases, tuberculosis, malaria, and measles.[11]

Pathogenic Agent

As described in Chapter 11, **pathogens** are organisms that can cause disease in the human host. They are classified according to shape (morphology), chemical composition, growth requirements, and viability. Pathogens rely on a host to supply their nutritional needs.

LOOK AGAIN
See Chapter 11: General Principles of Pathophysiology, pp. 242-245.

Some pathogens (e.g., certain bacteria) are metabolically equipped to survive outside a host. In contrast, others (e.g., certain viruses) can survive only in the human cell (Box 28-6). Some viruses, such as HIV and the hepatitis B virus (HBV), can survive for several hours outside a host. This is why blood products can be infectious.

Most bacteria are susceptible to certain drugs (antibiotics) (Box 28-7). These drugs either kill the bacteria or inhibit their growth. Viruses, however, are more difficult to treat because they reside in cells for most of their life cycle and become intricately enmeshed in the host cell's deoxyribonucleic acid (DNA). Factors that affect a pathogen's ability to cause disease include the following:

- The ability to invade and reproduce in a host and the mode by which it does so
- The speed of reproduction, the ability to produce a toxin, and the degree of tissue damage that results
- Potency
- The ability to induce or evade an immune response in the host

Reservoir

Pathogens may live and reproduce in humans or other animal hosts. They also may live and reproduce in an arthropod, a plant, soil, water, food, or some other organic substance, or a combination of these **reservoirs.** When infected, the human host may show signs of clinical illness. However, the host may be an *asymptomatic carrier* (i.e., a person who can pass the pathogen to others without showing signs of illness). As stated previously, the life cycle of the infectious agent depends on three factors: the demographics of the host, genetic factors, and the efficacy of therapeutic interventions once infection has been established.

Portal of Exit

The method by which a pathogenic agent leaves one host to invade another involves a **portal of exit.** The portal of exit from the human host depends on the agent. The portal may be single or multiple, involving the genitourinary (GU) tract, intestinal tract, oral cavity, respiratory tract, an open lesion, or any wound through which blood escapes. The time during which an actively infectious pathogen escapes to produce disease in another host coincides with the period of communicability (described later in this chapter). This period varies with each disease.

Mode of Transmission

The portal of exit and the portal of entry determine the **mode of transmission.** This mode may be direct or indirect. *Direct transmission* results from physical contact

BOX 28-6 Review of Infectious Agents and Their Properties

Bacteria

- Bacteria are *prokaryotic* (i.e., the nuclear material is not contained within a distinctive envelope).
- They can self-reproduce without a host cell.
- Signs and symptoms depend on the cells and tissues affected.
- Bacteria produce toxins (these are often more lethal than the bacterium itself).
- Endotoxins (chemicals, usually proteins) are integral parts of a bacterium's outer membrane and are constantly shed from living bacteria.
- Exotoxins (proteins) are released by bacteria and can cause disease symptoms by acting as neurotoxins or enterotoxins.
- Lysis of bacteria may result in the release of endotoxins.
- Bacteria can cause localized or systemic infection.

Viruses

- Viruses are living organisms without a nucleus.
- They must invade host cells to reproduce.
- Many cannot survive outside a host cell.
- Viruses may contain other microorganisms.

Fungi

- Fungi are *eukaryotic* (i.e., the nuclear material is contained within a distinct envelope).
- A protective capsule surrounds the cell wall to protect the organism from phagocytes.

Protozoa

- Protozoa are single-celled microorganisms.
- They are more complex than bacteria.

Helminths (Worms [Including Tapeworms], Roundworms)

- Helminths are pathogenic parasites.
- They are not necessarily microorganisms.

BOX 28-7 Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Staphylococcus aureus (often referred to as staph) is a bacterium commonly carried on the skin and in the nose of healthy people. Sometimes staph can cause infection. Staph bacteria are one of the most common causes of skin infections in the United States.[5] Most infections are minor (e.g., pimples and boils). Most of these can be managed without antibiotics. However, some infections are serious. These include surgical wound infections, bone infections, pneumonia, septicemia, and others, which may be resistant to penicillin-related antibiotics.

MRSA is a variety of staph that is resistant to penicillin and other antibiotics. MRSA occurs more often in elderly or very sick patients in hospitals and other health care facilities; patients often have an open wound (e.g., bed sore) or an indwelling urinary catheter or are receiving intravenous (IV) therapy. Staphylococci and MRSA most often are spread by direct physical contact and not by airborne transmission. Spread may also occur through indirect contact by the touching of objects (e.g., towels, sheets, wound dressings, clothes) contaminated by the infected skin of a person with MRSA or staph bacteria. It is important for all health care providers to (1) use universal precautions, (2) practice good hand washing before and after each patient encounter, and (3) avoid contact with open wounds or material contaminated by wounds.

Staph and MRSA can also cause illness in persons outside of hospitals and health care facilities. MRSA infections that are acquired by persons who have not been recently (within the past year) hospitalized or had a medical procedure (such as dialysis, surgery, catheter insertion) are known as community-associated (CA) MRSA infections. Staph or MRSA infections in the community are usually manifested as skin infections, such as pimples and boils, and occur in otherwise healthy people. Clusters of CA-MRSA skin infections have been noted among athletes, military recruits, children, Pacific Islanders, Alaskan Natives, Native Americans, men who have sex with men, and prisoners. Factors that have been associated with the spread of MRSA skin infections include close skin-to-skin contact, openings in the skin such as cuts or abrasions, contaminated items and surfaces, crowded living conditions, and poor hygiene.[12]

between the source and the victim. Examples of direct transmission include oral transmission and transmission by airborne mucus droplets, fecal contamination, and sexual contact.

In *indirect transmission,* the organism survives on animate or inanimate objects for a time without a human host. Diseases can be transmitted indirectly by air, food, water, soil, or biological matter.

Portal of Entry

The **portal of entry** is the means by which the pathogenic agent enters a new host. It may be by ingestion, inhalation, percutaneous injection, crossing of a mucous membrane, or crossing of the placenta. The time it takes for the infectious process to begin in a new host varies with the disease and host susceptibility. The duration of the exposure to the pathogen and the number of organisms required to initiate the infectious process also vary. Exposure to an infectious agent does not always produce infection.

SHOW ME THE EVIDENCE

Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Researchers at a large urban ambulance service performed a cross-sectional research study to determine whether methicillin-resistant *Staphylococcus aureus* (MRSA) could be cultured from any of five locations on an ambulance. Of the 21 ambulances tested, 10 (47.6%) were positive for MRSA. Positive cultures were obtained from the steering wheel, stretcher handrail, stretcher cushion, work area beside the stretcher, and Yankauer suction tip.

From Roline CE, Crumpecker C, Dunn T: Can methicillin-resistant *Staphylococcus aureus* be found in an ambulance fleet? *PEC* 11(2):241-244, 2007.

CRITICAL THINKING
Describe a precaution or intervention that could break each of the links in the chain of disease transmission.

Host Susceptibility

Host susceptibility is influenced by a person's immune response (described in Chapters 11 and 27). It also is influenced by several other factors. Some of these factors include the following:

1. Human characteristics
   - Age
   - Gender
   - Ethnic group
   - Heredity
2. General health status
   - Nutrition
   - Hormonal balance
   - Presence of concurrent disease
   - History of previous disease
3. Immune status
   - Prior exposure to disease (conferring resistance)
   - Effective immunization against disease (conferring host immunity)
4. Geographical and environmental conditions
5. Cultural behaviors
   - Eating habits
   - Personal hygiene
   - Sexual behaviors

PHYSIOLOGY OF THE HUMAN RESPONSE TO INFECTION

The human body is regularly exposed to pathogens that can cause illness. Even so, most people do not succumb to infectious disease. This protection is provided by external and internal barriers. These barriers act as lines of defense against infection.

External Barriers

The first line of defense against infection is the surface of the body (**external barriers**), which is exposed to the environment. This includes the skin and the mucous membranes of the digestive, respiratory, and GU tracts. These areas are inhabited by **indigenous flora** (agents that could produce disease if allowed access to the interior of the body). The surface of the body forms a continuous closed barrier between the internal organs and the environment (Figure 28-3).

FLORA

Nearly the whole body surface is inhabited by normal microbial flora. The flora enhance the effectiveness of the surface barrier. They do this by interfering with the establishment of pathogenic agents in several ways. Indigenous flora compete with pathogens for space and nutrients. They maintain a pH optimal for their own growth. This pH can be incompatible with that needed for many pathogenic agents to survive. Some flora also secrete germicidal substances and are thought to stimulate the immune system.

Normal flora play a key role in the body's defense. However, some indigenous flora can be pathogenic under certain conditions. For example, flora can cause infection when the skin or mucous membranes are interrupted. They also can cause infection when flora are displaced from their natural habitat to another area of the body. (This is a common cause of urinary tract infection after catheterization of the bladder.)

SKIN

Intact skin defends against infection. It does this in two ways. First, it prevents penetration. Second, it maintains an acidic pH level that inhibits the growth of pathogenic bacteria. In addition, microbes are sloughed from the skin's surface with dead skin cells, and oil and sweat wash microorganisms from the skin's pores.

GASTROINTESTINAL SYSTEM

The normal bacteria in the gastrointestinal (GI) system provide competition between colonies of microorganisms for nutrients and space. Normal bacteria help prevent the growth of pathogenic organisms (Box 28-8). In addition, stomach acid may destroy some microorganisms. It also may deactivate their toxic products. The digestive system eliminates pathogens through feces.

UPPER RESPIRATORY TRACT

The sticky membranes of the upper airway protect against pathogens. They do this by trapping large particles. These particles may then be swallowed or expelled by coughing or sneezing. Coarse nasal hairs and cilia also trap and filter foreign substances in inspired air. They prevent the pathogens from reaching the lower respiratory tract. In addition, the lymph tissues of the tonsils and adenoids allow a rapid local immunological response to pathogenic organisms that may enter the respiratory tract.

BOX 28-8 *Clostridium difficile*

Clostridium difficile, often called *C. difficile* or "C. diff," is a bacterium that normally is present in small numbers in the intestines. C. diff can overpopulate the colon, especially after extended antibiotic therapy. This can lead to **C. diff colitis.** The toxins attack the intestinal wall and cause ulcerations. Initially, diarrhea and cramping occur. This is followed by flulike symptoms, weakness, abdominal pain, fever, nausea, vomiting, dehydration, and bloody stools. In late stages, life-threatening inflammation of the colon can occur. This can result in sepsis and, rarely, death. Illness from C. diff most commonly affects older adults in hospitals or in long-term care facilities. The disease can be spread through the fecal-oral route. Universal precautions are indicated.

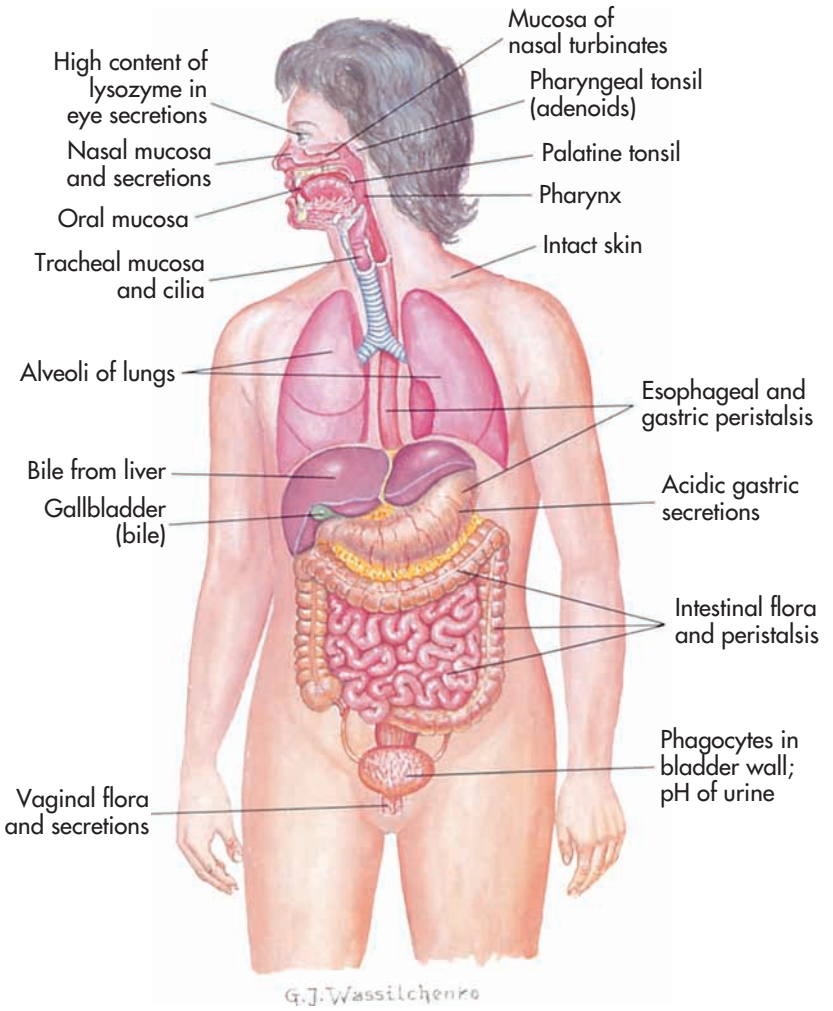

FIGURE 28-3 First line of defense: external barriers. (From Grimes D: *Infectious diseases,* St Louis, 1991, Mosby.)

GENITOURINARY TRACT

The natural process of urination and urine's ability to kill bacteria help prevent infections in the GU tract. Antibacterial substances in prostatic fluid and the vagina also help prevent infection in the GU system.

NOTE

Enterococci are bacteria that are normally present in the human intestines and in the female genital tract and are often found in the environment. These bacteria can sometimes cause infections. Vancomycin is an antibiotic that is often used to treat infections caused by enterococci. In some instances, enterococci have become resistant to this drug and thus are called *vancomycin-resistant enterococci* (VRE). Most VRE infections occur in hospitals. Enterococci also may become resistant to most or all other standard drug therapies (*multidrug-resistant enterococci*).

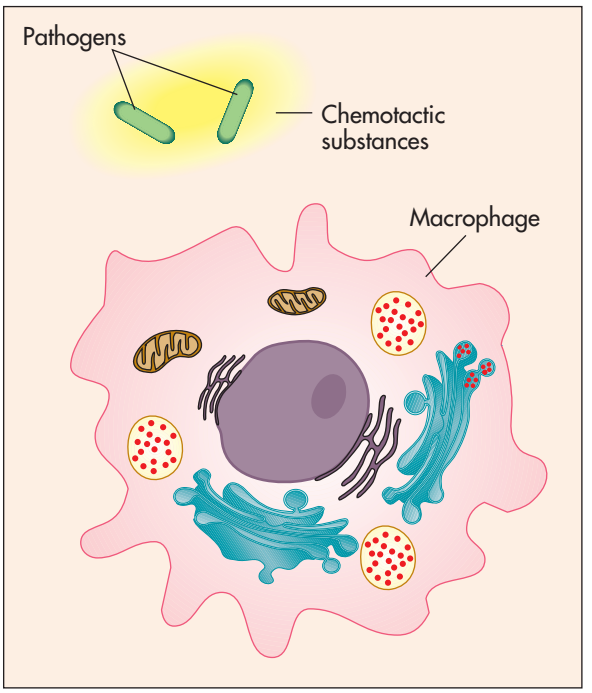
Internal Barriers

Internal barriers protect against germs when the external lines of defense cannot. Internal barriers include the inflammatory response and the immune response. These share many of the same processes and cellular components.

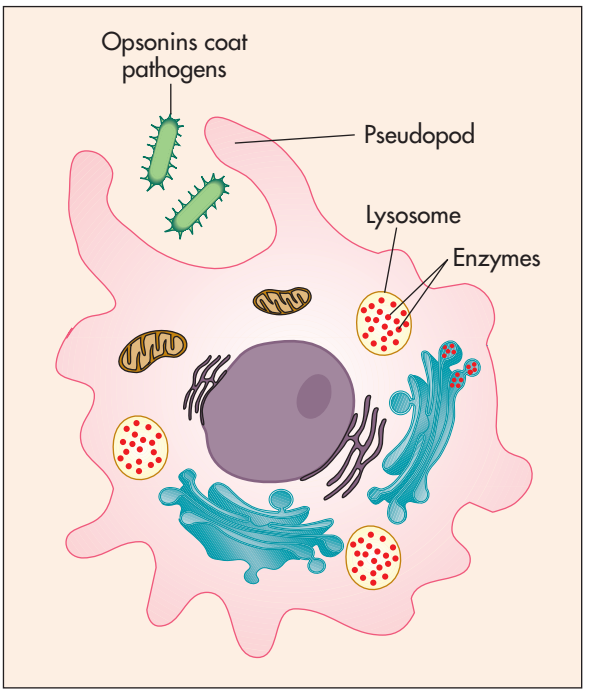
INFLAMMATORY RESPONSE

Inflammation (described in Chapters 11 and 27) is a local reaction to cellular injury. It occurs in response to a microbial infection. When invasion occurs, this line of defense is activated. It works to prevent further invasion of the pathogen by isolating, destroying, or neutralizing the microorganism (Figure 28-4).

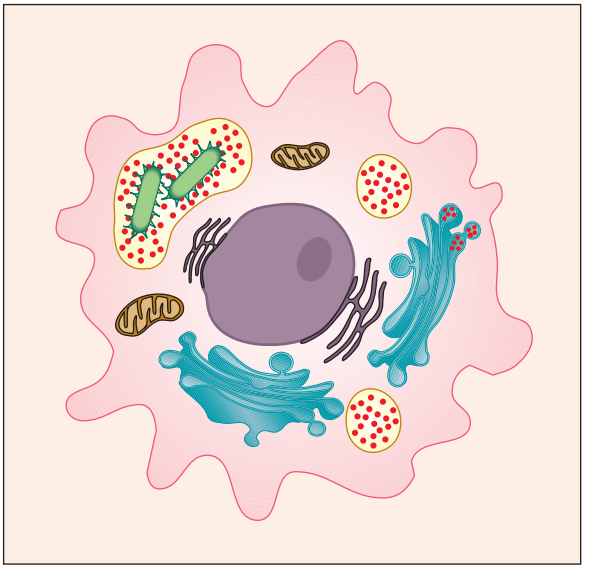
The inflammatory response usually is protective and beneficial. However, it may initiate destruction of the body's own tissue. It may be destructive if the response is sustained or directed against the host's own antigens. To review, the



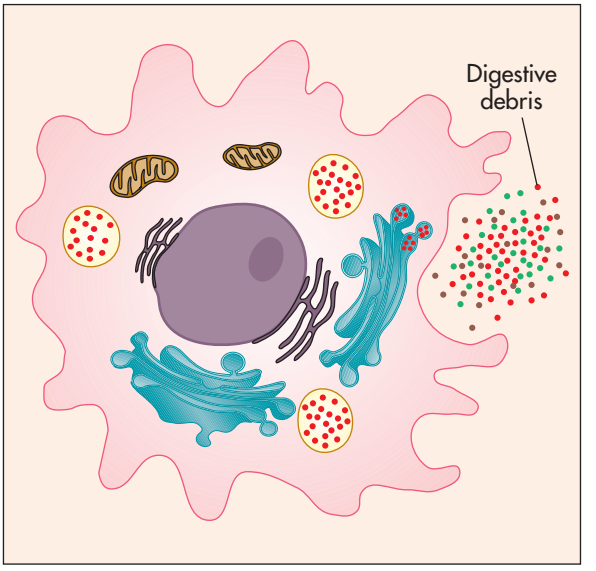
1. Injured area produces chemotactic exudate that attracts macrophages in area.



2. Opsonins facilitate phagocytosis.



3. The engulfed pathogen becomes digested by enzymes in the lysosomes.



4. The macrophage expels debris after digestion is complete, including prostaglandins, interferon, and complement components. These elements continue the immune response.

FIGURE 28-4 Second line of defense: inflammatory response. (From Grimes D: *Infectious diseases,* St Louis, 1991, Mosby.)

inflammatory response may be divided into three separate stages: first, cellular response to injury; second, vascular response to injury; and third, phagocytosis.

Cellular Response to Injury. The body mounts various types of cellular response to injury. The processes responsible for the cellular injury also are complex. Some cells are the targets of specific inflammatory mediators (e.g., leukotrienes, histamine). When these cells are injured, the cell's metabolism is damaged. This leads to decreasing energy reserves in the cell. When the energy reserves are depleted, an accumulation of sodium ions causes the cell to swell. Along with increasing acidosis, this swelling further impairs the cell's ability to function. It leads to deterioration of the cell membranes. Eventually, the membranes of the cells begin to leak. This contributes to cellular destruction, autolysis, and stimulation of the inflammatory response in surrounding tissues.

Vascular Response to Injury. Localized hyperemia (an increase in bloodflow in the area) develops after cellular injury. This produces edema. Leukocytes collect inside the vessels. There they release **chemotactic factors** (chemicals that attract more leukocytes to the area). These factors eventually migrate to the injured tissue.

CRITICAL THINKING

What physical examination finding is related to this infection fighting property?

Phagocytosis. Through phagocytosis, leukocytes engulf, digest, and destroy the invading pathogens. Circulating macrophages clear the area of dead cells and other debris. The ingestion of bacteria and dead cells (internal phagocytosis) releases chemicals that destroy leukocytes.

STAGES OF INFECTIOUS DISEASE

The progression from exposure to an infectious agent to the onset of clinical disease follows specific stages. The duration of each stage and the potential outcomes vary, depending on the infectious agent and individual host factors. These stages are the latent period, the incubation period, the communicability period, and the disease period (Table 28-2). The risk of infection may be *theoretical.* That is, transmission is acknowledged to be possible but has not actually occurred. The risk of infection is considered *measurable* when infection is confirmed or deduced from reported data.

Latent Period

The **latent period** begins when the pathogen invades the body. During this period, infection has occurred but the infectious agent cannot be passed (or "shed") to someone else or cause clinically significant symptoms. In some diseases (e.g., HIV), the latent period is quite stable and can last several years. In others (e.g., influenza), the latent period may last only 24 to 72 hours. The latent period as a stage of infectious disease is distinct from a latent infection. A *latent infection* is an inactive infection that can still shed and produce symptoms; a *latent disease* is characterized by periods of inactivity either before signs and symptoms appear or between attacks. Herpes viruses are examples of pathogens that readily enter a latent stage. During this stage, symptoms disappear. They reappear at a later time upon reactivation of the latent infection.

TABLE 28-2 Stages of Infectious Disease

Stage	Begins	Ends
Latent period	With invasion	When agent can be shed
Incubation period	With invasion	When disease process begins
Communicability period	When latent period ends	Continues as long as agent is present and can spread to others
Disease period	Follows incubation period	Variable duration

Incubation Period

The **incubation period** is the interval between exposure to the pathogen and the first onset of symptoms. Like the latent period, the incubation period varies in length. It can range from hours to 15 years or longer, as is seen with some individuals with HIV infection. During the incubation period, the infectious organism reproduces in the host. The body is stimulated to produce antibodies specific for the disease or antigen. A person's blood may test positive (seroconversion) for exposure to the disease. A *window phase,* however, follows infection. In this phase, the antigen is present but there is no detectable antibody. A person whose blood is tested for disease-specific antibodies in the window phase may test negative, even when infection is present.

Communicability Period

The **communicability period** follows the latent period. It lasts as long as the agent is present and can spread to other hosts. (Clinically significant symptoms from the infection may manifest during this period.) This stage is variable. It often is the major determining factor in ease of transmission. The communicability period and the method of transmission can be altered in some diseases (e.g., tuberculosis, syphilis, gonorrhea). This depends on the stage of the disease and the primary site of infection.

Disease Period

The **disease period** follows the incubation period. It varies in duration, depending on the specific disease. This stage may be free of symptoms or it may produce overt symptoms. These symptoms can arise directly from the invading organism or from the body's response to the disease. During the disease period, the body may be able to rid itself of the disease entirely. On the other hand, the organism may become incorporated and lie inactive inside certain cells (a latent disease). Several viruses (e.g., HIV and hepatitis) can lead to latent infection. The resolution of symptoms does not mean the infectious agent has been destroyed.

CRITICAL THINKING

Which of the four stages of infectious disease can overlap? What problems can the overlap (or overlaps) pose?

HUMAN IMMUNODEFICIENCY VIRUS

Human immunodeficiency virus (HIV) is present in the blood and serum-derived body fluids (semen, vaginal or cervical secretions) of people infected with the virus. The disease is directly transmitted person to person. It is passed through anal or vaginal intercourse, across the placenta, or by contact between infected blood or body fluids and mucous membranes or open wounds. It also can be transmitted indirectly. This occurs through transfusion with contaminated blood or blood products, transplantation of tissues and organs, and the use of contaminated needles or syringes. The incidence of HIV is highest in people with the following risk factors:

- High-risk sexual behavior
- Intravenous drug abuse
- Transfusion recipient between 1978 and 1985
- Hemophilia or other coagulation disorders requiring blood products
- Infant born to an HIV-positive mother

Other factors that may affect susceptibility to HIV include concurrent sexually transmitted diseases (STDs). This is especially true for those that cause skin ulcerations.

Pathophysiology

HIV infection results from one of two retroviruses that convert genetic ribonucleic acid (RNA) to deoxyribonucleic acid (DNA) after entering the host cell. The two types are known as *HIV-1* and *HIV-2*. Once the retrovirus is inside the cell, the cell's genetic material is altered into a hybrid of part virus and part cell. The virus basically takes over the cell to make more viral particles. When enough of the viral particles have been produced, the host cell ruptures. This destroys the cell and releases the virus into the blood to seek new target cells. The cell receptor sought by HIV is a T cell that has molecules called CD4 on its surface (CD4 T cell). When HIV attaches itself to the CD4 molecule, it allows the virus to enter and infect the cells, damaging them in the process. The CD4 T-cell count is used to determine how active the disease is; a very low count suggests severe disease. These CD4 molecules are also found on the surface of certain nerve cells, and monocytes and phagocytes, which probably carry the disease to other parts of the body. Even though the body develops antigen-specific antibodies to HIV, these antibodies do not protect against HIV. Secondary complications generally are caused by **opportunistic infections** that develop as the immune system deteriorates. These infections include the following:

- Pulmonary tuberculosis
- Recurrent pneumonia
- *Pneumocystis carinii* pneumonia
- Kaposi sarcoma
- Wasting syndrome
- HIV dementia
- Sensory neuropathy
- Toxoplasmosis of the central nervous system

NOTE

The two types of HIV (HIV-1 and HIV-2) are serologically and geographically distinct. However, they have similar epidemiological characteristics. HIV-1 is much more pathogenic than HIV-2. Most cases worldwide and in the United States are caused by HIV-1. HIV-2 seems to be more restricted to West Africa.[13] Some blood screening procedures test only for HIV-1.

Classification and Categories

The average interval from transmission of HIV to the development of serious complications is about 10 years if the condition is untreated. However, this time frame can vary greatly (Table 28-3).

The CDC has devised a classification system for HIV (revised in 1993) with three categories based on the CD4 T-cell count[14]:

Category 1: Cell count of 500/μL or higher
Category 2: Cell count of 200 to 499/μL
Category 3: Cell count below 200/μL

As the number of CD4 T cells decreases, the risk and severity of opportunistic illness increase. After viral transmission, the progression of HIV in adolescents and adults can be divided into three clinical categories: A, B, and C.

CATEGORY A

- *Acute retroviral infection:* This syndrome generally occurs 2 to 4 weeks after exposure. Clinical features include an infectious mononucleosis–like illness with fever, adenopathy, and sore throat. The febrile illness is self-limited. It usually lasts 1 to 2 weeks. During this stage, a transient decrease is observed in the CD4 T-cell count.

TABLE 28-3 Incubation and Communicability Periods of Various Infectious Diseases

Incubation Period	Communicability Period
Childhood Diseases	
Chickenpox	
2 to 3 weeks (average 13 to 17 days)	Occurs 1 or 2 days before onset of rash and until lesions have crusted over and not more than 6 days after appearance of vesicles
Mumps	
2 to 3 weeks (average 18 days)	Occurs 6 days before parotid symptoms to 9 days after; disease is most communicable 48 hours after parotid swelling develops
Pertussis	
7 to 14 days, commonly 7 to 10 days	Occurs 7 days after exposure and lasts 3 weeks after onset; highly communicable in early stage before cough; not communicable after 3 weeks, although cough may be present
Rubella	
14 to 23 days (average 16 to 18 days)	Occurs from 1 week before to 4 days after appearance of rash; infants with congenital rubella syndrome may shed virus for months after birth
Rubeola	
Commonly 10 days, 8 to 13 days until fever, 14 days until rash	Occurs a few days before fever to 5 to 7 days after appearance of rash
Hantavirus	
3 days to 6 weeks	No known human-to-human transmission
Hepatitis Virus	
Hepatitis A Virus (HAV)	
15 to 50 days (average 28 to 30 days)	Usually occurs in latter half of incubation period and continues for several days after onset of jaundice
Hepatitis B Virus (HBV)	
45 to 180 days (average 60 to 90 days)	Occurs during incubation period and lasts throughout clinical course (carrier state may persist for years)
Hepatitis C Virus (HCV)	
2 weeks to 6 months (average 6 to 9 weeks)	Occurs 1 or more weeks before onset of symptoms and indefinitely during chronic and carrier states
Human Immunodeficiency Virus (HIV)	
Varies: 6 to 12 weeks from exposure to seropositivity, up to 20 years for symptomatic immune suppression and to diagnosis of acquired immunodeficiency syndrome (AIDS)	Is lifelong from presence of HIV in serum until death; degree of communicability may vary during course of HIV infection
Influenza	
24 to 72 hours	Occurs 3 days after onset of symptoms; infection produces immunity to specific strain of virus, but duration of immunity varies
Meningitis	
2 to 10 days	Varies; lasts as long as infectious agents remain in nasal and oral secretions; microorganisms disappear from upper respiratory tract within 24 hours of antibiotic therapy
Mononucleosis	
4 to 6 weeks	Prolonged; pharyngeal excretion may last for years; 15% to 20% of adults are carriers

Continued

TABLE 28-3—cont'd

Incubation Period	Communicability Period
Pneumonia	
1 to 3 days	Occurs until organisms have been eliminated from respiratory discharges (24 to 48 hours after antibiotic treatment)
Rabies	
Usually 2 to 16 weeks	Human-to-human transmission by bite, scratch, or aerosolization has not been documented; theoretical transmission from contact with secretions of infected person
Severe Acute Respiratory Syndrome (SARS)	
10 days	Information to date suggests that people are most likely to be infectious when they have symptoms, such as fever or cough; however, it is not known how long before or after symptoms appear that disease can be transmitted
Sexually Transmitted Diseases	
Chlamydia	
5 to 10 days	Unknown
Gonorrhea	
2 to 7 days	Occurs for months if disease is untreated
Herpes Simplex Virus (HSV)	
HSV-1: 2 to 12 days	Occurs when lesions are present; virus is found in saliva as long as 7 weeks after recovery from lesions; transient shedding of virus is common
HSV-2: 2 to 12 days (average 6 days)	Occurs in 7 to 12 days with lesion; transient shedding of virus in absence of lesions probably occurs
Syphilis	
10 days to 10 weeks (average 3 weeks)	Varies; occurs during primary and secondary stages and in mucocutaneous recurrences (2 to 4 years if disease is untreated)
Tetanus	
3 to 21 days, commonly 10 days	Not directly transmitted; recovery from tetanus does not confer permanent immunity
Tuberculosis (TB)	
4 to 12 weeks after exposure or any time disease is in a latent stage	Occurs as long as bacilli are present in sputum, sometimes intermittently for years

- *Seroconversion:* The serological response with antigen-specific antibodies to HIV generally occurs 6 to 12 weeks after transmission. During this stage, the CD4 T-cell count returns to normal.

CRITICAL THINKING

What will probably happen if a sample is drawn for a blood test for HIV antibodies during the third week after exposure?

- *Asymptomatic infection:* The individual with HIV may have persistent generalized lymphadenopathy (enlarged lymph nodes involving two noncontiguous sites other than inguinal nodes) and a gradual decline in the CD4 T-cell count.

CATEGORY B

- *Early symptomatic HIV:* The usual CD4 T-cell count in this group is 100 to 300/μL. At this stage, common complications include localized candidal infections (thrush, *Candida* esophagitis, *Candida* vaginitis), oral lesions, shingles, pelvic inflammatory disease, peripheral neuropathy, and constitutional symptoms such as fever or diarrhea that last longer than 1 month.

CATEGORY C

- *Late symptomatic HIV:* This stage represents all acquired immunodeficiency syndrome (AIDS)-defining diagnoses found primarily with CD4 T-cell counts of 0 to 200/μL, including severe opportunistic infections; bacterial pneumonia (e.g., *P. carinii* pneumonia); pulmonary

FIGURE 28-5 Kaposi sarcoma of the heel and lateral foot. (Courtesy Centers for Disease Control and Prevention, 1990. In Grimes D: *Infectious diseases,* St Louis, 1991, Mosby.)

FIGURE 28-6 Kaposi sarcoma of the distal leg and ankle. (Courtesy Centers for Disease Control and Prevention, 1990. In Grimes D: *Infectious diseases,* St Louis, 1991, Mosby.)

tuberculosis; debilitating diarrhea; tumors in any body system, including Kaposi sarcoma (Figures 28-5 and 28-6); HIV-associated dementia; and neurological manifestations.

- *Advanced HIV:* In this stage, the person has a CD4 T-cell count of 0 to 50/μL. These patients have a limited life expectancy, and most of them die of AIDS-related complications.

Personal Protection

Strict compliance with universal precautions is the only preventive measure health care workers can take against HIV. However, the chance of EMS personnel acquiring the infection through exposure to infected blood appears to be low (0.2% to 0.44%).[6] HBV exposure is a much greater occupational hazard. The risk to health care workers increases under the following circumstances:

1. The exposure involves a large amount of blood. This can occur when a piece of equipment is visibly contaminated with blood; when care of the patient involves placing a needle in a vein or an artery; and when the patient has deep injuries. The needle size and type (hollow bore or suture) and the depth of penetration influence the volume transferred to the skin. Health care workers suffer 600,000 to 800,000 injuries from conventional needles and sharps each year.[15]

CRITICAL THINKING
Why would testing within 2 to 3 weeks of exposure be needed?

2. The exposure involves a patient with a terminal illness, possibly reflecting a higher dose of HIV in the late course of AIDS. The risk of exposure must be understood in terms of how the exposure occurred and what factors were involved. Although the potential may appear high, the probability actually may be quite low. Paramedics should follow agency protocol for notification and reporting of significant exposures to any infectious disease.

Postexposure Prophylaxis

If exposure is confirmed or suspected, the paramedic should immediately notify the DO (per protocol). This allows elective postexposure prophylaxis (PEP) to begin. Information on primary HIV indicates that systemic infection does not occur immediately; this leaves a narrow window of opportunity in which postexposure antiretroviral intervention may modify viral replication.[13] Several antiretroviral agents from at least four classes of drugs are available for the treatment of HIV. Examples include fusion inhibitors, nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), and protease inhibitors (PIs). After PEP, testing for HIV is performed 2 to 3 weeks after the exposure. It is performed again at 6 weeks, 3 months, 6 months, and 1 year.

NOTE

An important goal of PEP is to encourage and facilitate compliance with a 4-week PEP regimen of two drugs used for most HIV exposures. Combinations that can be considered for PEP include zidovudine (ZDV) and lamivudine (3TC) or emtricitabine (FTC); stavudine (d4T) and 3TC or FTC; and tenofovir (TDF) and 3TC or FTC. Moreover, an expanded regimen that includes the addition of a third drug is used for cases of HIV exposures that have an increased risk of transmission. When the patient's virus is known or suspected to be resistant to one or more of the drugs considered for the PEP regimen, the selection of drugs to which the virus is unlikely to be resistant is recommended.[16] All antiretroviral drugs have been associated with side effects (mainly gastrointestinal). In addition, some of these drugs (especially protease inhibitors) cause potentially serious drug interactions. Paramedics should receive counseling regarding evaluation and treatment after an exposure.

Psychological Reactions to HIV

HIV is almost always a progressive disease with morbid late consequences. Throughout the course of the infection, patients are likely to feel and express anger about many aspects of their illness. These include pain, dying prematurely and without dignity, and the social rejection and prejudice that the person may experience. Patient care should include helping these patients feel that they can obtain acceptance and compassion from health care workers.

Although no vaccine exists for HIV, many clinical trials are underway. Despite current limitations, the progression of the illness can be delayed with drug therapy and other strategies. This allows time for access to new therapeutic options.

HEPATITIS

As described in Chapter 30, **hepatitis** is a viral disease that produces pathological changes in the liver. The hepatitis viruses are divided into three main classes: **hepatitis A** (viral hepatitis), **hepatitis B** (serum hepatitis), and **hepatitis C** (non-A/non-B hepatitis) (Table 28-4).

NOTE

Hepatitis non-ABC is a fourth class of hepatitis caused by infection with the hepatitis D (delta) virus. HDV cannot sustain infection without the help of HBV. Two newer hepatitis viruses (E and G) can also cause infection of the liver. HVE and HVG (also known as GBV-C) are rare viruses. The routes of transmission for these viruses are thought to be similar to those for the hepatitis C virus (HCV).

Hepatitis A Virus

Hepatitis A (HAV) is the most common type of viral hepatitis in the United States, accounting for 42,000 infections in 2005.[14] The disease is acquired by ingesting HAV-contaminated food or drink. It also is acquired by the fecal/oral route. The virus localizes in the liver, reproduces, enters the bile, and is carried to the intestinal tract. From there it is shed in the feces. (Fecal shedding usually occurs before the onset of clinical symptoms.) Antibodies (anti-HAV) develop during acute disease. They also develop late in convalescence. Once infected, the person is immune to HAV for life. Hepatitis A is the only hepatitis virus that does not lead to chronic liver disease or a chronic carrier state. Many HAV infections are subclinical. They often manifest with influenza-like symptoms. About 1 in 100 patients with HAV suffers from a sudden and severe infection that may require a liver transplant.[17]

Immune globulin (IG) can provide temporary immunity to the virus (i.e., 2 to 3 months). It must be given before exposure to HAV or within 2 weeks after contact. Hepatitis A vaccines approved for people 2 years of age or older are recommended for the following groups:

- People who have close physical contact with those who live in areas with poor sanitary conditions or who are traveling or working in developing countries
- Employees in certain job classes, such as the foodservice industry (may be required in some communities)
- Men who have sex with other men
- Users of illicit drugs
- Children in populations that have repeated epidemics of hepatitis A (Native Alaskans, Native Americans, Pacific Islanders, and certain closed religious communities)
- People who have chronic liver disease or clotting factor disorders

The safety of the vaccine during pregnancy has not been determined.

Hepatitis B Virus

Infectious HBV particles are found in blood and in secretions containing serum (e.g., oozing, cutaneous lesions). They also are found in secretions derived from serum (e.g., saliva, semen, vaginal secretions). Like other viral types of

TABLE 28-4 The ABC's of Hepatitis

	Hepatitis A (HAV)	Hepatitis B (HBV)	Hepatitis C (HCV)	Hepatitis D (HDV)	Hepatitis E (HEV)
What Is It?	HAV is a virus that causes inflammation of the liver. It does not lead to chronic disease.	HBV is a virus that causes inflammation of the liver. It can cause liver cell damage, leading to cirrhosis and cancer.	HCV is a virus that causes inflammation of the liver. It can cause liver cell damage, leading to cirrhosis and cancer.	HDV is a virus that causes inflammation of the liver. It only infects those persons with HBV.	HEV is a virus that causes inflammation of the liver. It is rare in the U.S. Rarely it can cause chronic disease
Incubation Period	2 to 7 weeks. Average 4 weeks.	6 to 23 weeks. Average 17 weeks.	2 to 25 weeks. Average 7 to 9 wks.	2 to 8 weeks.	2 to 9 weeks. Average 40 days.
How Is It Spread?	Transmitted by fecal/oral (anal/oral sex) route, close person-to-person contact or ingestion of contaminated food and water. Hand to mouth after contact with feces, such as changing diapers.	Contact with infected blood, seminal fluid, vaginal secretions, contaminated needles, including tattoo and body-piercing tools. Infected mother to newborn. Human bite. Sexual contact.	Contact with infected blood, contaminated IV needles, razors, and tattoo and body-piercing tools, Infected mother to newborn. Not easily spread through sex.	Contact with infected blood, contaminated needles. Sexual contact with HDV infected person.	Transmitted through fecal/oral route. Outbreaks associated with contaminated water supply in other countries.
Symptoms	Children may have none. Adults usually have light stools, dark urine, fatigue, fever, nausea, vomiting, abdominal pain, and jaundice.	May have none. Some persons have mild flulike symptoms, dark urine, light stools, jaundice, fatigue, and fever.	Same as HBV	Same as HBV	Same as HAV
Treatment of Chronic Disease	Not applicable	Peginterferon, entecavir, and tenofovir are first-line treatment options.	Peginterferon with ribavirin and serine protease adjuncts.	Peginterferon with varying success.	Ribavirin for chronic hepatitis E but needs confirmation
Vaccine	Two doses of vaccine to anyone over 1 year of age.	Three doses may be given to persons of any age.	None for HCV. Should receive Hepatitis A and B vaccines	HBV vaccine prevents HDV infection.	None commercially available
Who Is at Risk?	Household or sexual contact with an infected person or living in an area with HAV outbreak. Travelers to developing countries, persons engaging in anal/oral sex, and injection drug users.	Infants born to infected mother, having sex with an infected person or multiple partners, injection drug users, emergency responders, health care workers, persons engaging in anal/oral sex, and hemodialysis patients.	Blood transfusion recipients before 1992, health care workers, injection drug users, hemodialysis patients, infants born to infected mother, multiple sex partners.	Injection drug users, persons engaging in anal/oral sex, and those having sex with an HDV-infected patient.	Travelers to developing countries, especially pregnant women.
Prevention	Vaccination or immune globulin within 2 weeks of exposure. Washing hands with soap and water after going to the toilet. Use household bleach (10 parts water to 1 part bleach) to clean surfaces contaminated with feces, such as changing tables. Safer sex.	Vaccination provides protection for 20 plus years. Clean up blood with household bleach and wear protective gloves. Do not share razors, toothbrushes, or needles. Safer sex. Hepatitis B immune globulin for vaccine non-responders after exposure.	Clean up spilled blood with household bleach. Wear gloves when touching blood. Do not share razors, toothbrushes, or needles with anyone. Safer sex.	Hepatitis B vaccine to prevent HBV/HDV infection, Safer sex.	Avoid drinking or using potentially contaminated water.

Hepatitis Foundation International, 504 Blick Drive, Silver Spring, Md 20904, 1-800-891-0707, www.HepatitisFoundation.org

hepatitis, HBV affects the liver and causes the signs and symptoms described previously. The virus may produce chronic infection. This can lead to cirrhosis and other complications. Although HBV usually lasts less than 6 months, the carrier state may persist for years.

NOTE
HBV is 100 times more infectious than HIV. One in 20 Americans will become infected with HBV at some time in their lives. There are an estimated 350 million people infected with the disease worldwide.[17]

The effects of HBV vary. Only a low-grade fever and malaise (influenza-like illness) may occur, with complete resolution of symptoms. On the other hand, extensive liver necrosis may develop that can lead to death. Other complications associated with HBV include coagulation defects, impaired protein production, impaired bilirubin elimination, pancreatitis, and hepatic cancer. Exposure generally occurs in one of five ways:

1. Direct percutaneous inoculation of infectious serum or plasma by needle or transfusion of infected blood or blood products
2. Indirect percutaneous introduction of infective serum or plasma (e.g., skin cuts or abrasions, tattoo/body piercing)
3. Absorption of infective serum or plasma through mucosal surfaces (e.g., the eyes or mouth), transplacentally, or through contamination from the mother's infected blood at birth
4. Absorption of infective secretions (e.g., saliva or semen) through mucosal surfaces, as might occur during vaginal, anal, or oral sexual contact (but never fecal transmission), and straws shared in snorting drugs
5. Transfer of infective serum or plasma via inanimate environmental surfaces

HBV is stable on environmental surfaces and can remain infective in visible blood for longer than 7 days.[17]

CRITICAL THINKING
Why is information about exposure risks important to paramedics?

PREEXPOSURE PROPHYLAXIS

With regulatory and legislative efforts and the publication of OSHA's *Bloodborne Pathogen Standard,* cases of HBV in health care workers have dropped dramatically. (The exposure risk for health care providers working with HBV-positive patients is estimated to be 2% to 40%.) Yet, even with this decline, HBV is a serious concern to all health care workers. The CDC recommends and OSHA requires that HBV vaccines be offered to all health care workers. The vaccine sometimes is given to newborns. Several states now require immunization of children who are middle school age.

Blood is the most important potential source of HBV in the workplace. The risk of infection is directly proportional to the probability that the blood contains HBV, the recipient's immunity status, and the efficacy of transmission. HBV vaccinations are available that provide protection for 18 years in those who respond to the inoculation.[16] The HBV vaccination schedule generally requires three doses over 6 months. These are intramuscular (deltoid) doses. For the best protection against HBV, the series should be completed before an exposure occurs. Vaccinations currently available include Recombivax HB and Engerix-B.

POSTEXPOSURE PROPHYLAXIS

Postexposure prophylaxis may be indicated if an unvaccinated person or a person who has not completed the vaccination schedule is exposed to HBV. Before treatment, a blood test is performed to determine immunity to HBV. People who are not immune generally receive the HBV vaccine and hepatitis B immune globulin. (This is an antibody used in postexposure treatment to provide passive immunity to HBV.)

Hepatitis C Virus

Hepatitis C virus (HCV) is a blood-borne virus. It causes a disease similar to HBV. The virus was associated with receipt of contaminated blood during transfusion before 1992. (It accounts for more than 90% of posttransfusion hepatitis cases in the United States.) Currently, about 4 million Americans are believed to be infected with the virus. Hepatitis C is the infection that most often results from needle-stick and sharps injury.[18,19] Of health care workers who become infected, 85% become chronic carriers. About one half to two thirds of those infected with HCV develop chronic hepatitis; one in five suffers severe liver disease, such as cirrhosis and liver cancer. No vaccine is available for HCV.

Although HCV is transmitted in the same manner as other forms of hepatitis, it is not easily spread through sexual contact. Signs and symptoms of the disease, when they occur, are similar to those of other types of hepatitis. Most people infected with HCV are asymptomatic.

Signs and Symptoms

Infection with any of the causative viruses may not produce any symptoms. On the other hand, it may cause a typical hepatitis with an abrupt onset of flulike illness that is followed by jaundice or dark urine, or both. A patient is most infectious during the first week of symptoms (see Table 28-3). Within 2 to 3 months of infection, the patient usually develops nonspecific symptoms. These may include anorexia, nausea and vomiting, fever, joint pain, and generalized rashes. About 1% of patients hospitalized with HBV develop full-blown liver crisis and die (Box 28-9).

BOX 28-9 Antiviral Therapy With Interferons

Interferons are proteins produced naturally by body cells in response to viral infection and other stimuli. Interferon alfa (Intron A and others) is effective at controlling the spread of common colds caused by rhinoviruses. It may be effective at treating chronic infections caused by the hepatitis B and C viruses (HBV and HCV, respectively) and the human immunodeficiency virus (HIV). The U.S. Food and Drug Administration (FDA) has approved combination therapy with Pegasys (peginterferon alfa-2a) and Copegus (ribavirin) for the treatment of adults with chronic hepatitis C who have compensated liver disease and have not previously been treated with interferon alpha.

Interferons work by attaching to the membranes of host cells and stimulating the host cells to attack the virus. If a virus invades a cell primed by interferon, enzymes are produced that impair viral copying. This nullifies the virus. Interferons also increase the activity of natural killer cells to stop or shorten the effects of the virus. Side effects of interferon include fever, malaise, headache, fatigue, hair loss, and bone marrow suppression.

Patient Management and Protective Measures

The management of patients out of the hospital is mainly supportive. The goal is to maintain circulatory status and prevent shock. All health care workers involved in the patient's care must follow careful personal protective measures. This includes effective hand washing. It also involves proper care in the use of diagnostic and therapeutic equipment (e.g., high-level disinfection of laryngoscope blades) and appropriate disposal of sharps.

TUBERCULOSIS

Each year, 9 million new cases of **tuberculosis** (TB) occur worldwide, and 2 million people die of the disease.[20] Reports of TB in the United States had declined continually since the turn of the twentieth century. However, in 1985 this trend reversed (attributed to the epidemic of HIV). The incidence of tuberculosis (TB) among patients with HIV is 40 times the incidence among people who are not infected with HIV. TB is the leading killer of people infected with HIV.[20] Other risk factors for TB include:

- Immigration of people from areas with a high prevalence of TB
- Transmission of TB in high-risk environments, such as correctional facilities, homeless shelters, hospitals, and nursing homes
- Deterioration of the TB public health care infrastructure

CRITICAL THINKING
Why is TB more prevalent in patients with HIV?

Pathophysiology

As described in Chapter 24, TB is a chronic pulmonary disease. It is acquired through inhalation of a dried-droplet nucleus containing tubercle bacilli (*Mycobacterium tuberculosis, Mycobacterium bovis,* or a variety of atypical mycobacteria). TB is passed mainly by infected persons coughing or sneezing the bacteria into the air. It can also be passed through contact with the sputum of an infected person. People who share the same air space as those who have infectious TB are at highest risk for infection. Transmission also may occur by ingestion or through the skin or mucous membranes. However, this is less common.

The pathology of TB is related to the production of inflammatory lesions throughout the body. It also is related to the ability of the TB bacillus to break through the body's natural defenses. This leads to the formation of caseating granulomas (necrotic inflammatory cells) and TB cavities. These may cause chronic and debilitating lung disease. Susceptibility to mycobacterial infection generally is highest in children younger than 3 years of age; in adults older than 65; and in chronically ill, malnourished, and immunosuppressed or immunocompromised individuals. The infection may remain dormant for an indefinite time (often not causing disease), or it may lead to active, contagious disease. As a result, two TB-related conditions exist. They are **latent TB infection** (LTBI) and **TB disease** (Table 28-5).

Signs and symptoms of TB include cough, fever, night sweats, weight loss, fatigue, and hemoptysis. The organ systems affected and the associated complications include the following:

1. Cardiovascular system
   - Pericardial effusions
   - Lymphadenopathy (cervical lymph nodes are usually involved)
2. Skeletal system
   - Intervertebral disk deterioration
   - Chronic arthritis of one joint
3. Central nervous system (CNS)
   - Subacute meningitis
   - Brain granulomas
4. Systemic miliary TB (extensive dissemination by the bloodstream of tubercle bacilli)

In the United States, an estimated 10 million to 15 million people are infected with *M. tuberculosis.* Without intervention, approximately 10% of these people will develop TB disease at some point in their lives.[21] Paramedics should maintain a high degree of suspicion for TB in individuals with undiagnosed lung disease, especially patients who are HIV positive.

TABLE 28-5 TB Disease: The Difference Between Latent TB Infection and TB Disease

A Person With Latent TB Infection	A Person With TB Disease
• Has no symptoms	• Has symptoms that may include: — a bad cough that lasts 3 weeks or longer — pain in the chest — coughing up blood or sputum — weakness or fatigue — weight loss — no appetite — chills — fever — sweating at night
• Does not feel sick	• Usually feels sick
• Cannot spread TB bacteria to others	• May spread TB bacteria to others
• Usually has a skin test or blood test result indicating TB infection	• Usually has a skin test or blood test result indicating TB infection
• Has a normal chest x-ray and a negative sputum smear	• May have an abnormal chest x-ray, or positive sputum smear or culture
• Needs treatment for latent TB infection to prevent active TB disease	• Needs treatment to treat active TB disease

From Centers for Disease Control and Prevention: *The difference between latent TB infection and TB disease,* Atlanta, www.cdc.gov/tb/topic/basics/default.htm, accessed 10-15-10.

Tuberculosis Testing

The signs and symptoms of initial infection may be minimal. However, early infection can be detected using the Mantoux tuberculin skin test (purified protein derivative [PPD]). A positive reaction to the PPD test indicates past infection and the presence of antibodies. Patients with positive test results usually have a chest x-ray and an acid-fast bacilli (AFB) sputum culture before treatment. Counseling and HIV antibody testing should be offered to all people infected with TB. This is because medical management may be altered if HIV is present. By law, every state is required to report cases of TB. A negative TB skin test result does not fully rule out TB infection. This is especially the case in people with TB-like symptoms, HIV, or AIDS. In these cases, a repeat skin test may be warranted 10 weeks after exposure.

Because identification and early treatment of TB are important, all health care workers should receive a routine evaluation consisting of PPD test and, in some cases, a chest x-ray and AFB culture. A negative immune response does not preclude reinfection with subsequent exposure.

FIGURE 28-7 High-efficiency particulate air (HEPA) respirator.

Patient Care and Protective Measures

Paramedics should be aware of areas with a high incidence of active TB in their service region. (This information is reported by the local health authorities.) Prehospital care for patients with infectious TB is mainly supportive. As with any other infectious disease, universal precautions should be taken during patient care. This includes respiratory barriers for the patient and the paramedic. Surgical masks are insufficient for preventing inhalation of tuberculosis bacteria. However, they do reduce the number of droplet nuclei escaping from the patient. Therefore they should be placed on the patient during transport. NIOSH recommends that health care workers use particulate filter respirators that filter at least 95% of airborne particles when caring for patients with tuberculosis (Figure 28-7 and Box 28-10).[22] Ambulance ventilation systems that include high-efficiency particulate air (HEPA) filtration and a non-recirculating ventilation cycle are another measure for preventing exposure to TB during patient transport. After each call, disinfection of all patient care equipment should be performed.

Treatment

If effective treatment is begun without delay, TB is usually curable. Multidrug-resistant TB is on the rise (Box 28-11). For this reason, most patients with TB are started on a lengthy, four-drug regimen of isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) or streptomycin (SM) until the drug susceptibility results are known. (Patients who undergo preventive therapy should be monitored for drug side effects. They should be watched especially for signs and symptoms of hepatitis.) Sputum and cultures usually become negative 3 to 8 weeks after the start of therapy.

BOX 28-10 Tuberculosis-Protective Respirators

The federal Occupational Safety and Health Administration (OSHA), in conjunction with guidelines established by the Centers for Disease Control and Prevention (CDC), currently requires the use of respirators. OSHA is enforcing their use while developing specific standards for preventing the exposure of health care workers to tuberculosis (TB). The required respirator certified by the National Institute for Occupational Safety and Health (NIOSH) must have a disposable (or replaceable) high-efficiency particulate air (HEPA) filter capable of trapping airborne particles. Whenever respirators (including disposables) are required, a complete respiratory protection program must be implemented in accordance with federal regulations.*

Elements of the required respiratory protection program include the following:

1. Permissible practices for respirator use
2. Respirator program administration
3. Selection of respirators
4. Inspection of respirators
5. Cleaning and maintenance of respirators
6. Storage of respirators
7. Training in respiratory protection
8. Fit testing of respirators (to ensure accurate sizing)
9. Respirator program evaluation
10. Medical surveillance of respirator users

Modified from U.S. Department of Health and Human Services, National Institute of Occupational Safety and Health: *NIOSH guide to the selection and use of particulate respirators,* certified under 42 CFR 84, Washington, DC, Publication No. 96-101, 1996, Author.
*These specifications are found in 29 Code of Federal Register (CFR) 1910.134.

BOX 28-11 Multidrug-Resistant Tuberculosis

During the resurgence of tuberculosis (TB) in the United States that began in 1985, outbreaks of multidrug-resistant TB (MDR-TB) occurred in hospitals and prisons. This resulted in high death rates. It also resulted in transmission to health care workers.

MDR-TB is resistant to conventional drugs (isoniazid and rifampin). It is a very serious form of TB, because preventive therapy is limited. People at high risk for MDR-TB include the following:

- Those recently exposed to MDR-TB (especially if they are immunocompromised)
- TB patients who fail to take medications as prescribed
- TB patients who were prescribed an ineffective treatment regimen
- Patients previously treated for TB

A major cause of treatment failure and drug-resistant TB is failure to follow the treatment regimen. This threatens the health of TB patients and poses a serious public health risk. It also leads to prolonged infectivity and the spread of TB in the community.

PROPHYLACTIC ISONIAZID

For individuals younger than 35 years of age who have a positive result on a PPD skin test and who have not previously been treated, administration of INH is recommended. Isoniazid is not routinely recommended for those younger than 35 years old because it may damage the liver. However, the drug is used if one or more of the following factors is present.[23]

- Recent infection, as evidenced by PPD skin test conversion
- Close or household contact with a known case of infectious TB
- Abnormal chest x-ray
- Prolonged therapy with immunosuppressive drugs
- HIV or other immunosuppressive disease

Patients who are receiving INH should avoid alcohol. This reduces the chance for chemical- or drug-induced hepatitis. (Patients who are receiving INH should also avoid pregnancy.) Side effects of INH include paresthesias, seizures (toxic reaction), orthostatic hypotension, nausea and vomiting, hepatitis, and hypersensitivity to the drug.

MENINGOCOCCAL MENINGITIS

Meningococcal meningitis is also known as *spinal meningitis.* It is inflammation of the membranes that surround the spinal cord and brain. Meningococcal meningitis can be caused by a variety of different bacteria, viruses, and other microorganisms. A major cause of bacterial meningitis is *Neisseria meningitidis.* Like *M. tuberculosis,* it is spread by airborne pathogens. The usual mode of transmission is prolonged, direct contact with upper respiratory tract secretions (discharge from the nose and throat) from an infected person or carrier. Once inhaled, the bacteria invade the respiratory passages. They travel by way of the blood to the brain and spinal cord. As the infecting agent spreads to more organs, it causes toxic effects in the involved organ system.

Meningitis strikes an estimated 15,000 Americans each year[24] and an estimated 2% to 10% of the population may carry meningococci at any one time. The throat's epithelial lining generally prevents the germ from invading the meninges and the cerebrospinal fluid. Although the conversion from carrier to clinical disease is rare in developed countries, outbreaks of disease in the United States have increased since the 1990s, partly because of increased rates of disease in people who may have a common organizational affiliation or who live in the same community.[25]

Other Infectious Agents Known to Cause Meningitis

Other common pathogens that cause meningitis include *Streptococcus pneumoniae* and *Haemophilus influenzae* type b (Hib), and some viruses. *S. pneumoniae* is the second most common cause of bacterial meningitis in adults, the most common cause of pneumonia in adults, and the most common cause of otitis media (middle ear infection) in

children. This bacterium is spread by droplets, prolonged personal contact, or extended contact with linen soiled with respiratory discharges.

H. influenzae has the same mode of transmission as *N. meningitidis.* Vaccines for children were introduced in 1981. Before that time, *H. influenzae* was the leading cause of bacterial meningitis in children 6 months to 3 years of age. (This bacterium is also responsible for conditions such as pediatric epiglottitis, septic arthritis, and generalized sepsis.) This type of meningitis can be treated with antibiotics. However, 50% of infected children have lasting damage to the nervous system.[26]

Fortunately, none of the bacteria that cause meningitis are as contagious as the common cold or flu. In addition, they are not spread by casual contact or by simply breathing the air where a person with meningitis has been.

Viral meningitis (aseptic meningitis) is a syndrome generally associated with an existing systemic viral disease (e.g., enteroviral infection, herpes virus infection, mumps, and, less commonly, influenza). Symptoms are similar to those of bacterial meningitis (described later). However, they are usually less severe. In most cases viral meningitis is self-limited, and the patient recovers fully. The patient may experience muscle weakness and malaise during prolonged convalescence.

NOTE

Viral meningitis that is caused by enteroviruses can be spread by direct contact with an infected person's stool. Examples of possible exposures include small children who are toilet training and adults who handle soiled diapers of infected infants. Enteroviruses and other viruses (such as mumps and varicella-zoster virus) can also be spread through direct or indirect contact with respiratory secretions (saliva, sputum, or nasal mucus). Although there are risks for infection through exposure, there is only a small chance of developing meningitis as a complication of the illness.[27]

Signs and Symptoms

The signs and symptoms of meningitis depend on the patient's age and general health. In infants, for example, signs of meningeal irritation may be absent. On the other hand, they may include only irritability, poor feeding or vomiting, a high-pitched cry, and fullness of the fontanelle. (Maternal antibodies generally protect neonates to 6 months of age.) In older infants and children, signs of meningitis may include malaise, low-grade fever, projectile vomiting, petechial rash (Figure 28-8), headache, and stiff neck from meningeal irritation (nuchal rigidity). Diagnostic signs of meningitis in older children include the *Brudzinski sign* (involuntary flexion of the arm, hip, and knee when the neck is passively flexed) and the *Kernig sign* (loss of the ability in a seated or supine patient to completely extend the leg when the thigh is flexed on the abdomen; the patient usually can extend the leg completely when the thigh is not flexed on the abdomen).

FIGURE 28-8 Petechial rash in meningococcal infection. (From Lissauer T, Clayden G: *Illustrated textbook of pediatrics,* ed 2, St Louis, 2001, Mosby.)

CRITICAL THINKING

What does a petechial rash look like?

The risk of **bacterial meningitis** is most significant in neonates and in children 6 months to 2 years of age. However, infection should be suspected in any patient with fever, headache, stiff neck, altered mental status, the presence of petechiae and purpura, or underlying health problems (e.g., recent neurosurgery, trauma, or immunocompromise). If extensive meningeal involvement develops in a toxic or debilitated patient, the illness may be accompanied by acute adrenal insufficiency, convulsions, coma, and disseminated intravascular coagulation (*Waterhouse-Friderichsen syndrome*). In this case, death can occur in 6 to 8 hours. Other conditions and long-term complications associated with severe meningitis include blindness and deafness (from cranial nerve damage), arthritis, myocarditis, and pericarditis. Death can follow overwhelming infection.

Immunization and Control Measures

Vaccines are available for Hib, some strains of *N. meningitidis,* and many types of *S. pneumoniae.* The vaccines against Hib are very safe and highly effective. By 6 months of age, infants should have received at least three doses of Hib vaccine; a fourth dose ("booster") is recommended between 12 and 18 months of age. Vaccine against some strains of *N. meningitidis* is not routinely used in the United States and is not effective in children under 18 months of age.[27] However, the vaccine is sometimes used to control outbreaks of some types of meningococcal meningitis. Vaccines to prevent meningitis caused by *S. pneumoniae* also can prevent other forms of infection arising from the bacterium. This vaccine is ineffective for children under 2 years of age. However, it is recommended for all people over age 65. It also is recommended for younger people with certain chronic medical problems. Vaccines against meningitis have been instrumental in preventing outbreaks of the disease among military recruits in the United States. Before 1971, such outbreaks were a common occurrence.

Patient Management and Protective Measures

Patient management focuses on ensuring an adequate airway and ventilatory and circulatory support. The paramedic must take protective measures when caring for patients who have signs and symptoms of meningitis. Universal precautions (with surgical masks on the patient) should be used during care and transport. The EMS agency should have an exposure control plan for meningitis.

Early diagnosis and treatment of bacterial meningitis are essential. The diagnosis usually is confirmed by finding the bacteria in a sample of the patient's spinal fluid. This is obtained through a spinal tap (lumbar puncture). The disease is then treated using several antibiotics. Drugs to prevent the disease are available for those who may have intimate contact with the patient (e.g., family members).

NOTE

Meningitis is a true medical emergency. A chief goal of emergency care is administration of a bacteria-specific antibiotic. The drug should be given 30 to 60 minutes after arriving at the emergency department.

Bacterial endocarditis (also known as *infective endocarditis*) is inflammation of the endocardium and one or more heart valves. The condition can be caused by a variety of diseases that permit bacteria to enter the bloodstream. (There are nonbacterial causes of endocarditis as well.) These bacteria settle in the heart and grow on the valves of the heart in structures called *vegetation*.

These structures damage the heart valves and may cause them to leak. In severe cases, heart failure develops. If the bacteria dislodge from the valves and enter the bloodstream, they can cause stroke, vision impairment, and severe damage to other organ systems. Bacterial endocarditis is most common in patients older than 60 years of age as a result of degenerative valve disease; about 20% of people die of the disease within 5 years of diagnosis.[28] Other factors associated with the development of endocarditis include intravenous drug use, recent dental surgery, permanent central venous access lines, and prior heart valve surgery.

Signs and symptoms of endocarditis may develop slowly or be acute. The disease can be difficult to diagnose, as early symptoms may resemble the flu or other illnesses. These signs and symptoms include:

- Fatigue
- Weakness
- Fever
- Chills
- Night sweats
- Weight loss
- Muscle aches and pains
- Excessive sweating
- Joint pain

Other signs and symptoms of endocarditis include red, painless skin spots located on the palms and soles (*Janeway lesions*); red, painful nodes in the pads of the fingers and toes (*Osler's nodes*); jaundice, and splinter hemorrhages under the nails. If the patient's heart valves are seriously affected, a heart murmur, shortness of breath, chest discomfort, and dysrhythmias may be present. Other findings during the physical examination may include retinal hemorrhages, petechiae in the conjunctiva, and an enlarged spleen. Diagnosis of endocarditis is made through blood cultures to identify the bacteria and transesophageal echocardiograms. Hospitalization is usually required along with long-term antibiotic therapy (4 to 6 weeks) and sometimes heart valve replacement. Following recovery, prophylactic antibiotic therapy is often prescribed for these patients before dental procedures and surgeries. Those who have had endocarditis are at a higher risk of contracting the disease again. Some patients will carry an endocarditis wallet card issued by the American Heart Association or other organizations to provide information to the health care personnel.

PNEUMONIA

As described in Chapter 24, **pneumonia** is an acute inflammation of the bronchioles and alveoli. It can be spread by droplets and by direct and indirect contact with respiratory secretions. Etiologic agents responsible for this disease may be bacterial (*S. pneumoniae, M. pneumoniae, Staphylococcus aureus, H. influenzae, Klebsiella pneumoniae, Moraxella catarrhalis, Legionella* sp.), viral, or fungal. These organisms may affect several body systems. They include the respiratory system (pneumonia); the CNS (meningitis); and the ears, nose, and throat (otitis, pharyngitis media). The signs and symptoms of pneumonia include the following:

- Sudden onset of chills, high-grade fever, chest pain with respirations, and dyspnea
- Tachypnea and chest retractions (an ominous sign in children)
- Congestion caused by the development of purulent alveolar exudates in one or more lobes
- A productive cough with yellow-green phlegm

Susceptibility and Resistance

Susceptibility to pneumonia is increased by processes such as smoking, pulmonary edema, influenza, exposure to inhaled toxins, chronic lung disease, and aspiration of any form (postalcohol ingestion, near drowning, regurgitation caused by gastric distention from bag-valve-mask ventilation). Extremes of age also appear to increase susceptibility to the disease (e.g., elderly individuals and infants with a low birth weight and/or malnourishment). Other high-risk groups for pneumonia include the following conditions:

- Sickle cell disease
- Cardiovascular disease
- Chronic respiratory disease (e.g., chronic obstructive pulmonary disease [COPD], asthma, cystic fibrosis)

- **Asplenia** (congenital absence or surgical removal of the spleen)
- Diabetes
- Chronic renal failure (or other kidney disease)
- HIV
- Organ transplantation
- Multiple myeloma, lymphoma, Hodgkin's disease, lung cancer

Patient Management and Protective Measures

Prehospital care for patients with pneumonia includes providing airway support, oxygen, ventilatory assistance (as needed), intravenous (IV) fluids, cardiac monitoring, and transport for evaluation by a physician. Bacterial pneumonia is usually managed with analgesics, decongestants, expectorants, and antibiotic therapy. Patients generally do not need to be isolated from others. In hospitals, pneumonia patients may be isolated from other patients who may be more susceptible to infection.

CRITICAL THINKING
Which locations in your area are at high risk for influenza outbreaks?

Measures for protecting health care workers include BSI precautions and effective hand washing. Airway barriers (described earlier) should be used if TB is suspected. Immunizations exist for some causes of pneumonia. However, they generally are not recommended for people who come in contact with patients who have the disease.

TETANUS

Tetanus is a serious, sometimes fatal, disease of the central nervous system. It is caused by infection of a wound with spores of *Clostridium tetani.* Tetanus spores live mainly in soil and manure. However, they are also found in the human intestine. If the spores enter tissue (e.g., through a puncture wound or burn), they multiply and produce a toxin that acts on the nerves controlling muscular activity. (Dead or necrotic tissue is a favorable environment for *C. tetani.*) About 500,000 cases of tetanus occur worldwide each year, with a mortality rate of 45%. These deaths often occur from wounds that appear too trivial for medical evaluation. Only about 100 cases of tetanus are reported annually in the United States. They occur most often in patients 50 years of age or older. The relatively low number of tetanus cases in the United States is a result of immunization of the general population with tetanus vaccines.[28]

Signs and Symptoms

The most common symptom of tetanus is *trismus* (stiffness of the jaw); it is also known as *lockjaw* because of the accompanying difficulty in opening the mouth (Figure 28-9). Other symptoms include the following:

FIGURE 28-9 Trismus as a result of mild tetanus that developed 10 days after the individual received a benign-looking leg wound. (From London PS: *A colour atlas of diagnosis after recent injury,* Ipswich, England, 1990, Wolfe Medical Publications, Ltd.)

- Muscular tetany (muscle spasms and twitching)
- Painful muscular contractions in the neck, moving to the trunk
- Abdominal rigidity (often the first sign in pediatric patients)
- Painful spasms (contortions) of the face (*risus sardonicus*), which produce a grotesque smile
- Respiratory failure

Patient Management and Protective Measures

The prehospital care goals are to support vital functions. This may include aggressive airway management (intubation and surgical or needle cricothyrotomy). Muscle spasms should be treated with ***diazepam*** or ***lorazepam*** (i.e., benzodiazepines) or paralytic agents (per medical direction). Other drugs that may be indicated include IV fluids, ***magnesium sulfate,*** narcotics, and antidysrhythmics. After evaluation by a physician and stabilization of the patient's condition, care for individuals with tetanus includes administration of antitoxin (tetanus immune globulin [TIG]) to provide postexposure passive immunity, treatment to eliminate the toxin, active immunization with tetanus toxoid, and wound care. Most patients recover fully if they receive prompt treatment.

CRITICAL THINKING
When a patient with an open skin wound refuses care, should you explain the risks of tetanus infection?

Immunization

Immunization against tetanus usually is started in children. It is achieved using diphtheria-pertussis-tetanus (DPT) vaccination. This is a combined immunization against diphtheria (laryngitis, pharyngitis with discharge), pertussis (whooping cough), and tetanus. After the initial immunization, children receive a booster shot before starting elementary school. After that, a booster shot is recommended every 10 years.

Patients who have a recent wound should be counseled about postinjury tetanus prophylaxis and effective wound care. If it is suspected that a wound could carry tetanus, the tetanus vaccination will not adequately prevent infection; the patient will need tetanus immunoglobulin. The "tetanus shot" (tetanus immunization) only prevents tetanus exposure in future wounds. All patients should be questioned about their tetanus immunization status. (Boosters should be given every 10 years; 5 years for a "dirty" wound.) Recovery from infection does not confer immunity.

RABIES

Rabies (*hydrophobia*) is an acute viral infection of the central nervous system. The disease mainly affects animals. However, it can be transmitted from an infected animal to a human through virus-laden saliva (e.g., by a bite or scratch). (Transmission from person to person is theoretical but has never been documented.[29]) In the United States, wildlife rabies is common in skunks, raccoons, bats, foxes, dogs, wolves, jackals, mongooses, and coyotes. Healthy wild animals (e.g., skunks) are seldom seen by casual observance. A high degree of suspicion for rabies is indicated for all animals found outside their natural habitat. Hawaii is the only rabies-free state in the United States.

Humans are highly susceptible to the rabies virus after exposure to saliva in a bite or scratch from an infected animal. Several factors govern the severity of infection, including the following:

- Severity of the wound
- Richness of nerve supply close to the wound
- Distance from the wound to the CNS
- Amount and strain of the virus
- Degree of protection provided by clothing

Signs and Symptoms

The incubation period between a bite and the appearance of symptoms ranges from 9 days to 7 years. Initial symptoms include low-grade fever, headache, loss of appetite, hyperactivity, disorientation, and, in some cases, seizures. Often the patient has an intense thirst, but attempts to drink result in violent, painful spasms in the throat (hence the name *hydrophobia*). Eye and facial muscles may become paralyzed as the disease progresses. Without medical intervention, the disease lasts 2 to 6 days, often resulting in death secondary to respiratory failure.

Patient Management and Protective Measures

Physicians treat the signs and symptoms of the disease and provide respiratory and cardiovascular support (as needed). Patients also are treated with sedatives and analgesics. Thorough debridement of the wound without sutures (if possible) is indicated. This allows free bleeding and drainage. Human rabies immune globulin may be given to provide passive immunization. Also, a rabies vaccine (Human Diploid Rabies Vaccine, Rabies Vaccine) is given by injections spread over several weeks. (Injections are no longer given in the stomach.) Tetanus prophylaxis and antibiotics may be indicated for treatment of the bite wound.

CRITICAL THINKING

Has a case of rabies ever occurred in your community? What animal was implicated?

Most cases of rabies in humans are the result of a bite from a rabid dog. However, the possibility of rabies must be considered with *all* mammal bites. Scene safety and use of BSI precautions during wound management are paramount. Law enforcement personnel and animal control authorities should be contacted to assist in scene control.

If given within 2 days of the bite, immunizations almost always prevent rabies. Immunizations should be given for contact with open wounds or for exposure of mucous membranes to saliva. Immunizations also should be given to people with a high probability of contact with animal reservoirs (e.g., animal care workers, animal shelter personnel, and outdoor workers). If an animal is suspected of being rabid, it should be killed by the proper authorities and its brain should be examined for rabies inclusion bodies. If no inclusion bodies are found, the patient's rabies treatment is stopped.

HANTAVIRUS

Hantavirus was previously known to be associated with hemorrhagic fever with renal syndrome that occurs in Asia. Hantaviruses also are associated with a syndrome of severe respiratory distress and shock. This syndrome has occurred in several areas of the United States.[30] The virus is carried by rodents. It is transmitted by inhalation of aerosol material contaminated with rodent urine and feces (see Table 28-3). Many forms of this disease occur in specific geographical areas.

Hantavirus can cause significant disease in humans. Patients are usually healthy adults who experience an onset of fever and malaise. This is followed several days later by respiratory distress. (The severity of the illness is determined by the strain of the virus.) Other signs and symptoms may include fever, chills, headache, GI upset, and capillary hemorrhage. With severe infection, oliguria, kidney failure, and hypotension occur. Death typically

results from decreased cardiac output and eventual cardiovascular collapse. Treatment is supportive and guided by medical direction. Body substance isolation precautions are indicated because of the infectious nature of these viruses.

VIRAL DISEASES OF CHILDHOOD

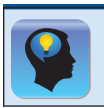
The childhood infectious diseases presented in this chapter include rubella (German measles), rubeola (red measles or hard measles), mumps (parotitis), chickenpox (varicella), and pertussis (whooping cough). These infectious diseases are preventable with immunization for chickenpox and with the triple immunization measles, mumps, and rubella (MMR) vaccine. The incidence of these childhood diseases has declined because of widespread immunization of children. Immunization provides long-lasting immunity. It is known to be 98% to 99% effective.

All health care workers should use personal protective measures when caring for children with viral infections. Protective immunization, effective hand washing, BSI (including the use of surgical masks for both the paramedic and the patient), and careful handling of linens, supplies, and equipment that may be contaminated are important in preventing the spread of these diseases.

Rubella

Rubella is a mild, febrile, and highly communicable viral disease caused by the rubella virus. It is characterized by a diffuse, punctate, macular rash (Figure 28-10). The disease usually is transmitted by direct contact with nasopharyngeal secretions or droplet spray from an infected person. It also may be passed transplacentally (producing active infection in the fetus) and by contact with articles contaminated with blood, urine, or feces. After inoculation, the virus invades the lymph system. From there it enters the blood and produces an immune response. The subsequent rash spreads from the forehead to the face to the torso to the extremities (lasting 3 days). (A rash that lasts longer than 3 days indicates the presence of rubeola.) Maximal communicability appears to be the first few days before and 5 to 7 days after the onset of the rash. Complications from the disease are rare. However, young females sometimes develop a self-limiting arthritis.

FIGURE 28-10 Acquired rubella (German measles) in an 11-month-old infant. (Courtesy Centers for Disease Control and Prevention, 1990. In Grimes D: *Infectious diseases,* St Louis, 1991, Mosby.)



CRITICAL THINKING

Is there any way a paramedic can avoid rubella other than being immunized for it?

Congenital rubella syndrome (CRS) affects approximately 90% of infants born to women who were infected with rubella during the first trimester of pregnancy.[31] The disease is associated with multiple congenital anomalies, mental retardation, deafness, and an increased risk of death from congenital heart disease and sepsis during the first 6 months of life. Infants with CRS shed large numbers of the virus in their secretions. The CDC recommends that all health care personnel receive immunization if they are not immune from previous rubella infection. This helps to reduce the risk of exposure to themselves and those they treat. Immunization is not recommended for pregnant women. This is due to the theoretical risk that the vaccine could cause developmental defects. As a precaution, pregnant EMS workers should not be exposed to patients with rubella.

Rubeola

Rubeola is an acute, highly communicable viral disease. It is caused by the measles virus. It is characterized by fever, conjunctivitis, cough, bronchitis, and a blotchy red rash (Figure 28-11). The virus is found in the blood, urine, and pharyngeal secretions. It usually is passed directly or indirectly through contact with infected respiratory secretions. With exposure, the virus invades the respiratory epithelium. It spreads via the lymph system. Rubeola may predispose a person to secondary bacterial complications such as otitis media, pneumonia, and myocarditis. The most serious life-threatening complication is *subacute sclerosing panencephalitis*. (This is a slowly progressing neurological disease. It is marked by loss of mental capacity and muscle coordination.)

Early (prodromal) symptoms that mark the onset of disease include high fever, nasal discharge, conjunctivitis, photophobia, and cough. About 1 or 2 days before the rash emerges, white spots are usually noted on the inside of the cheek (*Koplik spots*). The dermal rash begins a few days after respiratory tract involvement. The rash is red and maculopapular. It spreads from the forehead to the face, neck, and torso and eventually to the feet, usually by the third day. (The onset of the rash coincides with the production of serum antibodies.) Uncomplicated cases of rubeola usually last 6 days. Recovery from the illness confers lifelong immunity.

FIGURE 28-11 Rubeola (measles) rash on the third day. (Courtesy Centers for Disease Control and Prevention, 1990. In Grimes D: *Infectious diseases,* St Louis, 1991, Mosby.)

FIGURE 28-12 Submaxillary mumps in an infant. (Courtesy Centers for Disease Control and Prevention, 1990. In Grimes D: *Infectious diseases,* St Louis, 1991, Mosby.)

Mumps

Mumps is an acute, communicable systemic viral disease caused by the mumps virus. It is characterized by localized edema of one or more of the salivary glands (usually the parotid). The swelling may affect both or only one side of the neck (Figure 28-12). In some cases involvement of other glands also occurs. The virus is passed through direct contact with the saliva droplets of an infected person.

The virus invades and multiplies in the parotid gland or the upper respiratory tract passages. From there it enters the bloodstream and localizes in glandular or nervous tissue. The parotid, testes, and pancreas are the most frequently involved glands. When mumps occurs after the onset of puberty, it may cause a painful inflammation of the testicle (orchitis) and testicular atrophy; however, sterility is rare. The intensity of symptoms in mumps varies; 30% of infections are asymptomatic. Immunity after recovery is lifelong. Placental transfer of antibodies sometimes occurs.

FIGURE 28-13 Chickenpox skin lesions. (Courtesy Gary Quick, MD.)

CRITICAL THINKING
Why are some viral diseases of childhood still seen despite widespread immunization?

Chickenpox

Chickenpox is a common childhood disease caused by the *varicella-zoster virus*. (Varicella-zoster is a member of the herpes virus family.) The virus is passed by direct and indirect contact with droplets (mainly airborne) from the respiratory passages of an infected person. Exposure to linen tainted with vesicular or mucous membrane discharges of infected people has been implicated.

Chickenpox is highly communicable. It is characterized by a sudden onset of low-grade fever, mild malaise, and a skin eruption that is maculopapular for a few hours and vesicular for 3 to 4 days, leaving a granular scab (Figure 28-13). At first, the skin lesions appear on the trunk. They usually progress to the extremities. The crops of skin eruptions (each associated with itching) usually are more abundant on covered areas of the body. The scalp, conjunctivae, and upper respiratory tract may also be affected. The appearance of crops of vesicles (fresh vesicles appearing while other lesions are scabbed) differentiates chickenpox from smallpox. (Smallpox has vesicles of the same age.) Treatment is symptomatic. Moreover, the disease is self-limited. Complications may include secondary bacterial infections, aseptic meningitis, mononucleosis, and Reye syndrome. Children with chickenpox should be isolated from schools, medical offices, emergency departments, and public places until all lesions are crusted and dry.

FIGURE 28-14 Vesicles associated with shingles. (From Epsetein O, et al: *Clinical examination,* ed 4, St Louis, 2008, Mosby.)

After recovery, the virus is thought to remain in the body in an asymptomatic latent stage. (It is possibly localized in the dorsal root ganglia.) The virus may reactivate during periods of stress or immunosuppression. During these periods, it may produce an illness known as **shingles.** The vesicles associated with shingles appear on the skin area supplied by the sensory nerves of a single group or associated groups of dorsal root ganglia (Figure 28-14). Unlike chickenpox, shingles is not passed through respiratory droplets. However, it can cause chickenpox in susceptible individuals who come in contact with open skin lesions (lesions that are not yet scabbed).

Antiviral drugs may shorten the duration of symptoms and pain in older patients. EMS personnel who have not had chickenpox should consider receiving the vaccine. Data indicate that adult antibody production occurs in 78% of patients after one dose. It occurs in 99% of patients after two doses.[32] (The vaccine should not be given to people who received high doses of systemic steroids in the previous month.) About 5% of those who receive the vaccine develop a rash. Some develop frank chickenpox, which is very debilitating in adults. To protect the fetus, varicella-zoster immune globulin (VZIG) is recommended for pregnant women with significant exposure to chickenpox who do not have a history of previous exposure.

Pertussis

Pertussis is an infectious disease that mainly affects infants and young children. It is caused by *Bordetella pertussis* and is spread by direct contact with discharges from mucous membranes contained in airborne droplets. The disease causes inflammation of the entire respiratory tract. It also causes a subtle onset of cough that becomes paroxysmal in 1 to 2 weeks. This cough can last 1 to 2 months. The coughing episodes are violent (sometimes without an intervening inhalation, causing the high-pitched inspiratory "whoop") and end with expulsion of clear mucus and vomiting. (The whoop often is not present in children younger than 6 months of age.) Before the introduction of a vaccine against pertussis in the 1950s, the disease killed more children in the United States than all other infectious diseases combined. The incidence of the disease has increased since 1990, with a disproportionate increase in adolescents and adults.[33] Pertussis vaccine usually is given in combination with diphtheria and tetanus (DPT) vaccines to children at 2, 4, and 6 months of age; a booster dose is given at age 5.

The ability to spread pertussis is thought to be greatest before the onset of paroxysmal coughing. (This explains the need for BSI and surgical mask protection for the paramedic and the patient.) Erythromycin is known to shorten the communicability period, but it can reduce symptoms only if given during the incubation period. (This is before the onset of paroxysmal cough.) Infection with pertussis usually provides immunity. However, attacks after immunization in older children and adults indicate that immunity may diminish over time.

OTHER VIRAL DISEASES

Other viral diseases easily transmitted during the course of patient care include influenza, mononucleosis, and herpes simplex type 1 (HSV-1) infection (described later in this chapter). As with all other contacts with patients who may have infectious disease, BSI precautions are indicated during patient care.

Influenza

As described in Chapter 24, **influenza** is a respiratory infection that is spread by influenza viruses A, B, and C. The disease is popularly known as "the flu." It is spread by virus-infected droplets that are coughed or sneezed into the air. Influenza usually occurs in small outbreaks or, every few years, in epidemics. Resistance is normally conferred after recovery. However, this resistance is only to the specific strain or variant (Box 28-12).

NOTE

The 2009 H1N1 virus sickened about 50 million Americans and was responsible for more than 10,000 deaths. The virus is known to spread rapidly and is expected to reach all countries worldwide. This virus was originally referred to as "swine flu." This was because laboratory tests showed that many of the genes in this new virus were very similar to influenza viruses that normally occur in pigs (swine) in North America. Further studies showed that the virus is very different from what normally circulates in North American pigs. The H1N1 virus has two genes from flu viruses that normally circulate in pigs in Europe and Asia, and bird (avian) genes and human genes. Scientists call this a "quadruple reassortant" virus.[34] The seasonal influenza vaccination does not protect against new strains of flu such as H1N1.

DID YOU KNOW?

CDC Recommendations for EMS and Medical First Responder Personnel Including Firefighter and Law Enforcement First Responders During an Outbreak of Influenza (H1N1)

Patient Assessment: Interim Recommendations:

If there HAS NOT been swine-origin influenza reported in the geographical area, EMS personnel should assess all patients as follows:

1. EMS personnel should stay more than 6 feet away from patients and bystanders with symptoms and should exercise appropriate routine respiratory droplet precautions while assessing all patients for suspected cases of swine-origin influenza.
2. Assess all patients for symptoms of acute febrile respiratory illness (fever plus one or more of the following: nasal congestion/rhinorrhea, sore throat, or cough).
   - If no acute febrile respiratory illness, proceed with normal EMS care.
   - If symptoms of acute febrile respiratory illness, then assess all patients for travel to a geographical area with confirmed cases of swine-origin influenza within the last 7 days or close contact with someone with travel to these areas.
   - If travel exposure, don appropriate PPE for suspected case of swine-origin influenza.
   - If no travel exposure, place a standard surgical mask on the patient (if tolerated) and use appropriate PPE for cases of acute febrile respiratory illness without suspicion of swine-origin influenza (as described in PPE section).

If the CDC confirmed swine-origin influenza in the geographical area:

1. Address scene safety:
   - If Public Safety Answer Point (PSAP) advises potential for acute febrile respiratory illness symptoms on-scene, EMS personnel should don PPE for suspected cases of swine-origin influenza before entering scene.
   - If PSAP has not identified individuals with symptoms of acute febrile respiratory illness on-scene, EMS personnel should stay more than 6 feet away from patient and bystanders with symptoms and should exercise appropriate routine respiratory droplet precautions while assessing all patients for suspected cases of swine-origin influenza.
2. Assess all patients for symptoms of acute febrile respiratory illness (fever plus one or more of the following: nasal congestion/rhinorrhea, sore throat, or cough).
   - If no symptoms of acute febrile respiratory illness, provide routine EMS care.
   - If symptoms of acute febrile respiratory illness, don appropriate PPE for suspected case of swine-origin influenza.

Personal Protective Equipment (PPE): Interim Recommendations[35]*:*

- When treating a patient with a suspected case of swine-origin influenza as defined above, the following PPE should be worn:
  - Fit-tested disposable N95 respirator and eye protection (e.g., goggles, eye shield), disposable nonsterile gloves, and gown, when coming into close contact with the patient.
- When treating a patient that is not a suspected case of swine-origin influenza but who has symptoms of acute febrile respiratory illness, the following precautions should be taken:
  - Place a standard surgical mask on the patient, if tolerated. If not tolerated, EMS personnel may wear a standard surgical mask.
  - Use good respiratory hygiene—use nonsterile gloves for contact with patient, patient secretions, or surfaces that may have been contaminated. Follow hand hygiene including hand washing or cleansing with alcohol-based hand disinfectant after contact.
- Encourage good patient compartment vehicle airflow/ventilation to reduce the concentration of aerosol accumulation when possible.

BOX 28-12 Influenza Virus Types A, B, and C

People infected with certain strains of influenza type A or type B acquire immunity to that strain. However, the type A and type B viruses occasionally alter to produce new strains. This leads to a new infection. Type B virus is relatively stable. However, it occasionally changes to overcome resistance and may lead to small outbreaks of infection. Type A virus is highly unstable. It has caused worldwide flu epidemics. These variants are named for the geographical site and year of isolation (e.g., the Spanish flu in 1918, Asian flu in 1957, and Hong Kong flu in 1968) and the culture number (e.g., A/Japan/305/57).

Type C virus stimulates antibodies that provide immunity for life.

Signs and symptoms typically include chills, fever, headache, muscular aches, loss of appetite, and fatigue. These symptoms are followed by upper respiratory tract infection and a cough (often severe and drawn out) that lasts for 2 to 7 days. Patient management is mainly supportive. Mild cases of viral infection usually are not treated.

Severe cases (especially in the elderly and those with lung or heart disease) may result in secondary bacterial infection (e.g., *S. pneumoniae*). These cases can be fatal. Other viral respiratory diseases that can lead to bacterial complications include acute afebrile viral respiratory disease (excluding influenza) and acute febrile respiratory disease. Both diseases may cause illnesses in the upper and lower respiratory tracts. These illnesses include pharyngitis, laryngitis, croup, bronchitis, and bronchiolitis (Box 28-13).

Flu vaccines contain killed strains of type A and type B virus that are known to be currently in circulation. These vaccines may help prevent infection. A nasal spray flu

BOX 28-13 Bird Flu: The Next Pandemic?

A **pandemic** is an infectious disease outbreak that infects large numbers of people in a large geographical region and may occur worldwide. One occurs three to four times each century when new virus subtypes emerge and are easily transmitted from person to person. Any infectious disease may become a pandemic, but influenza is of great concern because it spreads easily and can kill many people. There were three influenza pandemics in the 20th century. They were the 1918 Spanish flu, which killed about 20 million people; the 1957 Asian flu, which killed as many as 4 million people; and the 1968 Hong Kong flu, which killed up to 2 million people. The World Health Organization (WHO) has predicted that the next pandemic influenza could kill between 2 million and 8 million people worldwide. The 2009 H1N1 virus was a pandemic.

Avian influenza (bird flu) is an infectious disease of birds, and less commonly pigs. It is caused by the A strain of the influenza virus, and is considered by many health officials as most likely to become the next pandemic. There are several strains and subtypes of avian influenza. One highly pathogenic strain of the virus (H5N1) began circulating in migratory birds in Southeast Asia in 2003 and more recently in parts of Europe. The virus is similar in makeup to the 1918 variety (believed by many to be a mutation of an avian virus) and can mutate rapidly. It also causes severe disease in humans who have come in contact with infected birds. The virus is easily spread among birds but has not yet acquired the ability to spread easily among humans. The fear is that as the virus continues to spread among migratory birds, it may mutate or merge with human strains of another virus, enabling the disease to be spread in humans. If this happens, the disease could sweep the world in as little as 3 months and could persist for years.

Because the virus has not mutated to easily spread infection among humans, a vaccine specific to the disease cannot be developed. Current vaccines under study may not be completely effective against the strain if it mutates. Two antiviral drugs, oseltamivir (Tamiflu) and zanamivir (Relenza), are clinically effective in interrupting the ability of the influenza A virus to replicate within the human body. The WHO recommends that nations stockpile enough of these antiviral drugs to cover 10% of their population. The prophylactic use of these antiviral drugs to prevent avian flu is not recommended. Doing so may result in a resistant strain of the virus. Annual flu vaccinations are not effective against bird flu. They are, however, effective against other flu viruses that may complicate the avian flu should an outbreak occur.

vaccine, FluMist (virus vaccine live, intranasal), has also been approved for protection against influenza A and B viruses in healthy people between 5 and 49 years of age. However, immunity does not last long. Therefore the vaccine must be repeated each year just before the start of the flu season (November to March in the United States). Health care workers should be immunized in the fall of each year with the current vaccine.

Amantadine, rimantadine, or zanamivir may be given to hospitalized patients to protect against influenza A. Despite advances in prevention and treatment, more than 36,000 people die each year in the United States from influenza and its complications.

CRITICAL THINKING

Will you get the influenza vaccine? What influenced your decision?

Mononucleosis

Mononucleosis is often referred to as "mono." It is caused either by the *Epstein-Barr virus* (EBV) or by *cytomegalovirus* (CMV) (Box 28-14). Both of these are members of the herpes virus family. Mononucleosis is spread from person to person via the oropharyngeal route and saliva (hence the name *kissing disease*). Blood transfusions also can be a mode of transmission. However, resultant clinical disease is rare. Most people with a healthy immune system are able to fend off the infection even after significant exposure. Transmission from caregivers to young children is common. About 90% of people over age 35 have antibodies to CMV or EBV. This is probably the result of mild, childhood infection, often attributed to a common cold or the flu. Previous infection with EBV generally confers a high degree of resistance to future exposures.

Signs and symptoms of mononucleosis appear gradually. They are characterized by fever (which may last for weeks), sore throat, oropharyngeal discharges, lymphadenopathy (especially posterior cervical), and splenomegaly with abdominal tenderness. About 10% of people also develop a generalized rash or darkened areas in the mouth that resemble bruises. Recovery usually occurs in a few weeks. However, some people take months to regain their former level of energy. The patient may remain a carrier for several months after symptoms disappear. No immunization is available for mononucleosis.

SEXUALLY TRANSMITTED DISEASES

A **sexually transmitted disease** (STD) is a disease that can be passed from person to person through sexual activity. It may be transmitted to another person even when the infected person has no symptoms. More than 20 pathogens have been identified as belonging to this group of diseases (including HBV and HIV). Other common STDs are syphilis, gonorrhea, chlamydia, and herpes virus infections.

Several pathogenic agents are responsible for the host of STDs. These include bacteria, viruses, protozoa, fungi, and ectoparasites. These pathogens can produce multiple disease syndromes. Also, patients with STD syndromes often have multiple STDs. These infections usually cause a

BOX 28-14 Facts about CMV

General Information[36]:

Between 50% and 80% of adults in the United States are infected with CMV by 40 years of age.
CMV is the most common virus transmitted to a pregnant woman's unborn child.
Approximately 1 in 150 children is born with congenital CMV infection.
Approximately 1 in 750 children is born with or develops permanent disabilities attributable to CMV.
Approximately 8000 children each year suffer permanent disabilities caused by CMV.
Congenital CMV (meaning present at birth) is as common a cause of serious disability as Down syndrome, fetal alcohol syndrome, and neural tube defects.

About the Virus

CMV is found throughout the world in all geographical and socioeconomic groups, but, in general, it is more widespread in developing countries and in areas of lower socioeconomic conditions.
CMV is a member of the herpes virus family, which includes the herpes simplex viruses and the viruses that cause chickenpox (varicella-zoster virus) and infectious mononucleosis (Epstein-Barr virus).
CMV is found in body fluids, including urine, saliva (spit), breast milk, blood, tears, semen, and vaginal fluids.
Once CMV is in a person's body, it stays there for life.
Most CMV infections are "silent," meaning they cause no signs or symptoms in an infected person.
CMV can cause disease in unborn babies and in people with a weakened immune system.

Transmission and Prevention (How People Become Infected With CMV)

Transmission of CMV occurs from person to person, through close contact with body fluids (urine, saliva [spit], breast milk, blood, tears, semen, and vaginal fluids), but the chance of getting CMV infection from casual contact is very small.
In the United States, about 1% to 4% of uninfected mothers have primary (or first) CMV infection during a pregnancy.
About 33% of women who become infected with CMV for the first time during pregnancy pass the virus to their unborn babies.
No actions can totally eliminate all the risks of getting CMV, but there are simple measures that can reduce spread of the disease. The CDC recommends that pregnant women:

- Wash hands often with soap and water, especially after changing diapers. Wash well for 15 to 20 seconds.
- Do not kiss young children under the age of 5 or 6 on the mouth or cheek. Instead, kiss them on the head or give them a big hug.
- Do not share food, drinks, or utensils (spoons or forks) with young children. If you are pregnant and work in a day care center, reduce your risk of getting CMV by working with children who are older than 2½ years of age, especially if you have never been infected with CMV or are unsure if you have been exposed.[37]

short-lived cellular immune response. They also can produce longer-lasting humoral antibody response. Neither of these protects against future exposures.

Syphilis

Syphilis is a systemic disease. It is characterized by a primary lesion, a secondary eruption involving the skin and mucous membranes, long latency periods, and late, seriously disabling lesions of the skin, bones, viscera, CNS, and cardiovascular system. The disease results from penetration of the skin, whether intact or broken, by the bacterium *Treponema pallidum*. Common modes of transmission include direct contact with fluid or pus from lesions on the skin and mucous membranes, blood transfusions or needlesticks (rare), and congenital transmission. After penetration, the organisms travel (within hours) to the lymph nodes. From there they are carried throughout the body. After the initial infection, syphilis follows well-defined stages of disease. It can be treated with antibiotic therapy. No immunization is available. It is estimated that 30% of exposures result in infection.

PRIMARY STAGE

Within 10 to 90 days of exposure, a primary lesion, or chancre, develops at the site of initial invasion (Figure 28-15). The surface of the chancre is usually crusted or ulcerated. It varies in size from 1 to 2 cm in diameter. The lesion usually is single and painless. In addition, it generally heals spontaneously within 1 to 5 weeks. Syphilis is highly communicable during this stage.

SECONDARY STAGE

The secondary stage begins about 2 to 10 weeks after the appearance of the primary lesion. This stage lasts for 2 to 6 weeks. It is heralded by systemic symptoms. These include headache, malaise, anorexia, fever, sore throat, lymphadenopathy, and bald spots in the area of infection. In addition, the patient may develop a rash, which usually is bilaterally symmetrical and often involves the palms and soles. Painless, wartlike regions (*condylomata lata*), which are extremely infectious, may also be found in moist, warm sites (e.g., the inguinal area). The CNS, eyes, bones, joints, or kidneys may be affected during this stage.

FIGURE 28-15 Primary syphilis chancre on the labia.

CRITICAL THINKING
Why do you think a patient in the secondary stage of syphilis would call EMS?

LATENCY

A latency period follows the secondary stage in untreated individuals. (This may range from 1 to 40 years or more.) During this period, recurrent episodes of secondary stage symptoms with subclinical infection may occur. This happens in about 25% of cases. About 33% of these patients progress to tertiary syphilis; the remainder remain free of symptoms. Tertiary syphilis is infectious involvement of the skin, CNS, and cardiovascular systems and may include the following manifestations:

1. Skin
   - Granulomatous lesions (gummas) on skin (painless) and bone (painful)
2. Central nervous system
   - Paresis
   - **Tabes dorsalis** (spinal column degeneration characterized by a wide gait and ataxia ["syphilitic shuffle"])
   - Loss of reflexes, pain, and temperature sensation
   - Meningitis
   - Psychosis
3. Cardiovascular
   - Cerebrovascular occlusion
   - Dissecting aneurysm of the ascending aorta
   - Myocardial insufficiency; aortic necrosis (which can lead to aortic rupture and death)

Gonorrhea

Gonorrhea is caused by the bacterium *Neisseria gonorrhoeae*. It is transmitted between individuals by fluids and pus from infected mucous membranes. It can also be spread from an infected mother to her baby during pregnancy and delivery. The disease occurs in both men and women. However, it differs in course, severity, and ease of recognition. Gonorrhea often is treatable with antibiotics. However, some strains brought into the United States from other countries are resistant to the usual antibiotic therapy. Immunization is not available. Antibodies develop after exposure, but the antibodies are specific to the strain of gonorrhea that caused the infection. Consequently, future reinfection with other strains can occur.

Affected areas of the male anatomy are the urethra, Littre's gland, Cowper's gland, prostate gland, seminal vesicles, and epididymis. A sudden onset of dysuria and urinary urgency and frequency is seen several days after exposure. The associated urethral discharge rapidly becomes purulent and profuse. Direct spread of the infection may result in prostatitis, epididymitis, and seminal vesiculitis. Primary gonorrheal infections may also affect the pharynx, conjunctivae, and anus.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 201-205.

Affected areas of the female anatomy are the Bartholin glands, Skene glands, urethra, cervix, and fallopian tubes. More than 50% of infected women remain free of symptoms; others have a mucopurulent discharge that varies from scant to profuse. Contiguous spread of the disease may lead to endometritis, salpingitis, and parametritis (pelvic inflammatory disease) and the formation of tuboovarian abscesses. Complete or partial occlusion of the fallopian tubes may result in sterility and increased risk for ectopic pregnancy.

Between 1% and 3% of gonococcal infections become disseminated in the blood. This extension of the disease may produce septicemia, arthritis, endocarditis, meningitis, and skin lesions. In the bacteremic stage, the patient may complain of fever, chills, and malaise. Erythematous lesions are common, especially on the extremities. They may occur in clusters or singly.

Chlamydia

Chlamydia (*Chlamydia trachomatis*) is a major cause of sexually transmitted nonspecific urethritis (NSU) or nongonococcal genital infection. The disease is the most common sexually transmitted disease in the United States. (An estimated 25% of men are carriers.) It is a leading cause of preventable blindness.[38] The signs and symptoms are similar to those of gonorrhea. This makes differentiation difficult. No immunization is available.

In men, NSU may cause a penile discharge. It also may cause complications such as swelling of the testes, which, if untreated, may lead to infertility. In women, NSU usually is symptomless. However, it may cause a vaginal discharge or pain with urination, salpingitis, and cervicitis. Transmission occurs secondary to direct contact with exudates,

FIGURE 28-16 Conjunctivitis from a chlamydial infection in an 8-day-old infant. (From Lissauer T, Clayden G: *Illustrated textbook of pediatrics,* ed 2, St Louis, 2001, Mosby.)

either sexually or during birth (Figure 28-16). Chlamydial infections are treated with antibiotics.

Herpes Virus Infections

Four herpes viruses have been described. One is the herpes simplex virus. The others are CMV, which is associated with mononucleosis, hepatitis, and severe systemic disease in the immunosuppressed host; EBV, which causes mononucleosis; and varicella-zoster virus, which causes chickenpox and shingles. This section of the text addresses only the herpes viruses associated with STDs.

HERPES SIMPLEX VIRUS

The two antigenically distinct herpes simplex viruses responsible for STDs are **herpes simplex virus type 1** (HSV-1) and **herpes simplex virus type 2** (HSV-2). Both pathogens can cause herpes infection. Also, both can cause infection anywhere in the body. As a rule, HSV-1 most often is associated with herpes above the waist. In contrast, HSV-2 generally is associated with genital herpes. However, either type can cause disease in the genital area. Immunization is not available for either virus.

HSV is common in the United States. It causes 300,000 to 500,000 new infections each year; about 42 million Americans are thought to carry the virus.[39] It is estimated that 70% to 90% of adults have antibodies against HSV-1. The mode of transmission for HSV is strictly skin-to-skin contact with an infected area of the body. The virus enters through a break in the skin or through mucous membranes. Sexual contact is not required for transmission. For example, touching the herpes virus may result in finger infection (*herpetic whitlow*). Many young children who develop oral herpes (HSV-1) probably contract the virus

FIGURE 28-17 "Fever blister" caused by the herpes simplex virus. (From Epsetein O, et al: *Clinical examination,* ed 4, St Louis, 2008, Mosby.)

through a casual kiss from a parent or relative. The virus also may be spread to other external body sites by autoinoculation (e.g., it may be spread from lip to finger to genitalia). Initial HSV-1 transmission usually occurs by 4 years of age. It is manifested by gingivostomatitis ("cold sores" or "fever blisters") (Figure 28-17). Initial HSV-2 infection generally results from sexual activity. It is manifested by painful vesicular lesions of the cervix, vulva, penis, rectum, anus, and mouth (depending on sexual practices).

Once present in tissue, HSV produces an acute infection, with tissue destruction limited to one site. This primary infection produces a vesicular lesion (blister). The lesion heals spontaneously from the outside in without lasting scarring. However, the virus remains alive in the body despite circulating antibodies.

After the primary infection, the HSV enters the central nervous system nearest to the site of initial infection. It travels along sensory nerve pathways to a sensory nerve ganglion. There it remains in a latent stage until reactivated. When triggered by another infectious disease, menstruation, emotional stress, trauma, or immunosuppression, the virus reaches the epidermis by way of peripheral nerves. It reproduces a recurrent infectious disease state. This state usually lasts 4 to 10 days. The lesions usually appear in the area of initial inoculation. The number of lesions a person might experience during any given episode varies considerably.

CRITICAL THINKING
Why do you think the incidence of herpetic whitlow in health care workers has declined over the last 10 years?

HSV can remain inactive for a long time. It is unknown why many infected people never develop the disease, whereas others experience a lifetime of periodic outbreaks. Antiviral agents such as acyclovir may shorten the duration of an outbreak. They also may be used as prophylactic agents in instances of frequent recurrence.

LICE AND SCABIES

Lice and scabies are potential health hazards for all health care providers. Both can transmit communicable skin diseases and systemic illness, as well as dermatitis and discomfort. (Other vector-borne illnesses [e.g., Lyme disease] were described in Chapter 34.)

Lice

Lice are small, wingless insects that are ectoparasites of birds and mammals. Most are host specific. Two of the species are human parasites. One is *Phthirus pubis,* the pubic, or crab, louse. The other is *Pediculus humanus,* which has two forms: *Pediculus capitis* (the head louse) and *Pediculus corporis* (the body louse, which was involved in outbreaks of epidemic typhus and trench fever in World War I) (Figure 28-18). Lice have a three-stage life cycle. The eggs hatch in 7 to 10 days; the nymph stage lasts 7 to 13 days; and the egg-to-egg cycle lasts about 3 weeks.

Lice subsist on blood from the host and have mouths modified for piercing and sucking. During biting and feeding, secretions from the louse cause a small, red macule and pruritus. Long infestation periods may result in a decrease in pruritus and often a thick, dry, scaly appearance to the skin. In severe cases, oozing and crusting may be present. If sensitization to lice saliva and feces occurs, inflammation may develop. Secondary infection may result from scratching of lesions. Lice spread through close personal contact, and sharing of clothing and bedding may result in outbreaks (e.g., at schools, in day care facilities, and in families).

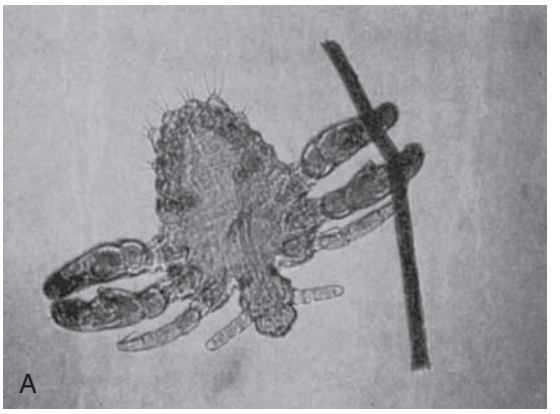


FIGURE 28-18 **A,** The pubic, or crab, louse. **B,** Male of the human head louse.

Pubic lice have a distinctive appearance, suggestive of miniature crabs. Gray-blue spots may be observed on the abdomen and thighs of infested patients. The eggs (*nits* or *ova*) often are evident on the shaft of pubic hairs. They are sometimes seen in the eyelashes, eyebrows, and axillary hairs. Pubic lice usually are acquired during sexual activity or from unchanged bedding in which egg-infested pubic hairs have been shed. Although primary bite lesions seldom are evident, the patient normally complains of intense pruritus and pubic scratching.

Head lice have an elongated body with a head that is slightly narrower than the thorax. Each louse has three pairs of legs, which possess delicate hooks at the distal extremities. The white ova of head lice (usually one nit to a shaft) are easily mistaken for dandruff, but the nits cannot be brushed out. These parasites most frequently affect children.

Body lice are slightly larger than head lice and concentrate around the waist, shoulders, axillae, and neck. Body lice and their nits usually are found in seams and on the fibers of clothing. The lesions from their bites begin as small, noninflammatory red spots, which quickly become papular wheals that resemble linear scratch marks (parallel scratch marks on the shoulders are a common finding). Head lice and body lice interbreed.

The treatment for all types of lice is designed to eradicate the parasites and nits and to prevent reinfestation. Patients usually are advised to wash all clothing, bedding, and personal articles thoroughly in hot water. They also are advised to wash the infected body area with gamma benzene hexachloride shampoo (Kwell), crotamiton (Eurax), Rid, or Nix. (Overtreatment should be avoided to prevent toxicity.)

FIGURE 28-19 Common site of burrows in scabies.

DID YOU KNOW

Bed Bugs

Bed bug infestations were common in the United States before World War II but were mostly eradicated in the 1940s and 1950s from the widespread use of DDT. In recent years, the common bed bug, *Cimex lectularius*, has made a comeback. It is increasingly being encountered in homes, apartments, hotels, motels, health care facilities, dormitories, shelters, schools, and modes of transport. Their resurgence may be the result of international travel since bed bugs are prevalent in other regions of the world. The most common place to find bed bugs is in bedding where they often hide within seams, tufts, and crevices of the mattress, box spring, bed frame, and headboard. The adult bed bug is reddish-brown, has a flattened body, and is easy to see. They can move quickly, but do not fly, and are commonly mistaken for ticks. Bed bugs usually bite at night while people are sleeping. The bites (which often occur in clusters) may cause an itchy welt or localized swelling, similar to a mosquito bite. These localized skin reactions may be immediate or delayed for several days after the bite. Scratching the bites can lead to skin infections. Although bed bugs can harbor pathogens in and on their bodies, transmission to humans is considered unlikely. Bed bugs require a blood meal to molt and can live 12-18 months. Visible signs of bed bugs include blood stains or fecal spots on bedding, furniture, and walls. If infestation is severe, there may be a sweet and musty odor in the room. Bed bug infestations require professional extermination.

EMS personnel should take the following precautions when faced with possible bed bug infestation:

- Tuck pant legs inside socks or boots.
- Wear disposable shoe covers while at the scene and dispose of them in a sealed, plastic bag. Inspect work shoes before entering the ambulance or EMS base. Infested gear should not be taken into living quarters.
- Place any clothing item with visible bed bugs in a plastic, sealed bag. Do not use the clothing again until it has been placed in a hot clothes dryer for at least 15 minutes to destroy the bed bugs.

From Potter M: Bed Bugs, University of Kentucky College of Agriculture, http://www.ca.uky.edu/entomology/entfacts/ef636.asp, accessed June 7, 2011.

Scabies

The human **scabies** mite (*Sarcoptes scabiei* var. *hominis*) is a parasite. It completes its entire life cycle in and on the epidermis of its host. Scabies infestation resembles a lice infestation. However, scabies bites generally are concentrated around the hands and feet, especially in the webs of the fingers and toes (Figure 28-19). Other common infestation areas include the face and scalp of children, the nipples in females, and the penis in males. The scabies mite usually is passed by intimate contact or acquired from infested bedding, furniture, and clothing. The mite can burrow into the skin within minutes.

Scabies infestation often is manifested by severe nocturnal pruritus. However, it takes 4 to 6 weeks for sensitization to develop and itching to begin. The adult female mite is responsible for symptoms. After impregnation, she burrows into the epidermis to lay her eggs. She remains in the burrow for a life span of about 1 month. Although vesicles and papules form at the surface, they often are disguised by the results of scratching. In severe cases (e.g., Norwegian scabies), oozing, crusting, and secondary infection may result. Susceptibility is general. However, people with a previous exposure usually develop fewer mites on later exposures and experience symptoms earlier (within 1 to 4 days).

The treatment is similar to that prescribed for lice infestation. Symptoms may persist for longer than 1 month until the mite and mite products are shed with the epidermis. (Mites are communicable until all mites and eggs have been destroyed.) Reinfestation is common; therefore the patient should be reexamined if the itching has not abated after several weeks. Antibiotic therapy may be needed to treat secondary bacterial infection. Immunization is not available. Protective measures against lice and scabies infestation are presented in Box 28-15.

REPORTING AN EXPOSURE TO AN INFECTIOUS OR A COMMUNICABLE DISEASE

An **exposure incident** (significant exposure) is any specific contact of the eyes, the mouth, other mucous membranes, or nonintact skin, or parenteral contact, with blood, blood products, bloody body fluids, or other potentially infectious materials. Exposures and all suspected exposures to an infectious or communicable disease must be reported to the DO. Reporting a possible exposure is important for the following reasons:

BOX 28-15 Protective Measures Against Lice and Scabies

1. Observe body substance isolation (BSI) and bag linen separately.
2. Spray the patient compartment of the ambulance with an effective insecticide. (Most commercial sprays contain effective pyrethrins, malathion, or carbamates.)
3. Spray the floor, gurney, and immediate areas where the patient's head was positioned (lice do not jump great distances).
4. Remove all insecticide residues with an appropriate solution.
5. Wear gloves during all steps and wash hands thoroughly when finished.
6. To treat a lice or scabies infestation:
   - Use an appropriate body or hair pediculicide; repeat in 7 to 10 days.
   - Launder personal clothing in hot water in a washer and dry on high heat in the dryer (of questionable benefit).

1. It permits immediate medical follow-up. This allows identification of infection and immediate intervention.
2. It enables the DO to evaluate the circumstances of the incident. It also allows the DO to determine what changes to make to prevent future exposures.
3. It aids follow-up testing of the source person if permission for testing can be obtained.

Reporting also ensures that if the health care worker is infected, it has been documented that the disease occurred from a work-related exposure.

NOTE

As described earlier in this chapter, under provisions of the Ryan White Act, an exposed employee has the right to request the infection status of the source patient from the patient's health care provider. Neither the agency nor the employee, however, can force testing of the source patient. As part of a good exposure control plan, employees must know what to do if an exposure incident occurs.

Submitting the Report

The Ryan White Act requires employers to appoint someone in the organization to whom an exposed employee can report. That person or officer follows the exposure control plan. The plan must comply with standards and guidelines relative to the exposure and must meet any local reporting requirements.

Medical Evaluation and Follow-Up

By law, employers must provide free medical evaluation and treatment to exposed employees. This would include the following:

- Counseling regarding the risks, signs and symptoms, probability of developing clinical disease, and how to prevent future spread of the potential infection
- Appropriate treatment in line with current U.S. Public Health Service recommendations
- A discussion of medications offered and their side effects and contraindications
- Evaluation of any reported illness to determine whether the symptoms are related to HIV or hepatitis

STEPS INVOLVED

Blood tests of exposed employees are always contingent on employee agreement. Employees have the option to provide blood samples. However, they can refuse permission for HIV testing at the time the sample is drawn. The employer must maintain the blood samples for 90 days in case employees change their mind regarding testing if HIV-like or hepatitis-like symptoms develop.

CRITICAL THINKING

How do you think you would feel if you were stuck by a contaminated needle and the patient refused HIV testing?

As an agent of the health care worker, the employer must take the following steps: (1) provide counseling to the employee based on test results; (2) provide informed consent regarding prophylaxis and therapeutic regimens; and (3) implement those regimens after receiving approval from the employee. Vaccines also should be made available to all employees who are exposed to blood and other potentially infectious materials during their work.

Written Report and Confidentiality

The agent of the employer will send a written report to the DO of the employer. This states whether vaccination was offered to the exposed employee. It also states whether the employee received it. The written report also must note that the employee was informed of the results of the evaluation and told of any medical conditions resulting from the exposure that may require further evaluation or treatment. A copy of this report must be provided to the employee and to the DO for the agency's files.

All other elements of the employee's medical record are confidential. They cannot be supplied to the employer. The employee must give written consent for anyone to view the records. The records must be maintained for the duration of employment plus 30 years. This complies with OSHA standards regarding access to employee exposure and medical records. (States who are not governed by OSHA must also follow these guidelines.)

PARAMEDIC'S ROLE IN PREVENTING DISEASE TRANSMISSION

Paramedics will have to deal with patients who have infectious diseases. It is important for them to be vigilant about the consequences to themselves and to their patients and co-workers. Part of this professional duty in preventing the spread of disease is knowing when *not* to go to work. A health care worker should not go to work if the following conditions are present:

- Fever
- Diarrhea
- Draining wound or any type of wet lesion
- Jaundice
- Mononucleosis
- Treatment with a medication and/or shampoo for lice or scabies
- Strep throat (unless antibiotics have been taken for longer than 24 hours)
- Cold with productive cough (unless the paramedic wears a surgical mask)

Health care workers also should ensure that their personal immunization status is current for MMR, hepatitis B, DPT, polio, chickenpox, and influenza.

CRITICAL THINKING

Have you come to school or work with any of these conditions?

Other Considerations in Disease Prevention

When called to provide emergency care, paramedics should always approach the scene with caution. They must keep in mind that an uncontrolled scene increases the likelihood of transmission of body fluids. Universal precautions should be observed at all times. These include wearing gloves, protective eyewear, a face shield, and a gown (if splash or spray is possible) and wearing an appropriate particulate mask when airborne disease is suspected. As mentioned previously, universal precautions are based on the premise that all body fluids, in any situation, may be infectious.

As a rule, if a patient has a productive cough, headache, general weakness, recent weight loss, nuchal rigidity, or high fever, the paramedic should immediately suspect an infectious process. Regardless of the patient's infectious status, however, the paramedic should do the following:

- Provide the same level of care to all patients.
- Disinfect equipment and the patient compartment with the proper disinfectant solution.
- Practice effective hand washing.
- Report any infectious exposure to the agency's DO.

CRITICAL THINKING

Imagine that you are on a call and get a small splash of blood in your eyes. What do you think would prevent you from reporting it immediately so that your postexposure care could begin?

SUMMARY

- National concerns about communicable disease and infection control have resulted in public laws, standards, guidelines, and recommendations to protect health care providers and emergency responders against infectious diseases. Paramedics must be familiar with these guidelines. They also must take personal protective measures against exposure to these pathogens.
- The chain of elements needed to transmit an infectious disease includes the pathogenic agent, a reservoir, a portal of exit from the reservoir, an environment conducive to transmission of the pathogenic agent, a portal of entry into the new host, and susceptibility of the new host to the infectious disease.
- The human body is protected from infectious disease by external and internal barriers. These serve as lines of defense against infection. External barriers include the skin, GI system, upper respiratory tract, and genitourinary tract. Internal barriers include the inflammatory response and the immune response.
- The progression of infectious disease from exposure to the onset of symptoms follows four stages. These are the latent period, the incubation period, the communicability period, and the disease period.
- The human immunodeficiency virus is directly transmitted person to person. This occurs through anal or vaginal intercourse, across the placenta, by contact with infected blood or body fluids on mucous membranes or open wounds, through blood transfusion or tissue transplant, or by the use of contaminated needles or syringes. The virus affects the CD4 T cells. Secondary complications are usually related to opportunistic infections that arise as the immune system deteriorates. Progression of the disease can be divided into category A (acute retroviral infection, seroconversion, and asymptomatic infection); category B (early symptomatic HIV); and category C (late symptomatic HIV and advanced HIV). Paramedics should observe strict compliance with universal precautions for protection against HIV. Patient care should include helping these patients feel that they can obtain acceptance and compassion from health care workers.
- Hepatitis is a viral disease. It produces pathological changes in the liver. The three main classes of hepatitis virus are hepatitis A, hepatitis B, and hepatitis C. Infection with hepatitis may cause mild symptoms, liver failure, or death.

Continued

- Tuberculosis is a chronic pulmonary disease. It is acquired through inhalation of tubercle bacilli. The infection is passed mainly when infected people cough or sneeze the bacteria into the air or by contact with sputum that contains virulent TB bacilli. The infection is characterized by stages of early infection (frequently asymptomatic), latency, and a potential for recurrent postprimary disease.
- Meningococcal meningitis is an inflammation of the membranes that surround the spinal cord and brain. It can be caused by bacteria, viruses, and other microorganisms.
- Bacterial endocarditis is inflammation of the endocardium and any one or more heart valves. The disease can be rapidly fatal if left untreated.
- Pneumonia is an acute inflammatory process of the respiratory bronchioles and alveoli. Bacteria, viruses, and fungi can cause this disease.
- Tetanus is a serious, sometimes fatal, disease of the CNS. It is caused by infection of a wound with spores of the bacterium *C. tetani*. The most common symptom is trismus (difficulty opening the mouth, lockjaw).
- Rabies is an acute viral infection of the CNS. Humans are highly susceptible to the rabies virus after exposure to saliva from the bite or scratch of an infected animal.
- Hantaviruses are carried by rodents. They are transmitted through inhalation of material contaminated with rodent urine and feces. Many forms of this disease occur in specific geographical areas.
- Rubella is a mild, febrile, highly communicable viral disease. It is characterized by a diffuse, punctate, macular rash. The CDC recommends that all health care providers receive immunization if they are not immune as a result of previous rubella infection.
- Rubeola is an acute, highly communicable viral disease caused by the measles virus. It is characterized by fever, conjunctivitis, cough, bronchitis, and a blotchy red rash.
- Mumps is an acute, communicable systemic viral disease. It is characterized by localized unilateral or bilateral edema of one or more of the salivary glands. Occasionally other glands are also involved.
- Chickenpox is highly communicable. It is characterized by a sudden onset of low-grade fever, mild malaise, and a maculopapular skin eruption that lasts for a few hours. This is followed by a vesicular eruption that lasts for 3 to 4 days, leaving a granular scab. The virus may reactivate during periods of stress or immunosuppression. At that time, it may cause an illness known as shingles.
- Pertussis is an infectious disease that leads to inflammation of the entire respiratory tract. It causes an insidious cough. The cough becomes paroxysmal in 1 to 2 weeks and lasts 1 to 2 months.
- Influenza is mainly a respiratory tract infection. It is spread by influenza viruses A, B, and C.
- Mononucleosis is caused either by the Epstein-Barr virus or by cytomegalovirus. Both of these are members of the herpes virus family.
- Syphilis is a systemic disease. It is characterized by a primary lesion; a secondary eruption involving skin and mucous membranes; long latency periods; and eventually by seriously disabling lesions of the skin, bone, viscera, CNS, and cardiovascular system.
- Gonorrhea is caused by the sexually transmitted bacterium *N. gonorrhoeae*. Gonorrhea can be treated with antibiotics. However, some strains brought into the United States from other countries do not respond to the usual antibiotic therapy.
- Chlamydia is a major cause of sexually transmitted nonspecific urethritis or genital infection. Signs and symptoms are similar to those of gonorrhea.
- Herpes simplex virus is transmitted by skin-to-skin contact with an infected area of the body. The primary infection produces a vesicular lesion (blister). This lesion heals spontaneously. After the primary infection, the virus travels to a sensory nerve ganglion. It remains there in a latent stage until reactivated.
- Lice are small, wingless insects that are ectoparasites of birds and mammals. During biting and feeding, lice secrete a substance that causes small, red macules and pruritus.
- The human scabies mite is a parasite. It completes its life cycle in and on the epidermis of the host. Scabies bites are usually concentrated around the hands and feet, especially in the webs of the fingers and toes.
- Reporting a possible communicable disease exposure permits immediate medical follow-up. It also enables the DO to make changes that might prevent exposures in the future. Moreover, it helps employees to obtain the proper evaluation and testing.
- Part of the paramedic's professional duty with regard to infectious disease transmission is to know when not to go to work. Paramedics also have a duty to use the proper BSI precautions at all times.

CHAPTER

29 Abdominal and Gastrointestinal Disorders

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Label a diagram of the abdominal organs.
2. Describe the function of the abdominal organs.
3. Outline the prehospital assessment of a patient complaining of abdominal pain.
4. Distinguish between pain characteristics in abdominal pain.
5. Describe general prehospital management techniques for a patient complaining of abdominal pain.
6. Describe signs and symptoms, complications, and prehospital management for the following abdominal and gastrointestinal disorders: gastrointestinal bleeding, acute and chronic gastroenteritis, ulcerative colitis, diverticulosis, appendicitis, peptic ulcer disease, bowel obstruction, Crohn's disease, pancreatitis, esophagogastric varices, hemorrhoids, cholecystitis, acute hepatitis, and hereditary hemochromatosis.

KEY TERMS

acute gastroenteritis Inflammation of the stomach and intestines with an associated sudden onset of vomiting, diarrhea, or both.

acute hepatitis An inflammatory condition of the liver associated with the sudden onset of malaise, weakness, anorexia, intermittent nausea and vomiting, and dull right upper quadrant pain, usually followed within 1 week by the onset of jaundice, dark urine, or both.

acute mesenteric ischemia An abrupt interruption of intestinal blood flow; it may result from an embolism, thrombosis, or a low-flow state (decreased perfusion).

anal fistula An abnormal opening of the cutaneous surface near the anus.

appendectomy Surgical removal of the appendix.

appendicitis Acute inflammation of the appendix.

ascites An abnormal accumulation of fluid in the space between the tissues lining the abdomen and abdominal organs.

bowel obstruction An occlusion of the intestinal lumen that results in blockage of normal flow of intestinal contents.

cholecystectomy Surgical removal of the gallbladder.

cholecystitis Inflammation of the gallbladder, most often associated with the presence of gallstones.

chronic gastroenteritis Inflammation of the stomach and intestines that accompanies numerous gastrointestinal disorders.

cirrhosis A chronic degenerative disease of the liver.

Crohn's disease A chronic, inflammatory bowel disease of unknown origin that usually affects the ileum, the colon, or both.

diverticulitis Inflammation of one or more diverticula.

diverticulosis The presence of pouchlike herniations through the muscular layer of the colon.

diverticulum A pouchlike herniation through the muscular wall of a tubular organ; it may be present in the stomach, small intestine or, most commonly, the colon.

emesis The forceful expulsion of stomach contents.

esophagitis Inflammation of the esophagus.

esophagogastric varices A complex of longitudinal, tortuous veins at the lower end of the esophagus that become enlarged and swollen as a result of portal hypertension.

fecalith A hard, impacted mass of feces in the colon.

gangrenous Necrosis or death of tissue.

gastroesophageal reflux disease (GERD) A condition in which the stomach contents leak backward from the stomach into the esophagus.

hematemesis Vomiting of bright red blood, indicating upper gastrointestinal bleeding.

hematochezia The passage of red blood through the rectum.

hemorrhoids Swollen, distended veins (internal, external, or both) in the rectoanal area.

hepatic encephalopathy A type of brain damage caused by liver disease and consequent ammonia intoxication.

hepatitis An inflammatory condition of the liver characterized by jaundice, hepatomegaly, anorexia, abdominal and gastric discomfort, abnormal liver function, clay-colored stools, and dark urine. The viruses responsible for hepatitis are hepatitis A virus (HAV), HBV, HCV, HDV, and HEV.

hereditary hemochromatosis An inherited condition in which the body absorbs and stores too much iron. The

extra iron accumulates in several organs, especially the liver, heart, and pancreas.

hernia Protrusion of any organ through an abdominal opening in the muscle wall of the cavity that surrounds it.

hiatal hernia An anatomical abnormality in which part of the stomach protrudes through the diaphragm and up into the chest.

ileus An obstruction of the intestines.

involuntary guarding An unconscious rigid contraction of the abdominal muscles; a sign of peritoneal inflammation.

lactose intolerance A sensitivity disorder that results in the inability to digest lactose because of a deficiency of or defect in the enzyme lactase.

Mallory-Weiss syndrome A condition characterized by massive bleeding after a tear in the mucous membrane at the junction of the esophagus and the stomach.

melena Abnormal black, tarry stools containing digested blood.

pancreatitis Inflammation of the pancreas, which causes severe epigastric pain.

paralytic ileus A decrease in or the absence of intestinal peristalsis; it may occur after abdominal surgery, illness, or injury, and it is the most common cause of intestinal obstruction.

peptic ulcer disease An illness that results from a complex pathological interaction among the acidic gastric secretions and proteolytic enzymes and the mucosal barrier.

permissive hypotension A fluid resuscitation strategy in which fluid and red cell products are withheld until bleeding has been surgically controlled.

rebound tenderness Pain caused by the sudden release of fingertip pressure on the abdomen; it is a sign of peritoneal inflammation.

rectal abscess An infected, pus-filled cavity near the anus.

referred pain Pain felt at a site distant from its origin.

somatic pain Pain that arises from skeletal muscles, ligaments, vessels, or joints.

ulcerative colitis An inflammatory condition of the large intestine characterized by severe diarrhea and ulceration of the mucosa of the intestine.

visceral pain Deep pain that arises from smooth vasculature or organ systems.

Acute abdominal pain is a common chief complaint in emergency care that may reflect serious illness. The condition accounts for up to 10% of all visits to the emergency department each year.[1] This chapter reviews the gastrointestinal anatomy and disorders that produce gastrointestinal bleeding and abdominal pain. Appropriate evaluation and management in the prehospital setting may prevent the development of life-threatening complications.

(Courtesy Ray Kemp, St. Charles, Mo.)

REVIEW OF GASTROINTESTINAL ANATOMY

As described in Chapter 10, the gastrointestinal (GI) system provides the body with water, electrolytes, and other nutrients used by the cells. The major organs of the GI system are the esophagus, stomach, small and large intestines, liver, gallbladder, and pancreas (Figure 29-1 and Box 29-1). The genitourinary system (see Chapters 30 and 31) also can produce abdominal pain and bleeding.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 196-199.

ASSESSMENT OF THE PATIENT WITH ACUTE ABDOMINAL PAIN

When caring for a patient with abdominal pain, the paramedic should begin the primary survey by ensuring that the scene is safe. This should include an initial scene size-up. The paramedic should determine whether the abdominal pain is a result of trauma or a medical condition. This may be evident from the initial scene survey. The nature of the pain also may become evident through information obtained from the patient, family, or bystanders. The paramedic should inspect the nearby area for medication bottles and signs of alcohol or other drug use. These signs may offer clues to the cause of the patient's condition. If alcohol or other drug use is suspected, any containers of **emesis**

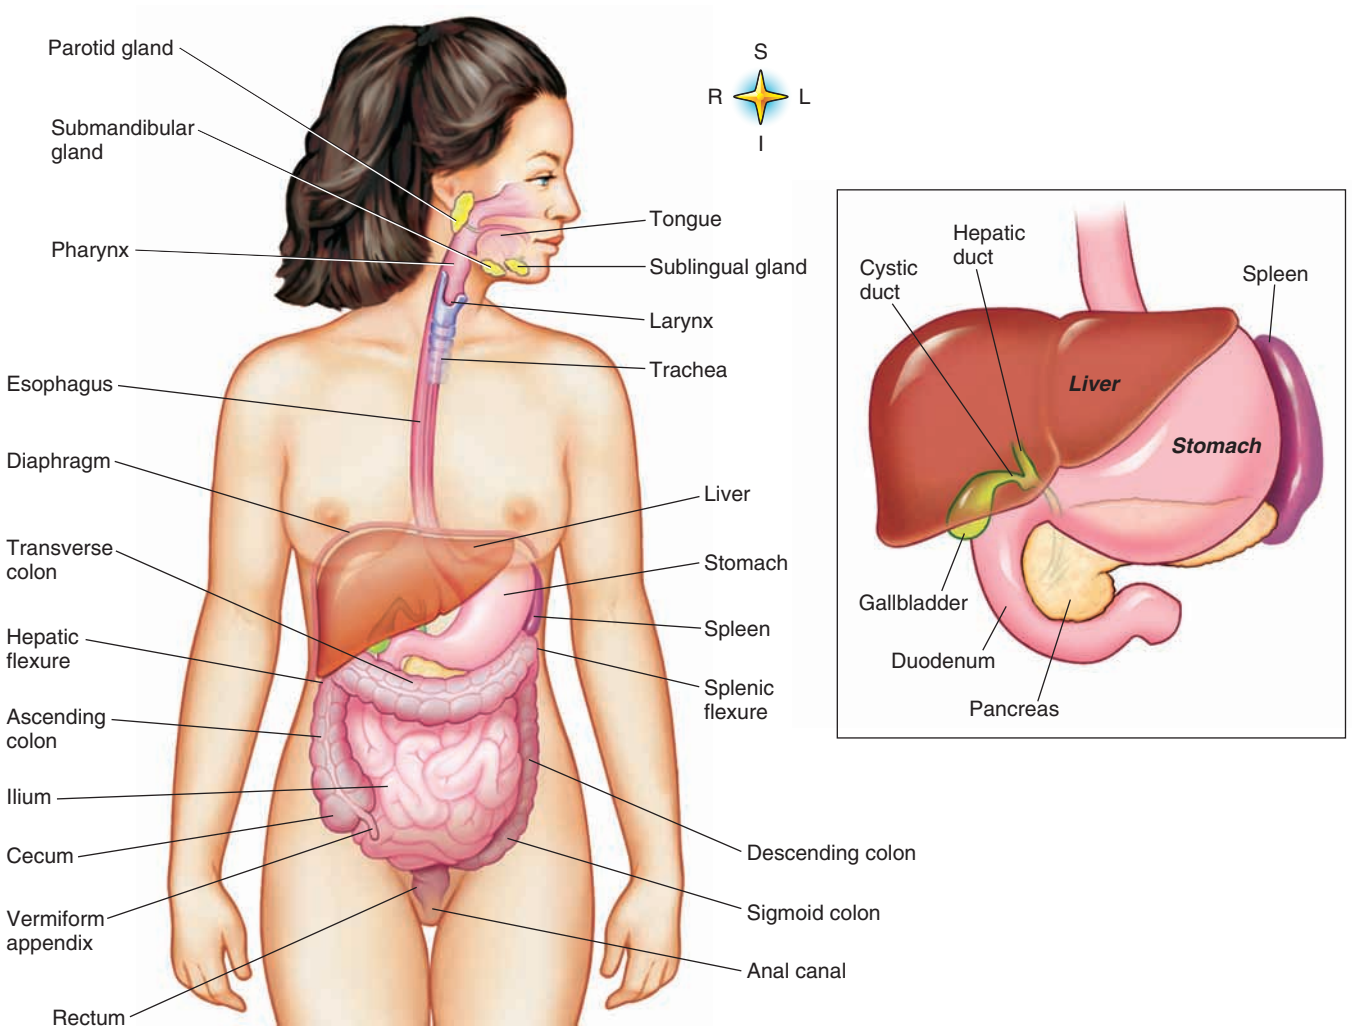

FIGURE 29-1 Location of the gastrointestinal system organs. (Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 7, St Louis, 2010, Mosby.)

BOX 29-1 Organs of the Gastrointestinal System

Esophagus: The muscular canal extending from the pharynx to the stomach.
Stomach: The major organ of digestion, located in the right upper quadrant of the abdomen.
Small intestine: The largest portion of the digestive tract; it is divided into the duodenum, jejunum, and ileum.
Large intestine: The portion of the digestive tract comprising the cecum; appendix; ascending, transverse, and descending colons; and rectum.
Liver: The largest and most complex gland of the body. It is located in the upper right quadrant of the abdomen. It produces and secretes bile; stores glucose as glycogen, synthesizes proteins and fats, stores vitamins; processes hemoglobin; filters harmful substances from the blood; metabolizes drugs; and converts poisonous ammonia to urea.
Gallbladder: A pear-shaped excretory sac on the visceral surface of the right lobe of the liver. It serves as a reservoir for bile.
Pancreas: A fish-shaped, nodular gland located across the posterior abdominal wall in the epigastric region of the body. It secretes various substances, including digestive enzymes and the hormones insulin and glucagon.

should be transported with the patient for laboratory analysis.

SHOW ME THE EVIDENCE

Kennedy and colleagues studied the protocols of medical priority dispatch systems to evaluate the protocols' ability to predict patients who needed advanced life support (ALS) skills. They included patients with a chief complaint of abdominal pain who were transported to selected study hospitals. Of the 343 patients with a complaint of abdominal pain, 67% met the inclusion criteria. Eighty-four percent of the patients did not meet ALS criteria. The researchers concluded that significant overtriage of patients with abdominal pain occurs.

Kennedy JD et al: Effectiveness of a medical priority dispatch protocol for abdominal pain, *Prehosp Emerg Care* **7**:89-93, 2003.

After the primary survey to ensure adequacy of airway, breathing, and circulation, assessment of the patient with acute abdominal pain begins with a thorough history focused on the chief complaint. The paramedic should assess and document baseline vital signs and perform a systematic physical examination. This exam helps the paramedic identify abdominal emergencies. These may indicate the development of shock or the need for immediate transport for surgical intervention.

NOTE

Abdominal surgery may be necessary for the treatment of many conditions. These include inflammatory bowel disease (e.g. Crohn's disease or ulcerative colitis), diverticulitis, small bowel obstruction, or malignant diseases, including colon cancer and rectal cancer. Other common types of abdominal surgery include weight-loss surgery; hernia repair; liver, pancreatic, or stomach cancer surgery; **appendectomy, cholecystectomy,** and adhesiolysis (removal of scar tissue). Persistent abdominal pain that lasts several hours or longer warrants transport of the patient for evaluation by a physician.

History

When obtaining a history of abdominal pain, the paramedic should attempt to identify the location and type of pain and any associated signs and symptoms. As described in Chapter 18, the mnemonic OPQRST or a similar method can help the paramedic organize this information. Sample questions that might be included in the OPQRST evaluation include the following:

LOOK AGAIN

See Chapter 18: History Taking, pp. 491-495.

O (Onset): Was the onset of pain sudden? What were you doing when it started?

P (Provocative/palliative): What makes the pain better? What makes the pain worse? Does a sitting or lying position affect your discomfort? Does a deep breath increase the pain? Does the pain change after you eat or drink?

Q (Quality): What does the pain feel like? Is it sharp, dull, burning, tearing?

R (Region): Where is the pain located? Does it travel (radiate) to another area of the body or does it stay in the same place?

S (Severity): Is the pain mild, moderate, or severe? What is the degree of discomfort on a scale of 0 to 10 (with 10 being the worst)?

T (Time): When did the pain begin? Is it constant or intermittent? If intermittent, how long does the pain episode last?

Other key elements of a patient history can be obtained through a SAMPLE history (*s*igns and symptoms, *a*llergies, *m*edications, *p*ast medical history, *l*ast meal or oral intake, and *e*vents before the emergency). This helps identify symptoms, allergies, the medical history, the last oral intake, and important events that preceded the chief complaint. Other important elements of a patient history include any recent illness and past significant medical history. Of particular importance are hypertension or cardiac or respiratory disease that may manifest in abdominal pain; medication use; alcohol or other drug use; the last bowel movement and any significant changes in the patient's bowel habits; and previous abdominal surgeries. Women of childbearing age also should be questioned about menstrual periods (including regularity and the date of the last menstrual period) and the possibility of pregnancy.

CRITICAL THINKING

What factors can influence a patient's perception and description of pain?

Location and Type of Abdominal Pain

To assess a specific disorder, the paramedic can use a method that relates the anatomical location of GI organs and structures to the origin of the pain. Table 29-1 lists locations of abdominal pain and possible causes of illness. The types of abdominal pain that may result from chronic or acute episodes may be classified as *visceral, somatic,* or *referred.*

VISCERAL PAIN

Visceral pain (or organ pain) is caused by the stimulation of autonomic nerve fibers that surround an organ. Visceral pain also can be caused by compression and inflammation of solid organs and by distention or stretching of hollow organs or the ligaments. The patient usually describes the

TABLE 29-1 Common Conditions That Cause Acute Abdominal Pain

Condition	Usual Pain Characteristics	Possible Associated Findings
Appendicitis	Initially periumbilical or epigastric; colicky; later becomes localized to RLQ, often at McBurney's point	Guarding tenderness; positive iliopsoas and obturator signs; RLQ skin hyperesthesia; anorexia, nausea, or vomiting after onset of pain; low-grade fever; positive Aaron, Rovsing, Markle, and McBurney signs
Peritonitis	Sudden or gradual onset; generalized or localized, dull or severe and unrelenting; guarding; pain on deep inspiration	Shallow respirations; positive Blumberg, Markle, and Balance signs; reduced or absent bowel sounds; nausea and vomiting; positive obturator and iliopsoas tests
Cholecystitis	Severe, unrelenting RUQ or epigastric pain; may be referred to right subscapular area	RUQ tenderness and rigidity; positive Murphy sign; palpable gallbladder; anorexia; vomiting; fever; possible jaundice
Pancreatitis	Dramatic, sudden, excruciating LUQ, epigastric, or umbilical pain; may be present in one or both flanks; may be referred to left shoulder	Epigastric tenderness; vomiting; fever; shock; positive Grey Turner and Cullen signs (both signs occur 2 to 3 days after onset)
Salpingitis	Lower quadrant; worse on left	Nausea, vomiting, fever, suprapubic tenderness, rigid abdomen, pain on pelvic examination
Pelvic inflammatory disease	Lower quadrant; increases with activity	Tender adnexa and cervix, cervical discharge, dyspareunia
Diverticulitis	Epigastric, radiating down left side of abdomen especially after eating; may be referred to back	Flatulence, borborygmus, diarrhea, dysuria, tenderness on palpation
Perforated gastric or duodenal ulcer	Abrupt onset in RUQ; may be referred to shoulders	Abdominal free air and distention with increased resonance over liver; tenderness in epigastrium or RUQ; rigid abdominal wall; rebound tenderness
Intestinal obstruction	Abrupt, severe, spasmodic; referred to epigastrium, umbilicus	Distention, minimal rebound tenderness, vomiting, localized tenderness, visible peristalsis; bowel sounds absent (with paralytic obstruction) or hyperactive high pitched (with mechanical obstruction)
Volvulus	Referred to hypogastrium and umbilicus	Distention, nausea, vomiting, guarding; sigmoid loop volvulus may be palpable
Leaking abdominal aneurysm	Steady throbbing midline over aneurysm; may radiate to back, flank	Nausea, vomiting, abdominal mass, bruit
Biliary stones, colic	Episodic, severe, RUQ, or epigastrium lasting 15 min to several hours; may be referred to subscapular area, especially right	RUQ tenderness, soft abdominal wall, anorexia, vomiting, jaundice, subnormal temperature
Renal calculi	Intense; flank, extending to groin and genitals; may be episodic	Fever, hematuria; positive Kehr's sign
Ectopic pregnancy	Lower quadrant; referred to shoulder; agonizing with rupture	Hypogastric tenderness, symptoms of pregnancy, spotting, irregular menses, soft abdominal wall, mass on bimanual pelvic examination; ruptured: shock, rigid abdominal wall, distention; positive Kehr and Cullen signs
Ruptured ovarian cyst	Lower quadrant, steady, increases with cough or motion	Vomiting, low-grade fever, anorexia, tenderness on pelvic examination
Splenic rupture	Intense; LUQ, radiating to left shoulder; may worsen with elevation of foot of bed	Shock, pallor, lowered temperature

From Seidel H, et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.
LUQ, Left upper quadrant; *RLQ,* right lower quadrant; *RUQ,* right upper quadrant.

pain as cramping or gas-type pain. Patients often describe the pain as varying in intensity, increasing to severe and then subsiding. Visceral pain generally is diffuse; therefore, the pain is difficult to localize. Often the pain is centered at the umbilicus or lower in the midline. Visceral pain often is associated with other symptoms of autonomic nerve involvement, such as tachycardia, diaphoresis, nausea, or vomiting. Common causes of visceral abdominal pain include early appendicitis, pancreatitis, cholecystitis, and intestinal obstruction (described later in this chapter).

SOMATIC PAIN

Somatic pain is produced by bacterial or chemical irritation of nerve fibers in the peritoneum (peritonitis). Unlike visceral pain, somatic pain usually is constant. Moreover, the pain is localized to a specific area. The patient often describes the pain as sharp or stabbing. Patients with somatic abdominal pain generally are hesitant to move about. They may lie on the back or side with the legs flexed to prevent additional pain from stimulation of the peritoneal area. These patients often show **involuntary guarding** of the abdomen during the physical examination and **rebound tenderness** (signs of peritoneal inflammation). Common causes of somatic pain are appendicitis and an inflamed or a perforated viscus (ulcer, gallbladder, or small or large intestine).

NOTE

Ask the patient to take a deep breath as you palpate the upper right quadrant (URQ) of the abdomen. An inflamed gallbladder descends during inspiration and causes discomfort. This is known as *Murphy's sign*. Other physical signs in patients with acute abdominal pain are presented in Table 29-2.[2]

REFERRED PAIN

Referred pain is pain in a part of the body considerably removed from the tissues that cause the pain. This mechanism results from branches of visceral fibers that synapse in the spinal cord with the same second-order neurons that receive pain fibers from the skin. When these pain fibers are stimulated intensely, pain sensations spread. The patient experiences the pain in areas distant from the source.

A knowledge of referred pain is important, because many visceral ailments cause no symptoms except referred pain (Figure 29-2). For example, cardiac pain may be referred to the neck and jaw, shoulders, and pectoral muscles and down the arms; biliary pain to the right subscapular area; renal colic to the genitalia and flank area; uterine and rectal pain to the lower back; and a leaking aortic aneurysm to the lower back or buttocks.

NOTE

Providing analgesics to manage abdominal pain in the prehospital setting is controversial. Some medical experts believe the drugs may mask serious signs and symptoms. Others believe that these medications do not alter the diagnosis and that they may produce a more reliable physical examination.[3] The paramedic should follow established protocol as provided by medical direction.

Signs and Symptoms

Although numerous signs and symptoms may be associated with acute abdominal pain, the following, along with possible causes, are common:

1. Nausea, vomiting, anorexia
   - Appendicitis
   - Biliary tract disease
   - Gastritis
   - High intestinal obstruction
   - Pancreatitis
2. Diarrhea
   - Inflammatory process (gastroenteritis, ulcerative colitis)
3. Constipation
   - Dehydration
   - Obstruction
   - Medication-induced decreased intestinal motility (codeine, morphine)

TABLE 29-2 Physical Signs in Patients With Acute Abdominal Pain

Sign	Characteristics
Murphy's sign	Cessation of inspiration during examination of the right upper quadrant (may indicate acute cholecystitis)
McBurney's sign	Tenderness midway between the anterior-superior iliac spine and the umbilicus (may indicate acute appendicitis)
Cullen's sign	Periumbilical bluish discoloration (may indicate retroperitoneal hemorrhage, pancreatic hemorrhage, or rupture of an abdominal aortic aneurysm [AAA])
Grey Turner's sign	Bluish discoloration of the flanks (may indicate retroperitoneal hemorrhage, pancreatic hemorrhage, or AAA rupture)
Kehr's sign	Severe left shoulder pain (may indicate splenic rupture or rupture of an ectopic pregnancy)
Obturator sign	Pain with flexed right hip rotation (may indicate appendicitis)
Psoas sign	Pain when raising a straight leg against resistance (may indicate appendicitis, right-side AAA)

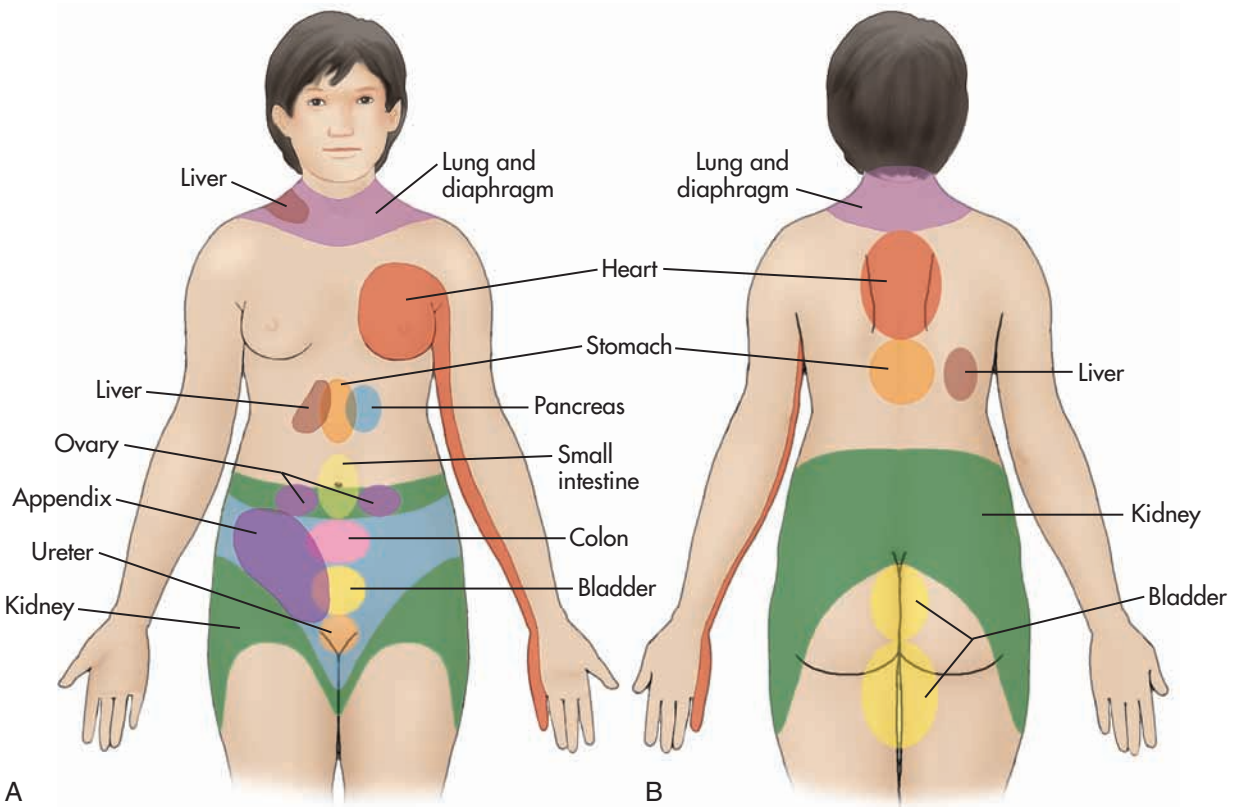

FIGURE 29-2 Referred pain. **A,** Anterior view. **B,** Posterior view.

4. Change in stool color
   - Biliary tract obstruction (clay-colored stools)
   - Lower intestinal bleeding (black, tarry stools)
5. Chills and fever
   - Appendicitis
   - Bacterial infection
   - Cholecystitis
   - Pyelonephritis

Vital Signs

Vital sign assessment should include evaluation and documentation of the patient's blood pressure, pulse rate (including electrocardiographic assessment), and respiratory rate and the color, moisture, temperature, and turgor of the skin. The presence or absence of orthostatic pulse and blood pressure changes should be noted if possible. As described in Chapter 22, rising from a recumbent position to a sitting or standing position, with an associated fall in systolic pressure (after 1 minute) of 10 to 15 mm Hg and/or a concurrent rise in the pulse rate (after 1 minute) of 10 to 15 beats/minute, indicates significant volume depletion and a decrease in perfusion status. The paramedic also should assess the blood pressure, pulses, and capillary refill in each extremity as a consideration for aortic dissection.

LOOK AGAIN
See Chapter 22: Cardiology, pp. 693-696.

Physical Examination

The physical examination of a patient with acute abdominal pain involves the skills of inspection, auscultation, percussion, and palpation. If a life-threatening illness is suspected, rapid stabilization and transportation of the patient are the first priorities. Further examination can be completed en route to the receiving hospital. The physical examination of a patient's abdomen is described in Chapter 20. The following discussion serves as a review. (Female physical examinations to evaluate genitourinary complaints are discussed in Chapter 31.)

LOOK AGAIN
See Chapter 20: Secondary Assessment, pp. 542-546.

INSPECTION

In the initial patient encounter, the paramedic should note the position in which the patient is lying. As stated previously, many patients with abdominal peritoneal irritation lie on the side. The knees often are flexed and pulled in toward the chest. Other visual clues that may indicate abdominal pain are skin color, facial expressions (e.g., grimacing), and the presence or absence of voluntary movement. The paramedic should remove the patient's clothing (while ensuring privacy) and inspect the abdominal wall for

bruises, scars, ascites (Figure 29-3), abdominal distention, or abdominal masses.

> **NOTE**
> **Ascites** is an abnormal accumulation of fluid in the space between the tissues lining the abdomen and abdominal organs (the peritoneal cavity). The fluid contains large amounts of protein and electrolytes. Ascites is caused by high pressure in the blood vessels of the liver (portal hypertension) and low albumin levels. A person with ascites usually has severe liver disease. Other disorders associated with ascites include congestive heart failure and pancreatitis.

AUSCULTATION

Determining the presence or absence of bowel sounds by auscultation usually is reserved for assessment in the emergency department. However, if auscultation is to be done, the paramedic should perform it for about 2 minutes in each quadrant before deciding that bowel sounds are absent. (Auscultation should always precede palpation and percussion, because these procedures may alter the intensity of bowel sounds.) An increase in the number, duration, or intensity of bowel sounds indicates the possibility of gastroenteritis or intestinal obstruction. A considerable decrease in the number and intensity of bowel sounds (or their absence) may indicate peritonitis or ileus (obstruction of the intestine).

PALPATION

The paramedic should begin palpation of the abdomen gently and avoid the painful area until the remainder of the abdomen has been examined. Signs of rigidity or spasm, tenderness or masses, and the patient's facial expressions should be noted. These may provide clues to the severity of the pain. In addition, the paramedic should identify the abdomen as soft or rigid.

PERCUSSION

If time permits, a general assessment of tympany and dullness by percussion may be performed. This is to detect the presence of fluid, air, or solid masses in the abdomen. The paramedic should use a systematic approach and move from side to side or clockwise. Tenderness and the temperature and color of the abdominal skin should be noted. To review, tympany is the major sound that should be noted during percussion because of the normal presence of air in the stomach and intestines. Dullness should be heard over organs and solid masses.

MANAGEMENT OF THE PATIENT WITH AN ABDOMINAL EMERGENCY

Patients with acute abdominal pain or GI bleeding cannot be managed effectively in the prehospital setting. Most require extensive evaluation in the emergency department, including laboratory analysis, radiological imaging, fluid and medication therapy, and perhaps surgical intervention. The role of the paramedic is to support the patient's airway and ventilatory status; to perform and document an initial patient assessment, including a thorough history; to monitor vital signs and cardiac rhythm; to initiate intravenous (IV) therapy for fluid replacement or fluid resuscitation; to administer analgesics and antiemetics per protocol; and to transport the patient rapidly for evaluation by a physician (Figure 29-4).

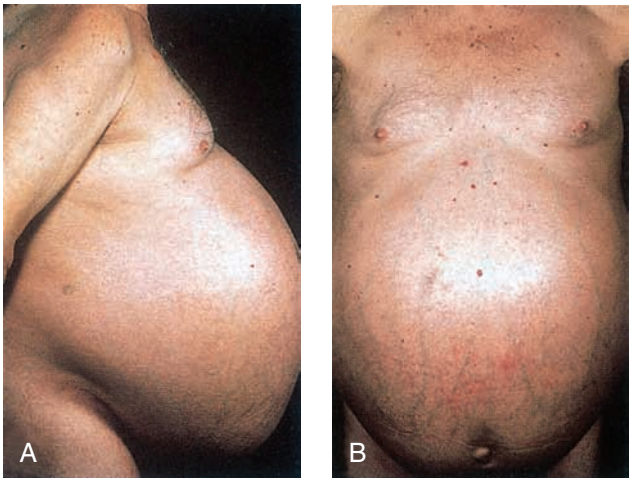

FIGURE 29-3 Gross ascites in a male patient. (Epstein O, et al: *Clinical examination,* ed 4, St Louis, 2008, Mosby.)

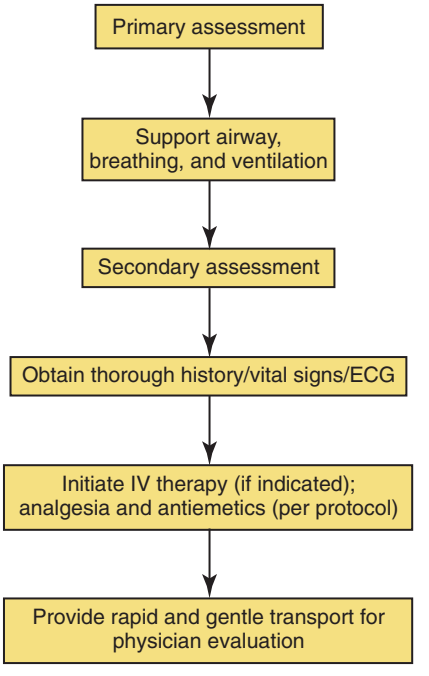

FIGURE 29-4 Abdominal pain algorithm.

SPECIFIC ABDOMINAL EMERGENCIES

Abdominal emergencies can result from inflammation, infection, and obstruction. Some disorders may be associated with upper gastrointestinal bleeding. (Examples of such disorders include lesions, peptic ulceration, and esophagogastric varices.) Some disorders may be associated with lower gastrointestinal bleeding. (Examples of these disorders include colonic lesions, diverticulosis, and hemorrhoids.) Other disorders, such as pancreatitis and cholecystitis, more often are associated with acute abdominal pain in the absence of bleeding. Box 29-2 lists the specific gastrointestinal disorders discussed in this chapter.[4]

Gastrointestinal Bleeding

Gastrointestinal bleeding is a common clinical problem seen by paramedics. It often requires hospitalization. It can vary from chronic blood loss to a massive, life-threatening hemorrhage. Massive hemorrhage may be difficult to control. Many bleeding episodes resolve spontaneously. However, evaluation by a physician to identify the bleeding site is crucial to help prevent a recurrence. Bleeding from the GI tract can be classified by site of origin as *upper* or *lower* gastrointestinal bleeding.

The most common causes of upper gastrointestinal bleeding are peptic ulcer disease and variceal rupture (e.g., esophageal varices that result from underlying chronic liver disease, such as cirrhosis). Another cause of upper gastrointestinal bleeding is **Mallory-Weiss syndrome** (an esophageal laceration that usually results from repeated vomiting or retching.) Other causes are tumors or cancers of the esophagus or stomach. Factors that may aggravate upper gastrointestinal bleeding include use of nonsteroidal anti-inflammatory drugs (NSAIDs) such as ***aspirin*** and other antiarthritic drugs, chronic liver disease, blood-thinning medications (e.g., warfarin), and underlying medical conditions, such as renal disease, hypertension, and cardiorespiratory diseases. Upper gastrointestinal bleeding accounts for more than 300,000 hospitalizations each year and has a mortality rate of about 10%.[1] Risk factors include advancing age, alcohol and tobacco use, and coexisting illnesses, such as hypertension, diabetes, and cardiorespiratory disease.

BOX 29-2 Gastrointestinal Disorders

- Acute gastroenteritis
- Acute hepatitis
- Acute mesenteric ischemia
- Appendicitis
- Bowel obstruction
- Hemorrhoids
- Cholecystitis
- Chronic gastroenteritis
- Crohn's disease
- Diverticulosis
- Esophagogastric varices
- Gastrointestinal bleeding
- Hereditary hemochromatosis
- Pancreatitis
- Peptic ulcer disease
- Ulcerative colitis

The most common cause of lower gastrointestinal (colon) bleeding is diverticulosis. Other causes include colon cancers, colon polyps, and inflammatory bowel disorders, such as ulcerative colitis and Crohn's disease. Like upper gastrointestinal bleeding, lower gastrointestinal bleeding may be mild or it may be brisk and difficult to control. Common complaints include cramping abdominal pain, diarrhea (which may be bloody), nausea, vomiting, and changes in the patient's stool and bowel habits.

The seriousness of gastrointestinal bleeding depends on the acuteness and the source of the blood loss. Mild chronic gastrointestinal blood loss may present without any noticeable bleeding. It can result in an iron deficiency anemia. These patients often are unaware that they are bleeding and may or may not notice small amounts of blood with their bowel movements. Patients with severe cases of chronic or acute bleeding can have signs of anemia, such as weakness, pallor, dizziness, shortness of breath, or angina. (The hematocrit of these patients may be within normal range in the early phase of the hemorrhage [see Chapter 32].)

More serious gastrointestinal bleeding may occur with **hematemesis** (bloody vomitus). Vomit may be red or may have a dark, coffee ground–like appearance. Blood in the stool could present as bright red, dark and clotted, or black and tarry. The presentation depends on the location of the bleeding source. A black, tarry stool **(melena)** often indicates an upper gastrointestinal source of bleeding where blood has been partially digested. However, bleeding also could originate from the small intestine or right colon. Bright red blood from the rectum **(hematochezia)** after a bowel movement usually signifies a bleeding source close to the rectal opening. Such bleeding often results from hemorrhoids. However, conditions such as rectal cancers, polyps, ulcerations, or infections also can cause this type of bleeding.

Any source of gastrointestinal bleeding that is active or severe usually requires hospitalization. With hospitalization the hypovolemia can be managed with IV fluids or blood transfusions if needed. Attempts to identify and stop the source of hemorrhage may include the use of medications, diagnostic tests (e.g., barium GI studies, nuclear scans, angiography, endoscopy, and colonoscopy), and other therapeutic measures, such as gastric lavage, placement of a *Sengstaken-Blakemore tube* (to tamponade bleeding in the esophagus) and, in some cases, surgery.

Prehospital care for patients with active and severe gastrointestinal bleeding includes provision of emotional support, administration of high-concentration oxygen, and airway and ventilatory management. IV fluid resuscitation should begin with a 2 L fluid bolus in adults (20 mL/kg in children) to maintain blood pressure.[1] A pneumatic antishock garment should be considered (per protocol). All patients require rapid transport for physician evaluation.

NOTE

GI bleeding often is uncontrollable in the prehospital setting. In some cases hypotension can be protective, because a reduced blood pressure can allow the bleeding site to stabilize.[5] Medical direction may recommend that the patient's systolic blood pressure be maintained between 80 and 90 mm Hg **(permissive hypotension)** until the patient has been delivered to the emergency department for definitive care (see Chapter 36).[6]

Acute Gastroenteritis

Acute gastroenteritis is inflammation of the stomach and intestines accompanied by the sudden onset of vomiting or diarrhea or both. The condition is a common problem worldwide and is responsible for more than 4 million deaths per year in developing countries.[7] It may be caused by bacterial or viral infection, parasites (e.g., organisms that cause "traveler's diarrhea," *Giardia lamblia* and *Cyclosporidium cayetanensis,* which is reported to be transmitted through ingestion of contaminated water), chemical toxins, and other conditions, such as allergies, lactose intolerance, and immune disorders. The inflammation causes hemorrhage and erosion of the mucosal layers of the gastrointestinal tract. Inflammation also can affect the way water and nutrients are absorbed.

DID YOU KNOW?

Lactose Intolerance

Lactose intolerance is the inability or insufficient ability to digest lactose, a sugar found in milk and milk products. (Lactose intolerance should not be confused with cow's milk allergy.) Lactose intolerance is caused by a deficiency of the enzyme *lactase,* which is produced by the cells lining the small intestine. Lactase breaks down lactose into two simpler forms of sugar called *glucose* and *galactose,* which then are absorbed into the bloodstream.

The cause of lactose intolerance is best explained by describing how a person develops lactase deficiency. *Primary lactase deficiency* develops over time and begins after about age 2 when the body begins to produce less lactase. Most children who have lactase deficiency do not experience symptoms of lactose intolerance until late adolescence or adulthood. A genetic link may be involved in primary lactase deficiency. *Secondary lactase deficiency* results from injury to the small intestine that occurs with severe diarrheal illness, celiac disease, Crohn's disease, or chemotherapy. This type of lactase deficiency can occur at any age but is more common in infancy. Infants born prematurely are more likely to have lactase deficiency, because an infant's lactase levels do not increase until the third trimester of pregnancy.

People with lactose intolerance may feel uncomfortable 30 minutes to 2 hours after consuming milk and milk products. Symptoms range from mild to severe, based on the amount of lactose consumed and the person's level of tolerance. Common symptoms include abdominal pain and bloating, gas, diarrhea, and nausea. Although the body's ability to produce lactase cannot be changed, the symptoms of lactose intolerance can be managed with dietary changes. Most people with lactose intolerance can tolerate some amount of lactose in their diet. The Dietary Guidelines for Americans 2005 recommended that people with lactose intolerance choose milk products with lower levels of lactose than regular milk, such as yogurt and hard cheese. Other options include over-the-counter lactase enzyme drops or tablets that may make foods more tolerable.[8]

Infectious forms of acute gastroenteritis usually are caused by exposure to rotavirus, adenovirus, astrovirus, Norwalk virus, or a group of noroviruses (see Chapter 28). The condition often is called the "stomach flu," although it is not caused by the influenza viruses. Typically, children under 5 years of age are most vulnerable to rotaviruses. (These are the most common cause of watery diarrhea in children.) Adenoviruses and astroviruses cause diarrhea mostly in young children, although older children and adults also can be affected. The Norwalk virus and noroviruses are more likely to cause diarrhea in older children and adults. Infectious acute gastroenteritis usually is transmitted through the fecal-oral route and by ingestion of infected food or contaminated water. The condition is common in institutional settings (e.g., schools, day care centers, and nursing homes) and other group settings (e.g., banquet halls, cruise ships, dormitories, and campgrounds), where it can spread quickly.

Infectious acute gastroenteritis also can arise among travelers in endemic areas (native populations generally are resistant) and in populations in disaster areas where water supplies are contaminated. Bacteria that may be responsible for acute gastroenteritis include *Salmonella* spp., *Escherichia coli, Campylobacter* spp., and *Staphylococcus* spp. Contamination generally results from poor sanitation, a lack of safe drinking water, or contaminated food.

As the name implies, acute gastroenteritis often is abrupt and violent in onset. It involves rapid loss of fluids and electrolytes from constant vomiting and diarrhea. Fluid loss and dehydration may be severe in pediatric patients, the elderly, and immunosuppressed individuals. Hypokalemia, hyponatremia, acidosis (from prolonged diarrhea), or alkalosis (from prolonged vomiting) may develop. Treatment mainly is supportive, requiring IV fluid replacement, sedation, bed rest, and medications to control vomiting and diarrhea. Bacterial causes of gastroenteritis can be treated with antibiotic therapy.

Emergency medical services (EMS) personnel working in disaster areas should observe the following guidelines:

- Avoid patient contact if you are ill.
- Know the source of water supplies, or drink hot beverages that have been boiled or disinfected.
- Avoid habits that aid fecal-oral/mucous membrane transmission.
- Observe body substance isolation precautions. Also observe good hand-washing procedures.

CRITICAL THINKING
What would be your main concern for a patient with a history of severe gastroenteritis?

Chronic Gastroenteritis

Chronic gastroenteritis results from inflammation of the stomach and intestines. This can produce long-term changes or damage to the gastric mucosa. The condition usually is due to microbial infection, hyperacidity, or chronic use of alcohol, ***aspirin,*** and other nonsteroidal anti-inflammatory medications. Chronic gastroenteritis commonly results from *Helicobacter pylori* infection but also may be caused by other bacteria, such as *E. coli, Klebsiella pneumoniae, Enterobacter* spp., *Campylobacter jejuni, Vibrio cholerae, Shigella* spp., and *Salmonella* spp. Many of the bacteria responsible for chronic gastroenteritis are part of the normal intestinal flora, which precludes effective vaccination against these strains. Other causes of chronic gastroenteritis include Norwalk virus and rotavirus infection and parasitic infection from protozoa such as *G. lamblia* and *Cryptosporidium parvum.* The pathogenic agents responsible for the disease may be contracted through fecal-oral transmission and from contaminated food and water. EMS personnel should follow the same guidelines for personal safety as described previously.

NOTE
The bacterium *Helicobacter pylori* resides between the epithelial surface and the overlying mucosa in the human stomach. It is more prevalent in developing countries with contaminated water. It may be spread in adults and children through the fecal-oral route. The presence of *H. pylori* is believed to cause mucosal inflammation. This inflammation disrupts the normal defense mechanism of the stomach and can lead to ulceration.

Signs and symptoms of chronic gastroenteritis include epigastric pain, nausea and vomiting (which may be severe), fever, anorexia, mucosal bleeding *(erosive gastritis),* and epigastric tenderness on palpation. In severe cases the patient may have hypovolemia and shock. The condition is treated with dietary regulation, medications (antibiotics, antacids), and fluid replacement or fluid resuscitation if hypovolemia or dehydration occurs.

Ulcerative Colitis

Ulcerative colitis also is known as *colitis* or *proctitis*. Ulcerative colitis is an inflammatory condition of the large intestine. It is classified as an inflammatory bowel disease. Ulcerative colitis is characterized by ulceration of the mucosa of the intestine. This usually occurs in the rectum and lower part of the colon but may affect the entire colon. The inflammation makes the colon empty often (causing diarrhea). In addition, the ulceration causes bleeding and produces pus. Ulcerative colitis can occur at any age, although it most often starts between ages 15 and 30 or, less often, between ages 50 and 70. The condition affects men and women equally. A family history of the disease is present in 10% to 15% of cases. The cause of ulcerative colitis is unknown. The disorder may be related to the way the immune system reacts to a virus or bacterium that causes chronic inflammation in the intestinal wall. Other possible causes include allergies to certain foods (e.g., lactose intolerance) and environmental and psychological factors.

The most common signs and symptoms of ulcerative colitis are fatigue, weight loss, anorexia, rectal bleeding, and loss of body fluids and nutrients. Some patients have only mild symptoms. Other patients experience frequent fever, bloody diarrhea, nausea, and severe abdominal cramping. Some patients with the disease have remissions that last for months or years; in most patients, the symptoms eventually return. After evaluation by a physician and stabilization of the condition, ulcerative colitis usually is managed with steroids, electrolytes, antibiotics, and dietary regulation. Few patients require surgery, although surgical removal of the diseased colon may be indicated in severe cases. Prehospital care is dictated by the severity of the patient's condition. The care may vary from providing only emotional support and transportation for evaluation by a physician to providing airway, ventilatory, and circulatory support to manage hypovolemia and shock.

NOTE
In patients with acquired immunodeficiency syndrome (AIDS), the chronic diarrhea and diffuse colonic involvement of Kaposi's sarcoma (see Chapter 28) may mimic chronic ulcerative colitis. Undiagnosed signs of human immunodeficiency virus (HIV) infection also may be the cause. In some cases surgical bowel resection may be required in these patients.

Diverticulosis

A **diverticulum** is a sac or pouch that develops in the wall of the colon (Figure 29-5). Diverticula are a common development with advancing years and is associated with diets low in fiber. Diverticular outpouchings (a condition known as **diverticulosis**) tend to develop because of the high pressure in the contracting sigmoid colon that regulates movement of stool into the rectum. The outpouchings are most common at the weakest point in the colon wall. This is on the left side, just above the rectum. As a diverticulum expands, it develops a thin wall compared to the rest of the colon. The thin wall may allow bacteria to seep through and cause infection. Often a small artery or arteriole is present in the neck of the diverticulum from which subsequent bleeding may occur.

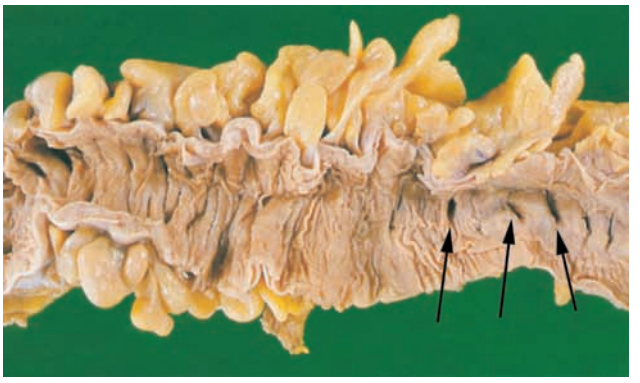

FIGURE 29-5 Diverticular disease. The outpouches of mucosa *(arrows)* in the sigmoid colon appear as slitlike openings from the mucosal surface of the opened bowel. (Modified from Stevens A, Lowe J: *Pathology,* London, 1995, Mosby.)

BOX 29-3 Abdominal Signs of Appendicitis

Rebound tenderness: Exert pressure in the right lower quadrant at McBurney's point and then release. Sharp abdominal pain when the pressure is released suggests appendicitis.

Iliopsoas muscle test: With the patient supine, ask the patient to raise the right leg and flex at the hip as you press down on the lower thigh. Lower quadrant pain may indicate appendicitis.

Obturator muscle test: With the patient supine, flex the right leg at the hip and knee. Then rotate the leg laterally and medially. Pain in the hypogastric region may indicate a ruptured appendix.

Most patients with diverticula are completely symptom free. However, up to 30% of these patients experience **diverticulitis** when one or more diverticula become obstructed with fecal matter. Mild complications of diverticulitis include irregular bowel habits (alternating constipation and diarrhea), fever, and lower left quadrant pain. Diverticulitis tends to recur within the first 5 years after the onset of symptoms. Definitive care for these patients includes dietary regulation, a high-fiber diet to stimulate daily bowel movements, antibiotic therapy and, in some cases, surgical repair.

Serious complications of diverticular disease are associated with perforation of the bowel. These complications include massive bright red rectal bleeding (or dark stools if bleeding is from a diverticulum in the right colon). Hemorrhage from a diverticulum can occur rapidly, is often painless, and is the most common cause of massive rectal bleeding in older adults. If bacteria escape into the abdomen, peritonitis or an abscess may develop. The hemorrhage often stops spontaneously. However, if the bleeding does not stop, emergency surgery may be necessary.

Appendicitis

Appendicitis is a common abdominal emergency. It occurs in 7% to 10% of the U.S. population.[9] The condition may present at any age, but most patients are 8 to 25 years old. Appendicitis is rare in children younger than 2 years.

Appendicitis occurs when the passageway between the appendix and the cecum is obstructed by fecal matter **(fecalith).** Appendicitis also may be due to inflammation of the area caused by a viral or bacterial infection. Obstruction of the passageway leads to distention of the appendix. Poor lymphatic and venous drainage allows bacterial infection to develop. If the condition continues, the inflamed organ eventually becomes **gangrenous.** The appendix then ruptures into the peritoneal cavity. This results in peritonitis (which may progress to shock) or the development of abscesses.

Because of variations in the position of the appendix, the patient's age, and the degree of inflammation, the clinical presentation of appendicitis often is inconsistent (Box 29-3). Also, many other disorders have similar signs and symptoms. Young children and older adults may have atypical illness because of a reduced inflammatory response associated with extremes of age. This makes appendicitis more difficult to diagnose in these age groups. The classic presentation of appendicitis is abdominal pain or cramping, nausea, vomiting, chills, low-grade fever, and anorexia. At first the pain is periumbilical and diffuse. Later it becomes intense and localized to the right lower quadrant just medial to the iliac crest *(McBurney's point).* If the appendix ruptures, the patient's pain diminishes before the development of peritoneal signs. The goal of definitive care for appendicitis is surgical removal of the appendix (appendectomy) before the organ ruptures.

CRITICAL THINKING

What other illness presents with similar signs or symptoms?

Peptic Ulcer Disease

Peptic ulcer disease results from a complex pathological interaction among the acidic gastric secretions and proteolytic enzymes and the mucosal barrier. As described in Chapter 10, digestion occurs as food passes through the GI tract. The stomach produces hydrochloric acid and an enzyme called pepsin to digest the food. From the stomach, food passes into the duodenum, where digestion and nutrient absorption continue. The stomach normally protects itself from the digestive fluids by producing mucus to shield stomach tissues. The stomach also produces

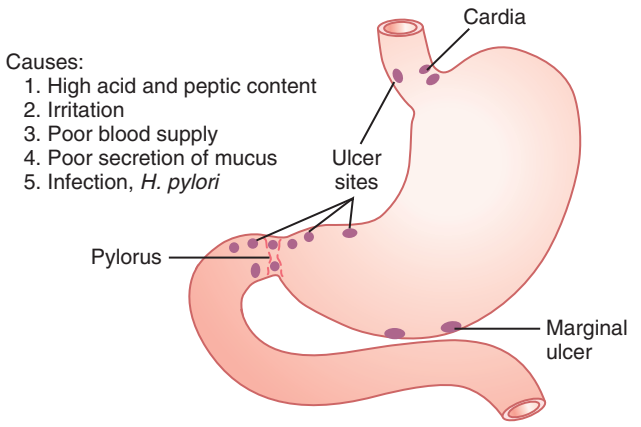

FIGURE 29-6 Peptic ulcer. *Helicobacter pylori (H. pylori)*. (Hall J: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders.)

bicarbonate to neutralize and break down digestive fluids into substances less harmful to stomach tissue. Blood circulation to the stomach lining, cell renewal, and cell repair also help protect the stomach (Figure 29-6).

Ulcers can form in the lining of the stomach or duodenum, where acid and pepsin are present. These sores cause the disintegration and death of tissue as they erode the mucosal layers in the affected areas. If the sores are left untreated, massive hemorrhage or perforation may result. The two main causes of peptic ulcer disease are *H. pylori* infection and the use of NSAIDs. Another and less common cause is increased circulatory gastrin from gastrin-secreting tumors *(Zollinger-Ellison syndrome)*.[1] All of these circumstances can cause the defense mechanisms of the stomach to fail. Ulcers can develop at any age but are rare among teenagers and even more uncommon in children. Duodenal ulcers occur for the first time usually between the ages of 30 and 50. They occur more often in men than in women.

A patient with a peptic ulcer usually is aware of the condition. The patient often uses over-the-counter antacids. The ulcer pain often is described as a burning or gnawing discomfort in the epigastric region or left upper quadrant (in the case of gastric ulcer). The discomfort develops before meals (classically, early morning) or during stressful periods, when the production of gastric acids increases. The pain usually is sudden in onset. Pain often is relieved by eating, taking antacids, or vomiting. In addition to pain and vomiting of blood, the patient may experience melena as a result of blood passing through the GI tract.

Prehospital care for patients with peptic ulcer disease includes obtaining a pertinent history, evaluating for hypotension, and providing circulatory support as needed. After evaluation by a physician, definitive care may involve antibiotics, antacids, H_2-receptor antagonists or other medications and, occasionally, dietary regulation (the benefit of which is controversial). Some patients with acute peptic ulcer disease require hospitalization for fluid or blood replacement or for surgery if medications are not effective or blood loss continues.

DID YOU KNOW?

GERD Versus Peptic Ulcer Disease

Gastroesophageal reflux disease (GERD) is a condition in which food or liquid travels backward from the stomach to the esophagus. This action can irritate the esophagus, causing heartburn and other symptoms. The classic symptoms of GERD are heartburn or regurgitation or both. If a patient complains of a burning sensation rising from the stomach into the chest or toward the neck, it is most likely due to GERD.[10] Hiatal hernia is an anatomical abnormality in which part of the stomach protrudes through the diaphragm and up into the chest, increases the likelihood of GERD. Classically, GERD symptoms (e.g., heartburn or regurgitation) often may be worsened by alcohol and certain foods, including fatty foods and foods containing caffeine, garlic, or peppermint. These foods and alcohol can cause relaxation of the lower esophageal sphincter, allowing the refluxate to enter the esophagus from the stomach, causing heartburn or regurgitation.

In contrast, **peptic ulcer disease** typically is manifested by symptoms such as pain or discomfort localized in the center of the abdomen. The symptoms often are improved when a patient either has an empty stomach or consumes enough food to be satisfied and fill the stomach.

Proton pump inhibitors often are recommended to inhibit production of acid in the stomach. These over-the-counter medications include Prevacid, Prilosec, and others.

Bowel Obstruction

Bowel obstruction is an occlusion of the intestinal lumen. It results in blockage of normal flow of intestinal contents. Bowel obstruction may be caused by an **ileus,** a condition in which the bowel does not work properly. However, bowel obstruction more commonly results from mechanical obstruction, such as adhesions, **hernia** (Box 29-4), fecal impaction, polyps, and tumors. Other causes of bowel obstruction are *intussusception* (telescoping of one portion of the intestine into another, which results in decreased blood supply of the involved segment), *volvulus* (twisting of the intestines), ingested foreign bodies, and foreign bodies introduced from the anus (sexual or intentional insertion). Most bowel obstructions occur in the small bowel (accounting for 20% of all hospital admissions for abdominal complaints) and usually are caused by adhesions or hernias.[11] Large bowel obstructions most often result from tumors or fecal impactions.

Signs and symptoms of intestinal obstruction include nausea and vomiting, abdominal pain, diarrhea, constipation (a late finding), and abdominal distention. The speed of onset and degree of symptoms depend on the anatomical

BOX 29-4 Hernia

A hernia is the protrusion of an organ from its normal position through a congenital or acquired opening. Herniation most often occurs through the musculature of the groin or abdominal wall. Increases in intraabdominal pressure can cause the peritoneum to push outward through such an opening. (Examples of such increases in pressure include straining, coughing, or lifting.) When this occurs a sac is formed, into which various organs in the peritoneal cavity may enter.

Most hernias are uncomplicated and can be placed back into the peritoneal cavity by a physician. If the hernia cannot be returned to its proper position, the trapped contents of the peritoneal sac (usually a portion of bowel) can become strangulated. Patients with this condition often have acute abdominal pain and systemic signs, such as fever and tachycardia. Incarcerated or strangulated hernias can lead to serious complications, including intestinal obstruction, perforation, and peritonitis. Definitive care for complicated hernias is in-hospital observation, intravenous rehydration, pain medication, and surgical repair.

BOX 29-5 Acute Mesenteric Ischemia

Acute mesenteric ischemia is the abrupt interruption of intestinal blood flow. It may result from an embolism, thrombosis, or a low-flow state (decreased perfusion). The ischemia disrupts the mucosal barrier, allowing the release of bacteria, toxins, and vasoactive mediators. This in turn leads to myocardial depression and a systemic inflammatory response. If the condition goes unrecognized and untreated, the ischemia can result in multisystem organ failure and death. Acute mesenteric ischemia should be suspected whenever a patient presents with abdominal pain that is out of proportion to the physical findings (especially in patients over age 50). Definitive care may include surgery (embolectomy, revascularization, resection), infusion of vasodilators, and long-term therapy with anticoagulation and antiplatelet drugs.

NOTE

Paralytic ileus can closely mimic bowel obstructions. (**Paralytic ileus** is a decrease in or the absence of intestinal peristalsis.) This pseudo-obstruction may result from a number of localized or systemic conditions, such as medications (especially narcotics), intraperitoneal infection, complications of abdominal surgery, and metabolic disturbances (e.g., decreased potassium levels).

CRITICAL THINKING

Have you ever responded to a call for "constipation"? Did the paramedics consider this diagnosis a possibility? What was their attitude toward the patient?

site of obstruction (small versus large bowel). The most significant danger is perforation of the bowel with generalized peritonitis and sepsis.

A patient with bowel obstruction often has abdominal pain; dehydration may result from vomiting, decreased intestinal absorption, and fluid loss into the lumen and interstitium (bowel wall edema). As the affected portion of the bowel distends, its blood supply is decreased and the segment becomes ischemic (Box 29-5). The wall is weakened and perforates, producing peritonitis. If the intestine becomes strangulated, blood or plasma also may be lost from the affected intestinal segment. Definitive care involves fluid replacement, antibiotics, placement of a nasogastric tube for decompression (see Chapter 15) and, frequently, surgery to correct the obstructing lesion.

LOOK AGAIN

See Chapter 15: Airway Management, Respiration, and Artificial Ventilation, pp. 433-435.

Crohn's Disease

Crohn's disease is a chronic inflammatory bowel disease that usually affects the ileum, the colon, or both. Crohn's disease may occur in individuals of all ages but is primarily a disease of young adults. (Most cases are diagnosed before age 30.) The disease is thought to be autoimmune in origin and tends to run in families and in certain ethnic groups. More than 20,000 cases are reported annually in the United States.[12]

The inflammation associated with Crohn's disease may cause blockage of the intestine. Blockage occurs because the disease tends to thicken the intestinal wall with swelling and scar tissue, narrowing the passage. The disease also may cause ulcers that tunnel through the affected area into surrounding tissues, such as the bladder, vagina, or skin. The areas around the anus and rectum often are involved. The tunnels, called *fistulae,* are a common complication and often become infected. Other complications associated with Crohn's disease include arthritis, skin problems, inflammation of the eyes or mouth, kidney stones, gallstones, or other diseases of the liver and biliary system.

Crohn's disease can be difficult to diagnose, because its symptoms are similar to those of irritable bowel syndrome and ulcerative colitis. Crohn's disease is characterized by frequent attacks of diarrhea, severe abdominal pain, nausea, fever, chills, weakness, anorexia, and weight loss. (Patients with Crohn's disease and like disorders often suffer from depression because of the relentless and painful characteristics of these conditions.) The paramedic should suspect the disease in any patient with chronic inflammatory colitis and a history of rectal fistulae or abscesses. These patients

frequently are hospitalized. Once the patient's condition has been stabilized, it may be managed with antibiotics, steroids, and antimotility agents in an attempt to induce remission, as well as with dietary regulation.

NOTE

The term *irritable bowel syndrome,* or *spastic colon,* is used to describe abnormally increased motility of the small and large intestines. Unlike inflammatory bowel disease, the abdominal pain of irritable bowel syndrome generally is associated with emotional and physical stress. The pain generally is also relieved by bowel movement.

Pancreatitis

As described in Chapter 10, the pancreas lies behind the stomach. This gland secretes digestive enzymes into the duodenum to help break down food into small molecules. These small molecules can be absorbed by the body. The pancreas also secretes insulin and glucagon into the bloodstream. These hormones help maintain an adequate glucose concentration. When the pancreas becomes inflamed **(pancreatitis),** it releases pancreatic enzymes into the blood, the pancreatic duct, and the pancreas itself. This causes further inflammation and autodigestion of the gland. Pancreatitis occurs in two stages, acute and chronic.

Acute pancreatitis is sudden in onset. It occurs soon after the pancreas becomes damaged or irritated by its own enzymes. Acute pancreatitis usually results from obstruction by gallstones in the bile duct or by alcohol abuse. Other, less common causes of acute pancreatitis include elevated serum lipids, thromboembolism, drug toxicity, infection, and some surgeries. Acute pancreatitis affects about 80,000 Americans each year.[13]

Chronic pancreatitis begins as acute pancreatitis. It becomes chronic when the pancreas becomes scarred. This condition usually results from long-term and excessive alcohol consumption. However, chronic pancreatitis also may develop from other causes of pancreatitis. Chronic pancreatitis can lead to exocrine and endocrine failure. In rare cases, pancreatitis leads to pancreatic cancer.

Pancreatitis may cause severe epigastric pain. It often is associated with nausea, vomiting, and abdominal tenderness and distention. The abdominal pain usually is described as severe, radiating from midumbilicus to the patient's back and shoulders. In severe cases the patient has fever, tachycardia, and signs of generalized sepsis and shock. These patients often are hospitalized. They are treated with IV fluids, pain medication, and placement of a nasogastric tube if the patient is vomiting.

Esophagogastric Varices

Esophagogastric varices are a complex of longitudinal, tortuous veins at the lower end of the esophagus that become enlarged and swollen as a result of portal hypertension. They are common in patients with liver disease and often result from portal hypertension caused by cirrhosis of the liver. Obstruction to blood flow in the liver, produced by the fibrosis in the liver, increases pressure. Obstruction also dilates vessels that drain into the liver. This subsequent dilation of thin-walled veins around the lower esophagus and upper end of the stomach produces esophagogastric varices (Figure 29-7). Varices can rupture. This results in life-threatening hemorrhage. Other causes of esophageal bleeding include **esophagitis** (associated with chronic use of alcohol and antiinflammatory nonsteroidal medications), malignancy, and episodes of prolonged, violent vomiting that produce a tear or laceration in the mucosa of the upper esophagus (Mallory-Weiss syndrome).

Clinically, a patient with esophageal bleeding has bright red hematemesis. This condition may be severe. If bleeding is profuse, melena may be evident. The patient also may manifest the classic signs of shock. Variceal bleeding usually is massive and generally difficult to control. Therapeutic intervention includes ensuring a patent airway and fluid resuscitation. (The placement of a nasogastric tube for gastric lavage is controversial.) Definitive care may include placement of a Sengstaken-Blakemore tube to tamponade bleeding vessels, surgical ligation of the bleeding varices, or transendoscopic injection of a sclerosing agent into the bleeding vessels. The mortality rate for patients with variceal bleeding is about 30%.[14]

Hemorrhoids

Hemorrhoids are swollen, distended veins inside the anus (internal) or under the skin around the anus (external). Hemorrhoids are common during pregnancy; they result from fetal pressure in the abdomen and hormonal changes that cause hemorrhoidal vessels to enlarge. Hemorrhoids are present in 50% of all individuals by age 50. Irritation of the distended veins is worsened by straining during bowel movements and by rubbing or cleaning around the anus, which may produce itching, bleeding, or both. As a rule, hemorrhoidal symptoms subside within a few days.

Pain from hemorrhoids is infrequent unless thrombosis, ulceration, or infection is present. If the patient has rectal pain, the paramedic should consider other possible causes (Box 29-6). Slight bleeding is the most common symptom. (Rarely do hemorrhoids cause significant hemorrhage.) The bleeding usually occurs during or after defecation. Blood dripping into the toilet after defecation or blood-streaked toilet tissue after wiping are common indications. Blood loss from hemorrhoids usually is slight. However, recurrent episodes of bleeding may be significant enough to produce anemia. Definitive care includes dietary modification, stool softeners, tissue fixation techniques, and operative hemorrhoidectomy for severe cases.

Cholecystitis

Cholecystitis is inflammation of the gallbladder. The disease is common in the United States. Cholecystitis occurs in 15% to 20% of the population and is more common

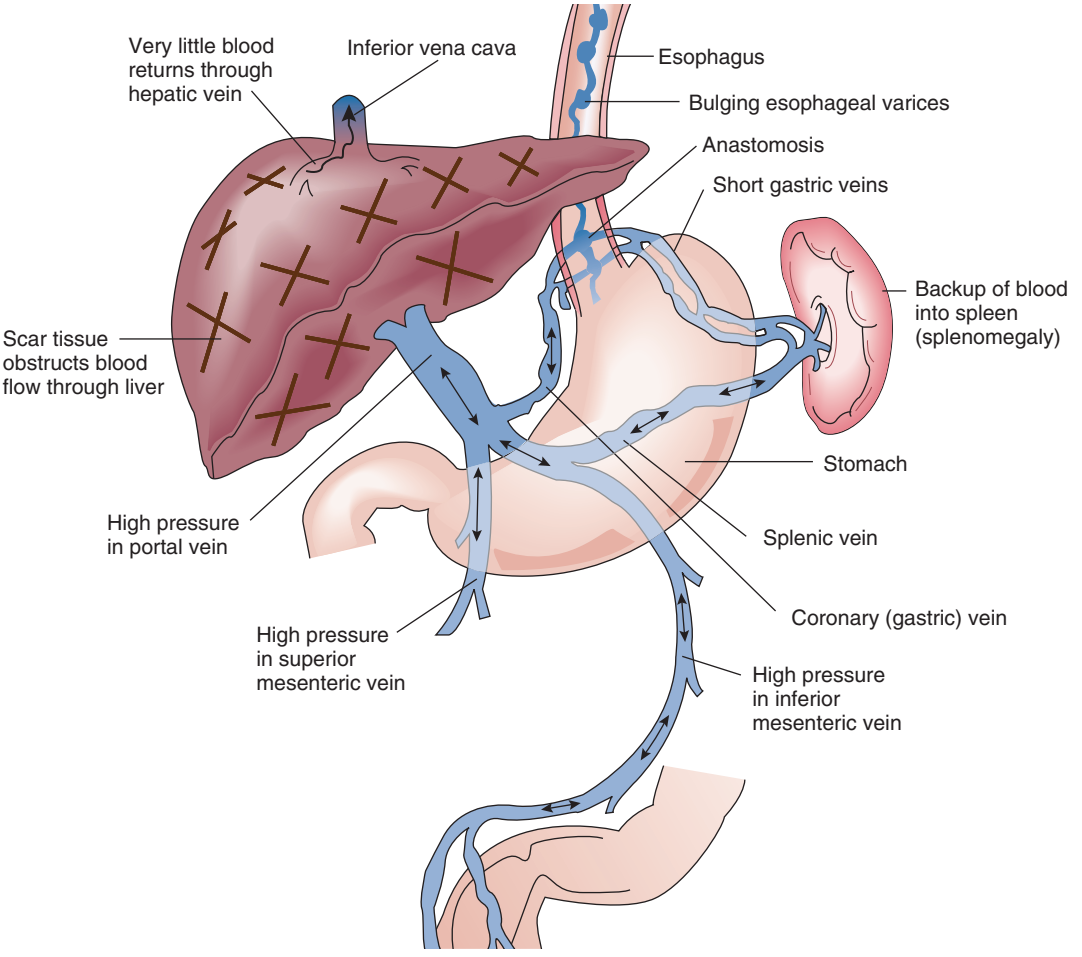

FIGURE 29-7 Development of esophageal varices. (Gould BE: *Pathophysiology for the health professional,* ed 3, St Louis, 2006, Saunders.)

BOX 29-6 Rectal Pain

Pain in the rectal area also may result from a rectal abscess, anal fistula, or foreign body. A **rectal abscess** is an infected cavity near the anus that is filled with pus. The condition results from blockage of the anal glands just inside the anus. Treatment consists of surgical drainage of the pus from the infected cavity. An incision also may be made near the anus to relieve pressure.

An **anal fistula** is an abnormal passage between the anal canal or rectum and the skin surface. Most fistulas begin as an abscess that opens spontaneously. This condition also is associated with some diseases, such as tuberculosis, cancer, and irritable bowel disorders. Pain occurs when the fistula becomes blocked, leading to recurrence of an abscess. Symptoms include discharge of pus and fecal material. The fistula requires surgical removal.

Foreign bodies placed in the rectum may result from self-exploration, sexual practices, or abuse. If a foreign body has been inserted in the rectum, no attempt should be made to remove it in the prehospital setting. Treatment by a physician is required.

in women 30 to 50 years of age than in men. The disease becomes more common with age in both men and women. Risk factors for cholecystitis include female gender, oral contraceptive use, increasing age, obesity, diabetes mellitus, chronic alcohol ingestion, and African American or Asian ethnicity. The condition may be chronic, with recurrent subacute symptoms, or acute as a result of gallstone obstruction.

In 90% of cases, acute cholecystitis is caused by gallstones (composed mainly of cholesterol) in the gallbladder. On occasion the gallstones completely obstruct the neck or cystic duct of the gallbladder, which leads to the common bile duct that empties into the small intestine. The trapped bile becomes concentrated. The bile causes irritation and pressure buildup in the gallbladder, which can lead to bacterial infection and perforation. The increased pressure causes a sudden onset of pain *(biliary colic),* which radiates to the right upper quadrant or right scapula. Patients with gallbladder disease commonly have episodes of pain at night. Generally, the episodes are associated with recent ingestion of fried or fatty foods. Severe illness, alcohol

BOX 29-7 Hepatitis and Liver Disease in the United States

- Approximately 25 million Americans (1 in 10) are or have been affected by liver and biliary disease. Up to 50% have no symptoms.
- Liver disease, including hepatitis, cirrhosis, and liver cancer, is the tenth leading cause of death in the United States. Hepatitis C alone is five times as widespread as human immunodeficiency virus (HIV) infection and affects more than 4 million Americans.
- There are six known kinds of viral hepatitis: A, B, C, D, E and G. Hepatitis B and hepatitis C have the greatest potential for long-term liver damage. A vaccine is available for the prevention of hepatitis A and hepatitis B but not for hepatitis C.
- About 1.2 million people in the United States have hepatitis B. The virus is responsible for 5000 deaths annually. One in 250 people is a carrier of hepatitis B and can pass it on to others, often unknowingly, through contact with blood or body fluids.
- Hepatitis B is 100 times more infectious than HIV, the virus that causes acquired immunodeficiency syndrome (AIDS). A teaspoonful of blood holds 500 million hepatitis viral particles, but only 5 to 10 HIV particles.
- More than 4 million people (1.9% of the population) have been exposed to hepatitis C, and most do not know they are infected. The virus is spread through infected human blood and blood products.
- Each year, 8000 to 10,000 people die of complications of chronic liver disease related to hepatitis C.
- The estimated medical and work loss cost per year from viral hepatitis is greater than $500 million.
- Hemochromatosis is a genetic disease of iron metabolism that results in excess iron deposits throughout the body. The disease may lead to the development of cirrhosis, diabetes, skin pigment changes, cardiac problems, arthritis, and testicular atrophy. Life expectancy is normal if the disease is diagnosed before these secondary disorders develop.
- Approximately 25,000 Americans die each year from chronic liver disease and cirrhosis. Cirrhosis causes the hospitalization of more than 300,000 people each year.
- Approximately 5000 liver transplantations were performed in 2000. Because of the shortage of organs, it is estimated that nearly 1700 prospective recipients died in 2001 while waiting for a transplant. Currently, more than 18,000 people are waiting for a liver transplant.

Modified from *Liver disease facts.* St. Louis University Liver Center. http://livercenter.slu.edu/index.php?page=liver-disease-facts. Accessed September 4, 2010.

abuse and, in rare cases, tumors of the gallbladder also can cause cholecystitis.

Other associated hallmarks of cholecystitis include previous episodes, a family history of gallbladder disease, low-grade fever, nausea, vomiting that may be bile stained and described as bitter (variable), and pain and tenderness on palpation in the right upper quadrant. Passage of stones into the common bile duct with subsequent obstruction may cause shaking chills, high fever, jaundice, and acute pancreatitis. Treatment may include hospitalization, IV fluid therapy, antibiotics, and placement of a nasogastric tube. Definitive treatment is surgical removal of the gallbladder.

Acute Hepatitis

Hepatitis is inflammation of the liver. Hepatitis is the single most important cause of liver disease in the United States and worldwide (Box 29-7).

Acute hepatitis is associated with the sudden onset of malaise, weakness, anorexia, intermittent nausea and vomiting, and dull right upper quadrant pain. These signs usually are followed within 1 week by the onset of jaundice, dark urine, or both. Many viruses can infect the liver. However, the three classes of viruses that are of main concern as causes of acute infectious hepatitis are hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV, formerly known as *non-A/non-B hepatitis virus*). All types produce similar pathological changes in the liver. These viruses also stimulate an antibody response that is specific to the type of virus causing the disease (Box 29-8).

BOX 29-8 Risk Factors for Hepatitis

Hepatitis A (spread by fecal-oral route)

- Health care practice without body substance isolation precautions
- Household or sexual contact with an infected person
- Living in an area with a hepatitis A virus outbreak
- Travel to developing countries
- Engaging in sex with infected partners or multiple partners
- Drug use by injection

Hepatitis B (spread by infectious blood)

- Health care practice without body substance isolation precautions
- Infant born to mother infected with hepatitis B virus
- Engaging in sex with infected partners or multiple partners
- Drug use by injection
- Receiving hemodialysis

Hepatitis C (spread by infectious blood)

- Health care practice without body substance isolation precautions
- Receiving a blood transfusion before July, 1992
- Infant born to mother infected with the hepatitis C virus
- Engaging in sex with infected partners or multiple partners
- Drug use by injection; blood-contaminated straws used to snort drugs
- Receiving hemodialysis

Many hepatitis infections are subclinical; they often present with influenza-like symptoms. Serious conditions associated with hepatitis are cirrhosis (scarring of the liver; Figure 29-8), hepatic encephalopathy (brain and nervous system damage that occurs as a complication of liver disease), and liver cancer. These conditions are discussed in Chapters 28 and 34.

The inflammation of hepatitis has many possible causes, including alcohol or other drug use, autoimmune disorders, and toxic bacterial, fungal, parasitic, and viral infections. Patients with hepatitis require a physician's evaluation and care. Proper immunization of paramedics against HAV and HBV is important. Strict adherence to body substance isolation procedures also is crucial when paramedics are caring for these patients.

Hereditary Hemochromatosis

Hereditary hemochromatosis is one of the most common genetic disorders in the United States.[15] It is an inherited condition in which the body absorbs and stores too much iron. The extra iron accumulates in several organs, especially the liver, heart, and pancreas. Many people with the disease have no symptoms, even in advanced stages. Joint pain is the most common complaint of people with hemochromatosis. Other common symptoms include fatigue, abdominal pain, decreased libido, and heart problems. Symptoms tend to occur in men between the ages of 30 and 50 and in women over age 50. If the disease is not detected early and treated by ridding the body of excess iron with regular phlebotomy, serious illness (including death) may result. Systemic illness that develops from hemochromatosis includes[16]:

- Arthritis
- Liver disease, including an enlarged liver, cirrhosis, cancer, and liver failure
- Damage to the pancreas, possibly causing diabetes mellitus
- Heart abnormalities, such as irregular heart rhythms or congestive heart failure
- Impotence
- Early menopause
- Abnormal pigmentation of the skin, making it look gray or bronze
- Pituitary damage
- Damage to the adrenal gland

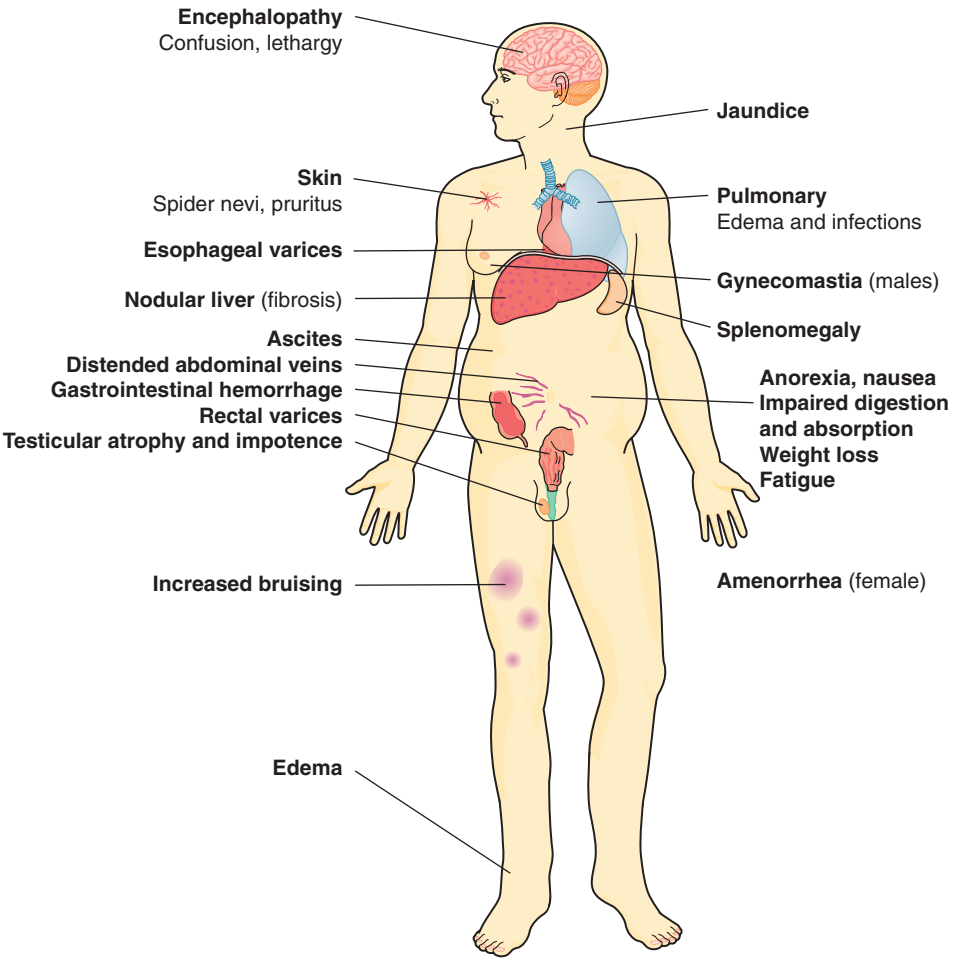

FIGURE 29-8 Effects of advanced cirrhosis. (Gould BE: *Pathophysiology for the health professional,* ed 3, St Louis, 2006, Saunders.)

To develop hemochromatosis, a person must inherit the defective gene from both parents. Those who inherit the defective gene from only one parent are carriers of the disease but usually do not develop it. Siblings of people who have hemochromatosis should have their blood tested to determine if they have the disease or are carriers. Parents, children, and other close relatives of people who have the disease should consider being tested.[15]

AGE-RELATED VARIATIONS IN ABDOMINAL PAIN

As discussed in Chapter 20, many physiological and anatomical differences exist among infant, child, and adult patients. The way in which these groups experience abdominal pain may also be quite different. For example, causes of abdominal pain in the elderly are more likely to be diseases that require surgical treatment; a vascular catastrophe; ischemic heart disease; or sepsis. Infants and young children are unable to communicate their history or degree of pain. As a result, they can become dehydrated and septic more quickly than adults. Vital signs in these groups often do not accurately reflect their degree of illness (see Chapters 48 and 49).[17]

CRITICAL THINKING

Why do you think a person would refuse the chance to be vaccinated against this deadly disease?

SUMMARY

- The major organs associated with the GI system include the esophagus, stomach, small and large intestines, liver, gallbladder, and pancreas.
- After the scene survey and primary assessment of a patient with abdominal pain, the paramedic should obtain a thorough history. The physical examination may help determine whether the pain is visceral, somatic, or referred.
- The type and location of the pain may help narrow the differential diagnosis.
- Important signs and symptoms associated with abdominal pain include nausea, vomiting, anorexia, diarrhea, constipation, stool color, and fever.
- The most common treatment for abdominal pain is provided at the hospital. The paramedic should provide supportive treatment, manage life threats, and transport the patient to an appropriate facility.
- Gastrointestinal bleeding can be slow and chronic or rapid and life threatening. Causes of GI bleeding include esophagogastric varices, Mallory-Weiss syndrome, cancer, medication use, and other systemic diseases.
- Gastroenteritis is inflammation of the stomach and intestines caused by infectious agents, chemicals, or other conditions.
- Gastritis is acute or chronic inflammation of the gastric mucosa. Gastritis commonly results from hyperacidity, alcohol or other drug ingestion, bile reflux, and *H. pylori* infection.
- Ulcerative colitis is an inflammatory condition of the large intestine. Colitis is characterized by severe diarrhea and ulceration of the mucosa of the intestine (ulcerative colitis).
- Diverticulosis may result in bright red rectal bleeding if perforation occurs.
- Diverticulitis results when a diverticulum becomes obstructed with fecal matter.
- Appendicitis occurs when the passageway between the appendix and cecum is obstructed by fecal material or by inflammation caused by infection.
- Peptic ulcer disease occurs when open wounds or sores develop in the stomach or duodenum.
- Bowel obstruction is an occlusion of the intestinal lumen. It results in blockage of the normal flow of intestinal contents.
- Crohn's disease is a chronic inflammatory bowel disease of unknown origin.
- Inflammation of the pancreas is called *pancreatitis*. It causes severe abdominal pain.
- Esophagogastric varices arise from obstruction of blood flow to the liver as a result of liver disease. Rupture of the varices can cause hemorrhage and death.
- Hemorrhoids are distended veins in the rectoanal area.
- Cholecystitis is inflammation of the gallbladder. It most often is associated with the presence of gallstones.
- Hepatitis is characterized by the sudden onset of malaise, weakness, anorexia, intermittent nausea and vomiting, and dull right upper quadrant pain. These signs usually are followed within 1 week by the onset of jaundice or dark urine or both.
- Hereditary hemochromatosis is a condition in which the body absorbs and stores too much iron. This can causes severe damage when the iron collects in the liver, heart, and pancreas.

CHAPTER

30 Genitourinary and Renal Disorders

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Label a diagram of the urinary system.
2. Distinguish between acute and chronic renal failure.
3. Outline the pathophysiology of renal failure.
4. Identify the signs and symptoms of renal failure.
5. Describe the process of hemodialysis and peritoneal dialysis.
6. Describe the signs and symptoms and care of emergency conditions associated with dialysis.
7. Describe the pathophysiology, signs and symptoms, assessment, and prehospital management of a patient with urinary retention, urinary tract infection, pyelonephritis, urinary calculus, epididymitis, Fournier's gangrene, phimosis, paraphimosis, priapism, benign prostatic hypertrophy, testicular masses, and testicular torsion.
8. Outline the physical examination of patients with genitourinary disorders.
9. Discuss the general prehospital management of a patient with a genitourinary disorder.

KEY TERMS

acute prostatitis Inflammation of the prostate gland that develops suddenly.

acute renal failure (ARF) A clinical syndrome that results from a sudden, significant decrease in filtration through the glomeruli, leading to the accumulation of salt, water, and nitrogenous wastes in the body.

acute tubular necrosis The death of tubular cells, which form the tubule that transports urine to the ureters.

anuria Inability to urinate; the cessation of urine production; a diminished urinary output (less than 100 to 250 mL a day).

arteriovenous fistula An internal anastomosis between an artery and a vein.

arteriovenous graft A synthetic material grafted between the patient's artery and vein.

autonomic hyperreflexia Overactivity of the autonomic nervous system that causes an abrupt onset of extremely high blood pressure.

azotemia A condition marked by retention of excessive amounts of nitrogenous compounds in the blood.

benign prostatic hypertrophy (BPH) Enlargement of the prostate gland.

chronic renal failure (CRF) A progressive, irreversible systemic disease, caused by kidney dysfunction, that leads to abnormalities in blood counts and blood chemistry levels.

circumcision Surgical removal of the penile foreskin.

creatinine A chemical waste molecule generated by muscle metabolism.

cystitis Inflammation of the urinary bladder and ureters.

dialysate A solution used in dialysis.

dialysis A technique used to normalize blood chemistry in patients with acute or chronic renal failure and to remove blood toxins in some patients who have taken a drug overdose.

disequilibrium syndrome A group of neurological findings that sometimes occur during or immediately after dialysis; they are thought to result from a disproportionate decrease in the osmolality of the extracellular fluid compared with that of the intracellular compartment in the brain or cerebrospinal fluid.

dysuria Difficult urination.

end-stage renal disease Complete or near complete failure of the kidneys to function.

epididymitis Inflammation of the epididymis, a tubular section of the male reproductive system that carries sperm from the testicle to the seminal vesicles.

Fournier's gangrene A bacterial infection of the skin that affects the genitals and perineum in both men and women.

genitourinary system The system comprising the genital and reproductive organs.

hematuria The abnormal presence of blood in the urine.

hemodialysis A procedure in which impurities or wastes are removed from the blood; it is used to treat renal insufficiency and various toxic conditions.

hydrocele A fluid-filled sac along the spermatic cord in the scrotum.

intrarenal disease Disease or damage within the kidney.
nephron The functional unit of the kidney.
nocturia Excessive urination at night.
oliguria A condition marked by diminished capacity to form or pass urine.
orchitis Painful inflammation of the testicle.
overflow incontinence Overflow of urine from the bladder.
paraphimosis A condition in uncircumcised men marked by the inability to pull the retracted foreskin back over the head of the penis.
peritoneal dialysis A dialysis procedure that uses the peritoneum as a diffusible membrane; it is performed to correct an imbalance of fluid or electrolytes in the blood or to remove toxins, drugs, or other wastes normally excreted by the kidney.
phimosis Tightness of the prepuce (foreskin) of the penis.
postrenal disease Disease that blocks the system that collects urine; it usually is caused by urinary tract obstruction.
prepuce In males, the free fold of skin that covers the glans penis; the foreskin. In females, the external fold of the labia minora that covers the clitoris.
prerenal disease Disease that compromises renal perfusion.
priapism Painful, persistent erection of the penis.
pseudoaneurysm A condition resembling an aneurysm that is caused by enlargement and tortuosity of a vessel.
pyelonephritis Inflammation of the kidney parenchyma caused by microbial infection.
spermatocele A benign cystic accumulation of sperm that arises from the head of the epididymis.
testicular mass An enlargement or growth on one or both testicles.
testicular torsion The twisting of a testicle on its spermatic cord, disrupting its blood supply.
urea A nitrogen-containing waste product.
uremia A condition marked by an excess of urea and other nitrogenous wastes in the blood.
urethritis Inflammation of the urethra.
urinary calculi Solid particles in the urinary system, commonly known as "kidney stones."
urinary retention Inability to urinate.
urinary tract infection (UTI) Infection of one or more structures of the urinary tract.
varicocele An abnormal enlargement of the veins that drain the testicle.

Like gastrointestinal disorders, many genitourinary and renal disorders can produce acute abdominal pain and systemic illness. Treatment for these patients frequently begins in the prehospital setting. Successful outcomes often are determined in large part by the assessment skills of the paramedic.

ANATOMY AND PHYSIOLOGY REVIEW

As described in Chapter 10, the genitourinary and renal systems work with other body systems to maintain homeostasis. The **genitourinary system** actually refers to two different body systems. *Genito* refers to genital organs and the reproductive system. This system is responsible for perpetuation of our species. The genital system is composed of the male and female reproductive organs (Figures 30-1 and 30-2 and Box 30-1). *Urinary* refers to the system responsible for the removal of metabolic waste products from the blood, the removal of concentrated urine, and the conservation of water. This system plays a primary role in the following processes[1]:

- Regulation of water and electrolytes
- Regulation of the acid-base balance
- Excretion of waste products and foreign chemicals
- Regulation of the arterial blood pressure
- Production of red blood cells
- Stimulation of glucose production

BOX 30-1 Reproductive Organs

Male Reproductive Organs
Testes
Epididymis
Ductus deferens
Seminal vesicles
Prostate gland
Bulbourethral glands
Scrotum
Penis

Female Reproductive Organs
Ovaries
Uterine (fallopian) tubes
Uterus
Vagina
External genital organs
Internal reproductive organs
Mammary glands

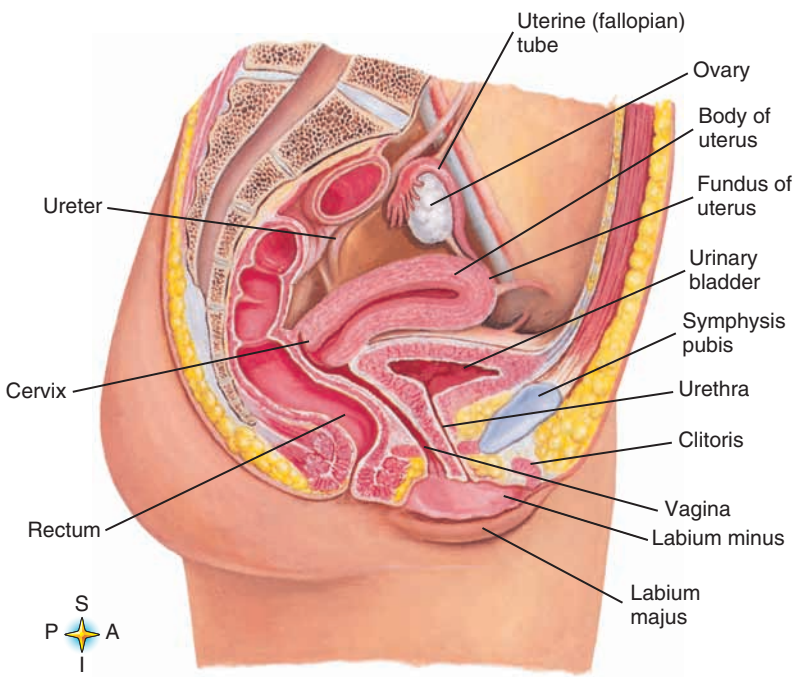

FIGURE 30-2 Female reproductive organs. (Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

The urinary system is made up of two kidneys, two ureters, the urinary bladder, and the urethra (Figure 30-3). The renal structures are the kidneys and their related structures (Figure 30-4). This chapter addresses renal diseases, urinary system conditions, and male genital tract conditions. Conditions that affect the female reproductive system are presented in Chapter 31.

See Chapter 10: Review of Human Systems, pp. 199-201.

RENAL DISEASES

The kidneys are two bean-shaped organs about the size of a person's fist. They lie on the posterior abdominal wall behind the peritoneum. The superior border of the kidney reaches the level of the twelfth thoracic vertebra. The inferior border lies just above the horizontal plane of the umbilicus, typically level with the third lumbar vertebra. The inferior border is one finger's breadth superior to the iliac crest. The center of the kidney, where the ureter is attached, is level with the intervertebral disc between the first and second lumbar vertebrae. The superior pole of each kidney is protected by the rib cage. As described in Chapter 10, the basic functional unit of the kidney is the **nephron.** There are millions of nephrons inside each kidney. The roles of the nephron are to filter blood, remove waste products, and produce urine. Damage to the nephrons results in renal (kidney) disease.

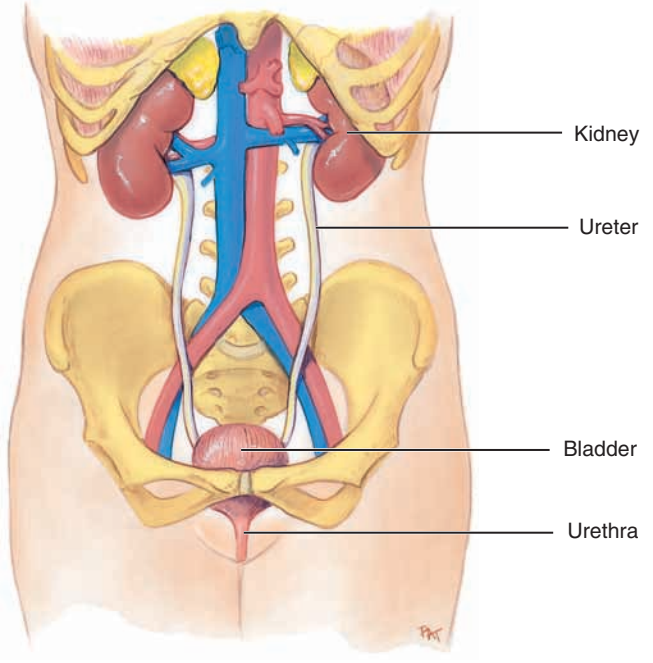

FIGURE 30-3 Components of the urinary system. (Applegate E: *The anatomy and physiology learning system,* ed 3, St Louis, 2006, Saunders.)

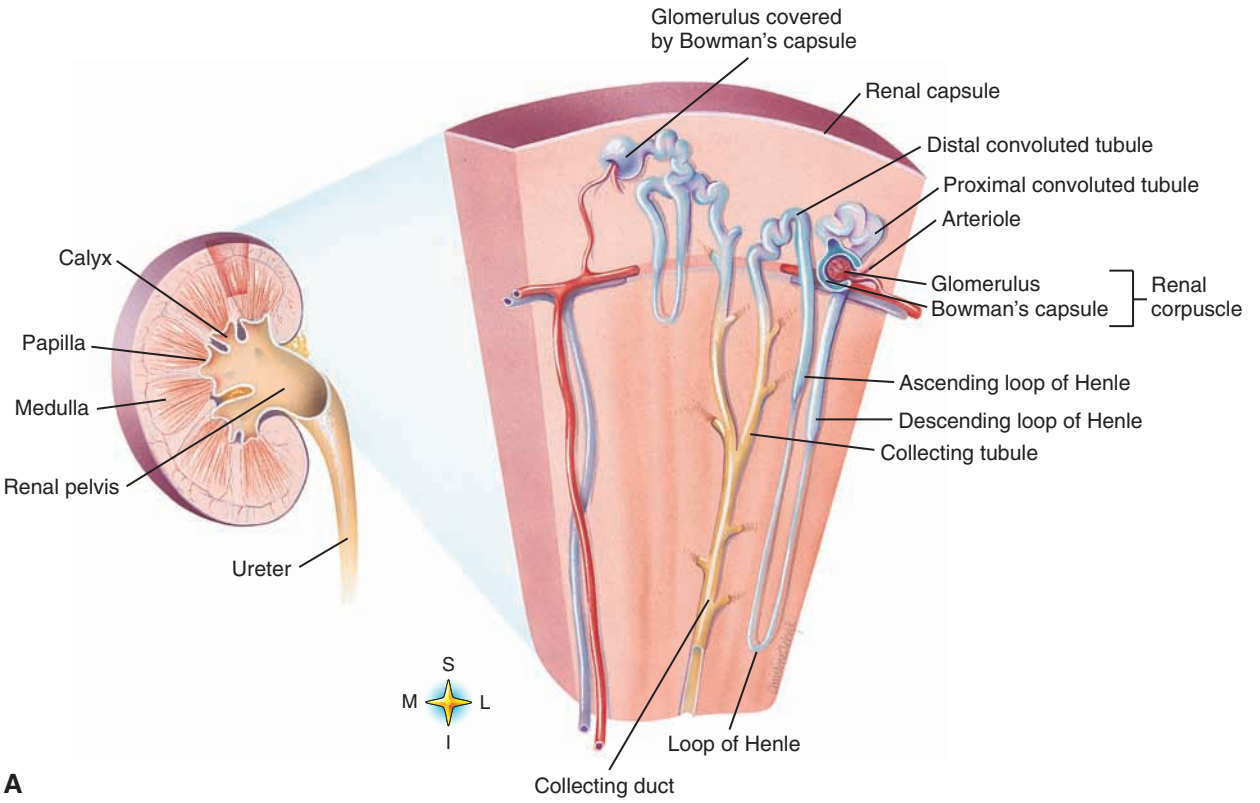
NOTE
Renal and urinary diseases affect an estimated 20 million Americans. They directly cause more than 95,000 deaths a year.[2] Diabetes is a major risk factor for renal disease.[3]

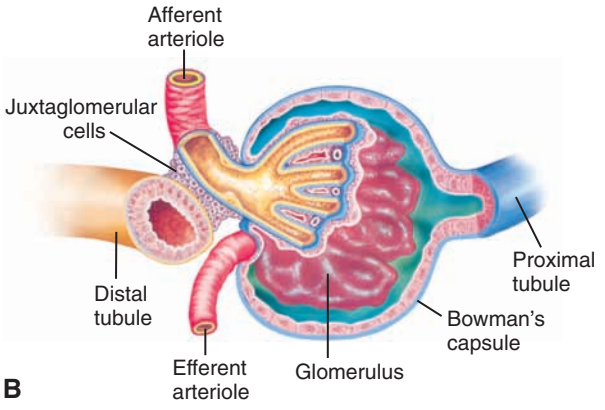
The causes of renal failure can be classified as *prerenal, intrarenal,* and *postrenal* (Table 30-1). **Prerenal disease** occurs before the kidney is reached. It is characterized by inadequate blood flow (perfusion) to the kidneys. **Intrarenal disease** *(intrinsic disease)* refers to disease or damage within the kidney. **Postrenal disease** refers to disease that blocks the system that collects urine. All of these conditions can result in acute or chronic renal failure, leading to end-stage renal disease. The classification of disease depends on the duration of renal failure and the potential for reversibility. Assessment findings and symptoms of renal failure are listed in Table 30-2.

CRITICAL THINKING
Think about why a patient would develop the complications just described.

Acute Renal Failure

Acute renal failure (ARF) (also known as *acute kidney injury* [AKI]) is a clinical syndrome that results from a sudden, significant decrease in filtration through the glomeruli. This leads to the buildup of high levels of uremic toxins in the blood. Acute renal failure occurs when the kidneys are unable to excrete the daily load of toxins in the urine. Patients with ARF can be divided into two groups, based on the amount of urine excreted in 24 hours. One group is *oliguric;* these patients excrete less than 500 mL a day. The other is *nonoliguric;* these patients excrete more than 500 mL a day. Acute renal failure is a life-threatening condition. The mortality rate for patients hospitalized for the disease is 40% to 50%.[4] However, if ARF is recognized early and treated appropriately, it may be readily reversible. A variety of conditions can cause ARF, such as trauma, shock, infection, urinary obstruction, and multisystem diseases.





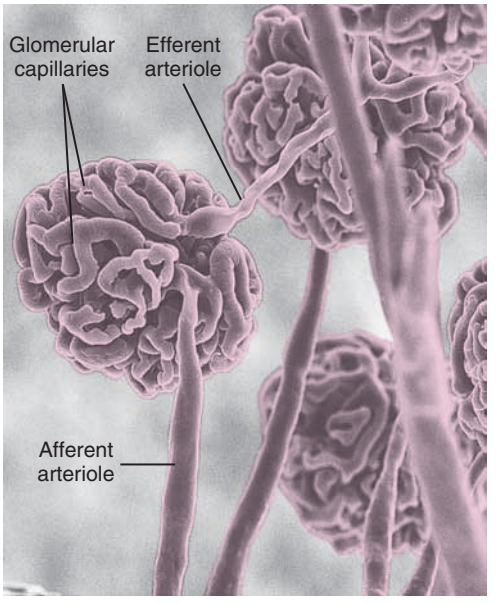


FIGURE 30-4 Location and components of the nephron. **A,** Magnified wedge cut from a renal pyramid. **B,** Schematic showing relationship of glomerulus to Bowman's capsule and adjacent structures. **C,** Scanning electron micrograph showing several glomeruli and their associated blood vessels. (Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

TABLE 30-1 Classification of Acute Renal Failure

Area of Dysfunction	Possible Causes

Prerenal	• Hypovolemia
	  • Hemorrhagic blood loss (trauma, GI bleeding, complications of childbirth)
	  • Loss of plasma volume (burns, peritonitis)
	  • Water and electrolyte losses (severe vomiting or diarrhea, intestinal obstruction, uncontrolled diabetes mellitus, inappropriate use of diuretics)
	• Hypotension or hypoperfusion
	• Septic shock
	• Cardiac failure or shock
	• Massive pulmonary embolism
	• Stenosis or clamping of renal artery

Intrarenal	• Acute tubular necrosis (postischemic or nephrotoxic) • Glomerulopathies • Malignant hypertension • Coagulation defects
Postrenal	• Obstructive uropathies (usually bilateral) • Ureteral obstruction (edema, tumors, stones, clots) • Bladder neck obstruction (enlarged prostate)

From McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children,* ed 4, St Louis, 2002, Mosby.

TABLE 30-2 Assessment Findings and Symptoms of Renal Failure[1]

Acute Renal Failure
- Reduced or no urinary output
- Excessive urinary output at night
- Lower extremity swelling
- Neuropathy of the hands and feet
- Anorexia
- Altered mental status
- Metallic taste in mouth
- Tremors or seizures
- Easy bruising or prolonged bleeding
- Flank pain
- Tinnitus
- Hypertension
- Abdominal pain or discomfort

Chronic Renal Failure
- Headache
- Weakness
- Anorexia
- Vomiting
- Increased urination
- Rusty-colored or brown urine
- Increased thirst
- Hypertension
- Pruritus

End-Stage Renal Disease
- Confusion
- Altered level of consciousness
- Shortness of breath
- Chest pain
- Bone pain
- Pruritus
- Nausea, vomiting, diarrhea
- Bruising
- Muscle twitching, tremors, seizures
- Hallucinations

The onset of ARF can occur within hours. As normal kidney function rapidly deteriorates, urine output frequently decreases **(oliguria)** or stops completely **(anuria).** This results in **uremia.** Uremia is an excess of **urea** and other nitrogenous wastes in the blood. The condition generally results from kidney malfunction. Uremia may be associated with the following (Table 30-3):

- Generalized edema from water and salt retention
- Acidosis from failure of the kidneys to rid the body of normal acidic products
- High concentrations of nonprotein nitrogens (especially urea) from failure of the body to secrete metabolic end products
- High concentrations of other products of renal excretion (e.g., uric acid and potassium).

Uremia must be recognized early and treated appropriately. If it is not, renal dysfunction leads to the development of heart failure, volume overload, hyperkalemia, and metabolic acidosis.

PRERENAL ACUTE RENAL FAILURE

Prerenal ARF results from inadequate perfusion of the kidneys. The damaged kidneys are unable to rid the blood of waste products such as urea and **creatinine.** This condition may be caused by hypovolemia or impaired cardiac output. Obstruction of renal arteries results in decreased blood flow to the kidneys. It also causes an increase in renal vascular resistance that effectively shunts blood away from the kidneys. Many patients with prerenal ARF are critically ill. They may have a number of preexisting medical conditions, such as atherosclerosis, chronic liver disease, and heart failure. (Dehydration caused by the use of diuretics in patients with heart failure is a major cause of prerenal ARF.) In addition, perfusion often is poor in many organs, and this may lead to multiple organ failure.

Signs and symptoms of prerenal ARF include dizziness, dry mouth, thirst, hypotension, tachycardia, and weight loss. The goal of treatment is to improve kidney perfusion and function by treating the underlying condition (e.g.,

TABLE 30-3 Systemic Effects of Uremia

System	Manifestations	Mechanisms	Treatment
Skeletal	Osteitis fibrosa (bone inflammation with fibrous degeneration); bone demineralization (principally subperiosteal loss of cortical bone in the fibers, lateral ends of the clavicles, and lamina dura of the teeth); spontaneous fractures, bone pain; osteomalacia (rickets) with end-stage renal failure	Bone resorption associated with hyperparathyroidism, vitamin D deficiency, and demineralization; lowered calcium and elevated phosphate levels	Control of hyperphosphatemia to reduce hyperparathyroidism; administration of calcium and aluminum hydroxide antacids, which bind phosphate in the gut, together with a phosphate-restricted diet; vitamin D replacement; avoidance of magnesium antacids because of impaired magnesium excretion
Cardiopulmonary	Hypertension, pericarditis with fever, chest pain, and pericardial friction rub, pulmonary edema, Kussmaul respirations	Extracellular volume expansion as cause of hypertension; hypersecretion of rennin also associated with hypertension; fluid overload associated with pulmonary edema and acidosis leading to Kussmaul respirations	Volume reduction with diuretics that are not potassium sparing (to avoid hyperkalemia); angiotensin-converting enzyme (ACE) inhibitors; combination of propranolol, hydralazine, and minoxidil for those with high levels of rennin; bilateral nephrectomy with dialysis or transplantation
Neurological	Encephalopathy (fatigue, loss of attention, difficulty problem solving); peripheral neuropathy (pain and burning in the legs and feet, loss of vibration sense and deep tendon reflexes); loss of motor coordination, twitching, fasciculations, stupor, and coma with advanced uremia	Uremic toxins associated with end-stage renal disease	Dialysis
Endocrine	Retarded growth in children	Decreased growth hormone	Exogenous recombinant human growth hormone
	Osteomalacia	Elevated parathyroid hormone levels	Same as for skeletal system manifestations
	Higher incidence of goiter	Decreased thyroid hormone	Hormone replacement when indicated
Hematological	Anemia, usually normochromic normocytic; platelet disorders with prolonged bleeding times	Reduced erythropoietin secretion associated with loss of renal mass, leading to reduced red cell production in the bone marrow; uremic toxins associated with shortened red cell survival	Dialysis; recombinant human erythropoietin and iron supplementation; conjugated estrogens; 1-desamino-8-D-arginine vasopressin (DDAVP); transfusion
Gastrointestinal	Anorexia, nausea, vomiting; mouth ulcers, stomatitis, ruinous breath (uremic fetor), hiccups, peptic ulcers, gastrointestinal bleeding, and pancreatitis associated with end-stage renal failure	Retention of urea, metabolic acids, and other metabolic waste products, including methylguanidine	Protein-restricted diet for relief of nausea and vomiting
Integumentary	Abnormal pigmentation and pruritus	Retention of urochromes, contributing to sallow, yellow color; high plasma calcium levels associated with pruritus	Dialysis with control of serum calcium levels
Immunological	Increased risk of infection that can cause death	Suppression of cell-mediated immunity; reduction in number and function of lymphocytes, diminished phagocytosis	Routine dialysis
Reproductive	Sexual dysfunction: menorrhagia, amenorrhea, infertility, and decreased libido in women; decreased testosterone levels, infertility, and decreased libido in men	Elevated hormones: luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin, and LH-releasing hormone; decreased testosterone, estrogen, and progesterone	No specific treatment

From McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children,* ed 4, St Louis, 2002, Mosby.

infection, congestive heart failure, or liver failure). Fluids are administered intravenously to most patients to treat dehydration. After this, urine output generally increases and renal function improves.

INTRARENAL ACUTE RENAL FAILURE

Intrarenal ARF is also known as *intrinsic ARF*. It results from conditions that damage or injure both kidneys. Examples include glomerular and other microvascular diseases, tubular diseases, and interstitial diseases that directly damage the kidney parenchyma. Nearly 90% of cases are caused by ischemia or toxins. Both of these causes can lead to **acute tubular necrosis** (death of tubular cells).[5] Ischemic causes of intrarenal ARF are associated with renal hypoperfusion. These occur most often as a result of hemorrhage, trauma, and sepsis, and in patients undergoing cardiovascular surgery. Nephrotoxic causes of intrarenal ARF occur most often in the elderly and in patients with chronic renal failure**.** Drugs and other compounds that can trigger intrarenal ARF include antibiotics, nonsteroidal antiinflammatory drugs (NSAIDs), anticancer drugs, radiocontrast dyes, alcohol, and other drugs (e.g., cocaine). The condition also is associated with hypertension, autoimmune diseases (e.g., systemic lupus erythematosus), and pyelonephritis (described later in this chapter).

Signs and symptoms of intrarenal ARF include fever, flank pain, joint pain, headache, hypertension, confusion, seizure, and oliguria. The goal of treatment is to restore adequate renal blood flow. This is done by resolving the underlying cause and its complications. In severe cases, renal dialysis (described later) or kidney transplantation may be needed to manage the disease.

POSTRENAL ACUTE RENAL FAILURE

Postrenal ARF is caused by obstruction to urine flow from both kidneys. This form of renal failure may be caused by ureteral and urethral obstructions (e.g., bilateral calculi, prostatic enlargement, urethral strictures). It also can result from obstruction of a urinary catheter. The blockage of urine causes pressure to build in the renal nephrons and ultimately can cause the nephrons to shut down. The degree of renal failure corresponds directly to the degree of obstruction. Signs and symptoms of postrenal ARF include urine retention; a distended bladder; gross **hematuria;** pain in the lower back, abdomen, groin, or genitalia; and peripheral edema. The condition can be reversed by removing the obstruction to urine flow.

Chronic Renal Failure

Chronic renal failure (CRF) is a progressive, irreversible systemic disease. It develops over months to years as internal structures of the kidney are slowly damaged. As renal function steadily declines, CRF leads to **end-stage renal disease,** which eventually requires dialysis or kidney transplantation. CRF may be caused by congenital disorders or prolonged pyelonephritis. In the industrialized world, however, CRF more often results from systemic diseases (e.g., diabetes and hypertension) and autoimmune disorders. The kidneys try to make up for renal damage by hyperfiltration in the remaining working nephrons. Over time, hyperfiltration causes further nephron damage and loss of kidney function. Chronic loss of function causes generalized wasting and progressive scarring in all parts of the kidney. This damage results in a reduction in nephron mass and renal mass.

NOTE

Chronic renal failure and end-stage renal disease affect more than 2 in 1000 people in the United States. More than 50,000 Americans die each year from the disease.[6]

As does ARF, CRF results in the buildup of fluid and waste products in the body. This causes **azotemia** (the retention of excessive amounts of nitrogenous compounds in the blood). It also causes uremia. Most body systems are affected by CRF. Complications of the disease may include hypertension, congestive heart failure, anemia, electrolyte abnormalities, and others. Once CRF has been diagnosed and the cause has been identified, treatments are started to delay or possibly stop the progressive loss of kidney function. In its final stages, CRF often requires treatment with dialysis (hemodialysis or peritoneal dialysis) or kidney transplantation for the patient to survive. In addition to oliguria, a patient with CRF may show the following six systemic manifestations.

1. Gastrointestinal manifestations
   a. Anorexia
   b. Nausea
   c. Vomiting
   d. Metallic taste in the mouth
2. Cardiopulmonary manifestations
   a. Hypertension
   b. Pericarditis
   c. Pulmonary edema
   d. Peripheral, sacral, and periorbital edema
   e. Myocardial ischemia
3. Nervous system manifestations
   a. Anxiety
   b. Delirium
   c. Progressive obtundation
   d. Hallucinations
   e. Muscle twitching
   f. Neuropathies of the hands and feet
   g. Tremors or seizures
4. Metabolic or endocrine manifestations
   a. Glucose intolerance
   b. Electrolyte disturbances
   c. Anemia
5. Personality changes
   a. Fatigue
   b. Mental dullness
   c. Confusion

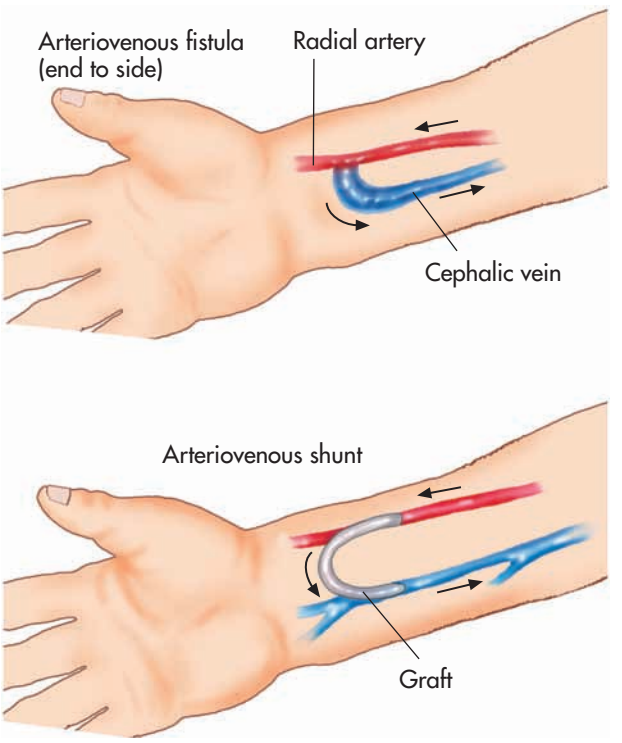

FIGURE 30-6 Arteriovenous shunts. (Ferguson DG, Fodden DI: *Accident and emergency medicine,* New York, 1998, Churchill Livingstone.)

6. Signs of uremia
   a. Pasty, yellow skin and thin extremities from protein wasting
   b. Uremic frost (Figure 30-5), caused by the formation of urea crystals on the skin (late finding)

Renal Dialysis

Dialysis is a technique used to normalize blood chemistry and remove excess fluid in patients with acute or chronic renal failure. Dialysis also removes blood toxins in some patients who have taken a drug overdose. The two types of dialysis are *hemodialysis* and *peritoneal dialysis*. Both of these techniques bring the patent's blood into contact with a semipermeable membrane, across which water-soluble substances diffuse into a dialyzing fluid **(dialysate).** Eventually electrolytes are balanced between the patient's blood and the dialysis fluid, and waste products are eliminated.

The amount of substance that transfers during dialysis depends on the difference in the concentrations of solutions on the two sides of the semipermeable membrane, the molecular size of the substance, and the length of time the blood and the dialysate remain in contact with the membrane. In patients with end-stage renal disease, hemodialysis usually is performed three times a week. Each session may last 4 to 5 hours.

HEMODIALYSIS

In **hemodialysis** the patient's heparinized blood is pumped through a surgically constructed **arteriovenous fistula** (an internal anastomosis between an artery and a vein) or an **arteriovenous graft** (a synthetic material grafted between the patient's artery and vein [Figure 30-6]). These internal shunts usually are located in the inner aspect of the patient's forearm. Less often, they may be located in the upper arm or medial aspect of the lower extremity (see Chapter 52).

PERITONEAL DIALYSIS

In **peritoneal dialysis** the dialysis membrane is the patient's own peritoneum (Figure 30-7). The dialysate is infused into the peritoneal cavity by a temporary or permanently implanted catheter. Fluid and solutes diffuse from the blood in the peritoneal capillaries into the dialysate. Equilibration occurs after 1 to 2 hours. At this point, the dialysate is drained and fresh fluid is infused. Peritoneal dialysis works much more slowly than hemodialysis. Over time, however, it is just as effective. In addition, peritoneal dialysis does not require chronic blood access. A major complication of peritoneal dialysis is peritonitis. This usually results when the proper aseptic technique is not used. Peritoneal dialysis may be performed regularly in the home by the patient or by the family caregiver.

DIALYSIS EMERGENCIES

Emergencies the paramedic may encounter when caring for a patient with acute or chronic renal failure may result from the disease process itself or from complications of the dialysis. For example, these patients may experience problems associated with vascular access, hemorrhage, hypotension, chest pain, severe hyperkalemia, disequilibrium syndrome (described later), and the development of an air embolism. In addition, the paramedic should be aware of problems that may result from concurrent medical illness and its

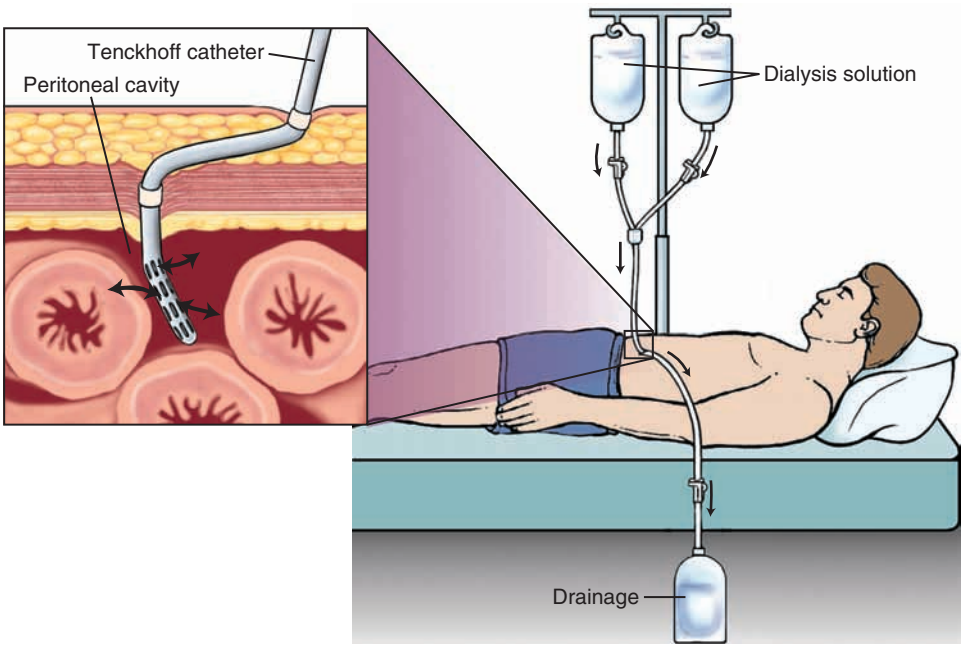

FIGURE 30-7 Peritoneal dialysis. (Linton AD: *Introduction to medical surgical nursing,* ed 4, St Louis, 2007, Saunders.)

treatment. Examples include decreased ability to tolerate the stress of significant illness or trauma, inadvertent overadministration of IV fluid, and altered metabolism and unpredictable action of drugs.

CRITICAL THINKING
Which of these complications could pose an immediate threat to life?

NOTE
Renal failure is a common cause of pericardial disease, including pericarditis and pericardial effusions.[2] These conditions may result from uremia *(uremic pericarditis)* and may also occur in patients on maintenance dialysis. Most patients with pericardial disease complain of fever and pleuritic chest pain. The chest pain often is worsened by movement or breathing and may intensify when the patient is lying down. A pericardial friction rub may be audible. Signs of cardiac tamponade may be seen, particularly in patients with rapid accumulation of pericardial fluid.[7]

SHOW ME THE EVIDENCE
More than 50% of dialysis patients experience cardiac arrest in the first 5 years of hemodialysis. Davis and colleagues sought to describe the outcome of cardiac arrests at hemodialysis centers to which EMS responded. They examined the records of 110 patients who had a cardiac arrest that met their criteria between 1990 and 2004. Of that group, 104 patients suffered an arrest before EMS providers arrived. Four had return of spontaneous circulation (ROSC) before EMS providers arrived after dialysis center personnel defibrillated the patient with an automatic external defibrillator (AED). Ventricular fibrillation (VF) and pulseless ventricular tachycardia (VT) were reported in 67% of cases. When an AED was available, it was used in only 53% of arrests.

Davis TR, et al: Outcome of cardiac arrests attended by emergency medical services staff at community outpatient dialysis centers, *Kidney Int* 73:933-939, 2008.

Vascular Access Problems. Problems associated with vascular access include bleeding at the site of puncture for dialysis, thrombosis, and infection. Bleeding from the fistula or graft usually is minimal. The bleeding usually can be controlled by direct pressure at the site. (However, excessive pressure can cause thrombosis in the graft or fistula.) A rare but potential complication of an internal shunt is the development of a **pseudoaneurysm** (a dilation resembling an aneurysm that occurs at the site of the graft). The pseudoaneurysm can rupture and may cause a large hematoma and possible hypovolemia. If this occurs, the paramedic should apply direct pressure to the hematoma and assess and treat the patient for significant blood loss. This situation requires rapid transport for care by a physician.

Fistulae and grafts that become occluded as a result of thrombus formation usually require surgical intervention or the administration of a thrombolytic agent to restore flow. Patients with a surgical anastomosis are instructed to check periodically for a bruit or "thrill," which verifies unobstructed circulation. Attempts to clear the graft by irrigation or aspiration generally are not advised. If thrombosis occurs while the patient is undergoing dialysis, the dialysis should be stopped. Fluids then should be given intravenously in an alternative site. Decreased blood flow is a common trigger for thrombosis and is the main reason the blood pressure should not be taken in the arm with a vascular access.

An infection at the site of vascular access usually is the result of the puncture made during dialysis. Therefore, careful sterile technique is the rule when caring for these patients. Routine vascular access using the dialysis route should be discouraged. Vascular access infection should be considered when a dialysis patient has unexplained fever, malaise, or other signs of systemic infection.

NOTE

When drawing blood or intravenously infusing fluids in a patient with a surgical anastomosis, the paramedic should choose an alternative site. The paramedic also should avoid taking blood pressure measurements and using tourniquets in an extremity with an arteriovenous fistula or graft. In rare cases medical direction may advise using the internal shunt to obtain vascular access. If so, the paramedic must be careful not to puncture the back wall of the vessel. Careful, aseptic technique must be used during the procedure. IV infusions must be monitored closely to prevent a "runaway IV." Also, the IV catheter should be taped securely in place.

Hemorrhage. Patients undergoing dialysis are at increased risk of hemorrhage. This risk arises from their regular exposure to anticoagulants during hemodialysis and from the decrease in their platelet function. Therefore, a patient who experiences hemorrhage from trauma or a medical condition (e.g., gastrointestinal bleeding) should be monitored closely for signs of hypovolemia. Most patients on dialysis have anemia related to a decrease in the production of erythropoietin. This lowers their ability to compensate for blood loss when they have acute hemorrhage. Any significant blood loss (whether external or internal) may produce dyspnea or angina. If hemorrhage from trauma occurs in an extremity with a fistula or graft, the paramedic should control the bleeding and immobilize the extremity. Special care must be taken not to obstruct circulation in the anastomosis.

Hypotension. Hypotension can occur with hemodialysis. This may result from the rapid reduction in intravascular volume, abrupt changes in electrolyte concentrations, or vascular instability that may occur during the procedure. In addition, the patient's mechanisms for coping with these physiological changes may be impaired. This may result in an inability to maintain normal blood pressure. Patients with hypotension caused by dialysis must be managed cautiously with the administration of volume-expanding fluids. The paramedic should be careful not to produce a fluid overload. This may manifest as hypertension and the classic signs of congestive heart failure (Box 30-2). Most patients respond to a small fluid challenge (200 to 300 mL). If they do not, other potentially serious causes should be considered.

Chest Pain. The episodes of hypotension and mild hypoxemia that often occur during dialysis may result in myocardial ischemia and chest pain. The patient also may complain of other symptoms associated with decreased oxygen delivery, such as headache and dizziness. These complaints may indicate an evolving myocardial infarction. They often are relieved by the administration of oxygen, fluid replacement, and antianginal medications. Regardless, all patients with chest pain should be treated as though a myocardial infarction has occurred.

Dysrhythmias that result from myocardial ischemia also may be associated with dialysis. The most common ischemic rhythm disturbances are premature ventricular contractions. If dialysis is in progress, the procedure should be stopped and the paramedic should confer with medical direction.

Severe Hyperkalemia. Severe hyperkalemia is an emergency that poses a serious threat to life. It can occur rapidly in patients with acute renal failure. Severe hyperkalemia often results from poor dietary regulation and missed dialysis treatments. Patients with severe hyperkalemia may have weakness but often are asymptomatic. As described in Chapter 22, typical electrocardiographic (ECG) changes seen with hyperkalemia initially demonstrate a tall or tented T wave. As the potassium levels rise, conduction slows. This results in a prolonged P-R interval, depressed ST segments, and sometimes the loss of P waves. This may be followed by a widened QRS complex and delayed conduction in the interventricular conducting system. The ECG patterns resemble bundle branch blocks (Figure 30-8). Hyperkalemic disturbances may not become apparent until dangerous levels of potassium are present. Therefore, any patient with renal failure who is in cardiac arrest should be suspected of having severe hyperkalemia. Based on the patient history, medical direction may recommend separate administration of ***calcium*** and ***sodium bicarbonate*** during resuscitation. High-dose nebulized ***albuterol*** to reduce the plasma potassium concentration also has been reported to be effective.[8]

BOX 30-2 Classic Signs of Congestive Heart Failure

- Crackles
- Engorged neck veins
- Liver congestion and engorgement
- Pitting edema
- Pulmonary edema
- Shortness of breath

NOTE

Dialysis patients with chronic renal failure tolerate increased potassium levels better than do patients with normal kidney function.

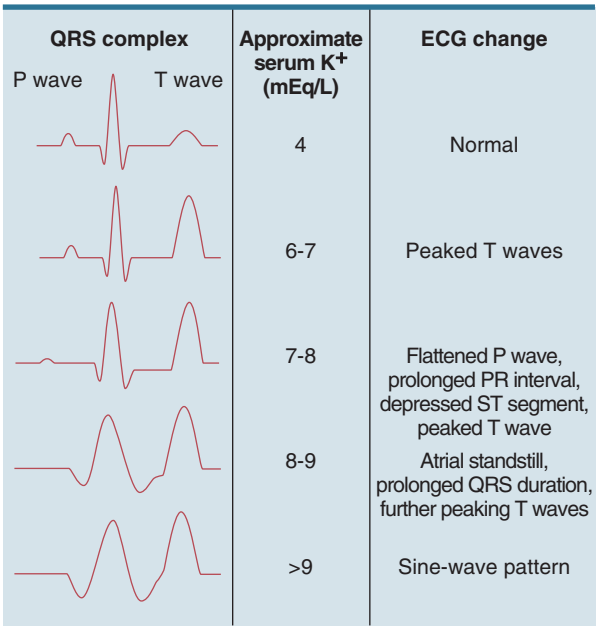

FIGURE 30-8 Electrocardiographic (ECG) changes seen in hyperkalemia. (Sole ML: *Introduction to critical care nursing,* ed 5, St Louis, 2009, Saunders.)

Disequilibrium Syndrome. Disequilibrium syndrome refers to a group of neurological findings that sometimes occur during or immediately after dialysis. These symptoms usually are mild (e.g., headache, restlessness, nausea, and fatigue), but they may be severe (confusion, seizures, and coma). The syndrome is thought to result from a disproportionate decrease in the osmolality of the extracellular fluid compared with that of the intracellular compartment in the brain or cerebrospinal fluid.[9] This results in an osmotic gradient between the blood and the brain. This in turn causes the movement of water into the brain and then cerebral edema and increased intracranial pressure. If seizures occur, an anticonvulsant may be indicated.

Air Embolism. Negative pressure on the venous side of the dialysis tubing or a malfunction in the machine can allow an air embolus to enter the patient's bloodstream. This is a rare occurrence. If air embolism occurs, the embolus may be carried to the right ventricle of the heart, where it may block the passage of blood to the left myocardium. The patient may experience severe dyspnea, cyanosis, hypotension, and respiratory distress. A patient with an air embolus requires high-concentration oxygen and rapid transport to a medical facility. In an effort to trap the embolism where it will be least likely to obstruct blood flow, the paramedic should position the patient on the left side. The patient should be transported in the modified Trendelenburg position.[10]

Management. To review, the prehospital management of patients with chronic or acute renal failure includes the following:

- Airway and ventilatory support with supplemental high-concentration oxygen
- Vascular access for fluid replacement, medication therapy (diuretics, antidysrhythmics, vasopressors), or fluid resuscitation if needed
- Meticulous aseptic technique during intravenous access
- ECG and other vital sign monitoring
- Rapid transport to an appropriate medical facility

URINARY SYSTEM CONDITIONS

There are many types of urinary tract diseases, which can range from mild to severe. Urinary system disorders that may cause acute pain include urinary retention, urinary tract infection (cystitis, urethritis), pyelonephritis, and renal calculi. As do disorders of the abdomen, urinary system disorders may produce visceral, somatic, and referred pain.

Urinary Retention

Urinary retention is the inability to urinate. Possible causes include urethral stricture, an enlarged prostate (benign or malignant *prostatic hypertrophy*), central nervous system (CNS) dysfunction, foreign body obstruction, and use of certain drugs, such as parasympatholytic or anticholinergic agents. Men develop urinary retention more often than women do, most commonly because of an enlarged prostate. However, other common causes can be found in both genders.

The signs and symptoms of urinary retention include severe abdominal pain associated with an urgent need to urinate and a distended bladder. The distended bladder often is palpable. Patients with a progressive obstruction, such as prostatic hypertrophy, often have a history of urinary hesitancy, a poor urine stream, a sense of incomplete emptying of the bladder, **nocturia** (excessive urination at night), and **overflow incontinence** (an overflow of urine from the bladder). The condition may also cause delirium, especially in elderly patients. In the emergency department, passage of a urethral catheter to empty the bladder often is required. Urinary retention is painful for the patient. Prehospital care for these patients mainly is supportive. If abdominal pain is present, an IV line to keep the vein open may be indicated. The cause of the retention should be sought; if it is not easily correctable after examination by a physician, the patient may require hospitalization. Some EMS systems may permit urinary catheterization in the prehospital setting to empty the patient's bladder (see Chapter 52).

CRITICAL THINKING

Have you ever been in a situation in which you needed to urinate urgently but could not because of the circumstances? How did you feel?

NOTE

Normal urination is essentially a spinal reflex coordinated by the central nervous system (CNS; brain, brainstem, and spinal cord). CNS injury or disease (e.g., spinal cord injury or multiple sclerosis) can affect this spinal reflex, resulting in autonomic hyperreflexia (also called *autonomic dysreflexia*). **Autonomic hyperreflexia** is overactivity of the autonomic nervous system, resulting in the abrupt onset of extremely high blood pressure. A common cause of autonomic hyperreflexia in patients with CNS injury or disease is urinary retention. Inability to urinate causes overstretching or irritation of the bladder wall. The irritation sends nerve impulses to the spinal cord, where they travel upward until they are blocked by the area of injury or dysfunction. Because the impulses cannot reach the brain, a reflex is activated that increases the activity of the sympathetic portion of the autonomic nervous system. This results in vasoconstriction, which causes a rise in the blood pressure. In rare cases autonomic hyperreflexia can be fatal.

Urinary Tract Infection

Urinary tract infections (UTIs) account for 7 million to 8 million visits to physicians' offices each year and for 100,000 hospitalizations.[2] UTIs are the second most common problem seen by physicians, after respiratory tract infections. These infections usually develop first in the lower urinary tract (the urethra or bladder.) If left untreated, they can progress to the upper urinary tract (ureters or kidneys.) Upper tract infections often are associated with kidney infection (pyelonephritis, described later in this chapter) or abscesses that form in the kidney tissue. These conditions can lead to reduced kidney function, and untreated, severe cases can be fatal.

The more common lower UTI of the urethra **(urethritis)** and bladder **(cystitis)** occurs when enteric flora (particularly *Escherichia coli,* normally found in the bowel) enter the opening of the urethra and colonize the urinary tract. These infections are more common in women, because the urethra is short and close to the vagina and rectum. The infection also occurs in men (as a result of urethritis, prostatitis, and cystitis) and children. However, urethritis and prostatitis in young men most often results from venereal disease rather than a true UTI. Other factors that may contribute to a lower UTI include the use of contraceptive devices (women who use a diaphragm develop infections more often; condoms with spermicidal foam may cause the growth of *E. coli* in the vagina, which may enter the urethra), unsafe sexual practices, the presence of renal stones, bladder catheterization, and a suppressed immune system. In addition, men and women infected with *Chlamydia trachomatis* or *Mycoplasma hominis* can transmit the bacteria to their partner during sexual intercourse. These bacteria then could cause a UTI.

Signs and symptoms of UTI include painful or difficult urination **(dysuria),** urinary frequency, hematuria, cloudy or rust-colored urine (sometimes with an unusual or foul odor), and flank or suprapubic abdominal pain. Often the patient has a history of UTI episodes. In addition, fever, chills, and malaise may be present. The diagnosis is confirmed in the hospital through urinalysis and microscopic examination for blood cells, sediment, and bacteria. Urinary tract infections generally are treated with antibiotic therapy.

Pyelonephritis

Pyelonephritis is inflammation of the kidney parenchyma (upper urinary tract). This inflammation most often occurs as a result of a lower UTI. The disease is associated with bacterial infection, particularly in cases of occasional or persistent backflow (reflux) of infected urine from the bladder into the ureters or kidney pelvis. The bacterial infections may also be carried to one or both kidneys. They may be carried through the bloodstream or lymph glands from the infection that began in the bladder. Pyelonephritis is more common in adult women, but the condition can affect individuals of any age and either gender. Acute episodes can be severe in the elderly and in immunosuppressed people (e.g., those with cancer or acquired immunodeficiency syndrome [AIDS]).

The onset of signs and symptoms of pyelonephritis usually is abrupt. Patients often mistake the pain of pyelonephritis for lower back strain. The condition may be complicated by systemic infection, with signs and symptoms that include fever, chills, flank pain, cloudy or bloody urine, nausea, and vomiting. Left untreated, pyelonephritis can progress to a chronic condition that can last for months or years. It may lead to scarring and possible loss of kidney function. Therapeutic intervention consists primarily of antibiotics, fluid replacement, and sometimes hospitalization.

CRITICAL THINKING

How would you examine the patient for flank pain?

Urinary Calculus

Urinary calculi (kidney stones) are pathological concretions that originate in the renal pelvis. They are one of the most painful and most common disorders of the urinary tract, accounting for about 250,000 hospitalizations each year. It is estimated that 7% of men and 3% of women in the United States will have a kidney stone at some point in their lives.[2] Kidney stones result from supersaturation of the urine with insoluble salts. When the level of insoluble salts or uric acid in the urine is high, the urine lacks *citrate* (a chemical that normally inhibits the formation of stones). Kidney stones also can form if insufficient water is present

in the kidneys to dissolve waste product,. Kidney stones are more common in men than in women; they most often occur in men between the ages of 20 and 50, and the disease is recurrent. Associated risk factors for this condition include dehydration, CNS disorders (absent sensory/motor impulses from injury or disease), drug use (anesthetics, opiates, psychotropic agents, some herbal medicines), and surgery (postoperative complication).

SHOW ME THE EVIDENCE

Safdar and coworkers conducted a randomized, controlled study to evaluate pain management in 130 patients presumed to have kidney stones. One group was treated with IV morphine, another with IV ketorolac, and the third group received both drugs. The group that receive the combination of morphine and ketorolac had better pain relief. This group also experienced less nausea and vomiting than the morphine group.

Safdar B et al: Intravenous morphine plus ketorolac is superior to either drug alone for treatment of acute renal colic, *Ann Emerg Med* 48:173-181, 2006.

The chemical composition of the kidney stones depends on the chemical imbalance in the urine. The four most common types of stones are composed of calcium, uric acid, struvite, and cystine. Calcium stones are calcium compounds that are chemically bound to oxalate (most common) or phosphate; they account for about 85% of all kidney stones. Calcium stones typically occur in patients with metabolic (e.g., gout) or hormonal disorders (e.g., hyperparathyroidism). Stones composed of uric acid account for about 10% of kidney stones; their formation is more common in men. These stones may have a heritable component. Struvite stones (also known as infection stones) are more common in women. These stones often are linked to chronic bacterial UTI or frequent bladder catheterization. Cystine stones are the least common and result from a rare congenital condition that results in large amounts of cystine (an amino acid) in the urine. Cystine stones are difficult to treat and may require lifelong therapy.

Signs and symptoms of urinary calculus vary according to the location of the stones. Most stones obstruct the ureters at points where they narrow in their passage from the kidneys to the bladder. This produces acute, excruciating pain. The pain originates in the flank area and radiates to the right or left lower abdominal quadrant, groin, and testes (in males). Renal or ureteral colic produces severe cyclical pain. The pain occurs as the ureter tries to use forceful contractions to push the stone into the bladder. This pain often has been described as having the same intensity as labor pain. The pain may be accompanied by restlessness, nausea and vomiting, urinary urgency or frequency, diaphoresis, low-grade fever, hematuria, dysuria, and elevated blood pressure (because of the pain). Prehospital care may include IV fluids, transport in a position of comfort, antiemetics, and pain management as needed (***nitrous oxide, ketorolac,*** narcotic analgesics). Care by a physician may include analgesics (anesthetics, opiates, psychotropics), fluid replacement, antiemetics, and possibly hospitalization. If the calculus does not pass spontaneously, surgical intervention may be required (Box 30-3).

BOX 30-3 Strategies for Preventing the Recurrence of Renal Calculi

The composition of a kidney stone determines the strategy used to prevent the formation of more stones. Patients may be advised to do the following:

- Increase water consumption
- Avoid foods containing calcium oxalate (e.g., chocolate, celery, grapes, strawberries, beans, and asparagus)
- Take daily supplements of vitamin B_6 and magnesium (to reduce the formation of oxalates)
- Avoid foods that raise uric acid levels (e.g., anchovies and sardines)
- Reduce uric acid by eating a low-protein diet
- Limit salt intake to reduce the level of calcium oxalate in the urine

NOTE

It is not uncommon for "drug seekers" to feign symptoms of kidney stones to obtain narcotics. Most hospitals check the patient's urine for blood before providing narcotics. Blood in the urine in a symptomatic patient indicates that a kidney stone is passing through the ureters.

CRITICAL THINKING

Have you cared for or known someone who had a urinary calculus? How did that person describe the pain? What was the level of discomfort?

MALE GENITAL TRACT CONDITIONS

Paramedics encounter numerous genital tract conditions in the prehospital setting. Some may be related to disease; others may be the result of trauma (traumatic conditions are presented in Chapter 43: Abdominal and Genitourinary Trauma). Disorders of the male genital tract discussed in this chapter include epididymitis, Fournier's gangrene, and various structural conditions (phimosis, priapism, benign prostatic hypertrophy, testicular masses, and testicular torsion). The anatomy of the male genital tract is presented in Chapter 10.

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 201-202.

Epididymitis

Epididymitis is inflammation of the epididymis, a tubular section of the male reproductive system that carries sperm from the testicle to the seminal vesicles. Epididymitis often is caused by a bacterial infection associated with other structures of the genitourinary tract. Infection tends to occur in sexually active young men. The most common type of epididymitis in young men results from venereal disease. In men older than age 35, urinary tract pathogens are the most common cause.[2]

The signs and symptoms of epididymitis include a gradual onset of unilateral scrotal pain that radiates to the spermatic cord. At times, tender swelling of the scrotum and testicle occurs. This swelling produces inflammation of one or both testes **(orchitis).** The patient may have a recent history of UTI, fever, and malaise, and a urethral discharge may be present. After evaluation by a physician, therapeutic intervention includes antibiotics, bed rest, analgesics, and elevation of the scrotum.

Fournier's Gangrene

Fournier's gangrene is a bacterial infection of the skin that affects the genitals and perineum in both men and women. It is a urological emergency that results after a wound or an abrasion becomes infected. A combination of microorganisms (e.g., staphylococci) and fungi (e.g., yeast) causes the infection to spread. It can lead to necrosis of the skin, subcutaneous tissue, and muscle. Fournier's gangrene can be fatal if the infection enters the bloodstream, causing sepsis, shock, and organ failure. Men are 10 times more likely to develop the disease. Men 60 to 80 years of age who have predisposing conditions are the most susceptible. Predisposing factors and conditions include alcoholism, IV drug use, genital piercing, obesity, diabetes, leukemia, and immune system disorders. The condition also can develop as a complication of surgery. Hallmarks of the disease are intense pain and tenderness in the genitalia (Figure 30-9).

FIGURE 30-9 Fournier's gangrene. (Courtesy Mark Dropkin, M.D., Newton Wellesley Hospital, Newton, Mass.)

Depending on the stage of disease, assessment findings in the genital area may include crepitus of the skin, gray-black coloration from decay (gangrene), drainage of pus, and fever.[1] Fournier's gangrene usually progresses through five stages[11]:

1. Prodromal symptoms of fever and lethargy, which may be present for 2 to 7 days
2. Intense genital pain and tenderness, usually associated with edema of the overlying skin
3. Increasing genital pain and tenderness with progressive erythema of the overlying skin
4. Dusky appearance of the overlying skin; subcutaneous crepitation
5. Obvious gangrene of a portion of the genitalia; purulent drainage from wounds

Prehospital care may range from providing only emotional support and rapid transport to full resuscitation measures to manage shock. After the patient's condition has been stabilized, care by a physician includes various methods to restore normal organ perfusion and function. These methods may include antibiotic therapy, hyperbaric oxygen therapy, and surgery (including reconstruction).

Phimosis

Phimosis is tightness of the **prepuce** (foreskin) of the penis. The condition prevents retraction of the foreskin over the glans (Figure 30-10). It can be caused by failure of the foreskin to loosen during growth, infection, genital disease, and trauma. Phimosis usually is a painless condition. However, infection can occur with ineffective cleaning of the penis, resulting in swelling, redness, and discharge. In rare cases a patient may complain of problems with urination or intercourse.

DID YOU KNOW?

Circumcision is the surgical removal of the foreskin. The procedure often is performed on healthy boys for cultural or religious reasons. In the United States, if a newborn is to be circumcised, the procedure usually is done before the infant leaves the hospital. Jewish boys, however, are circumcised when they are 8 days old. In other parts of the world, including Europe, Asia, and South and Central America, circumcision is rare in the general population. The merits of circumcision have been debated. Opinions about the need for circumcision in healthy boys vary among health care professionals. Some believe there is great value to having an intact foreskin, such as allowing for a more natural sexual response during adulthood. Rather than routinely recommending circumcision for healthy boys, the American Academy of Pediatrics and the American Medical Association recommend that parents make an informed decision based on accurate, nonbiased information.[12]

Paraphimosis is inability to pull the retracted foreskin back over the head of the penis. This condition can restrict blood flow and requires emergency care. A hallmark sign of paraphimosis is a "doughnut" of swollen skin around the

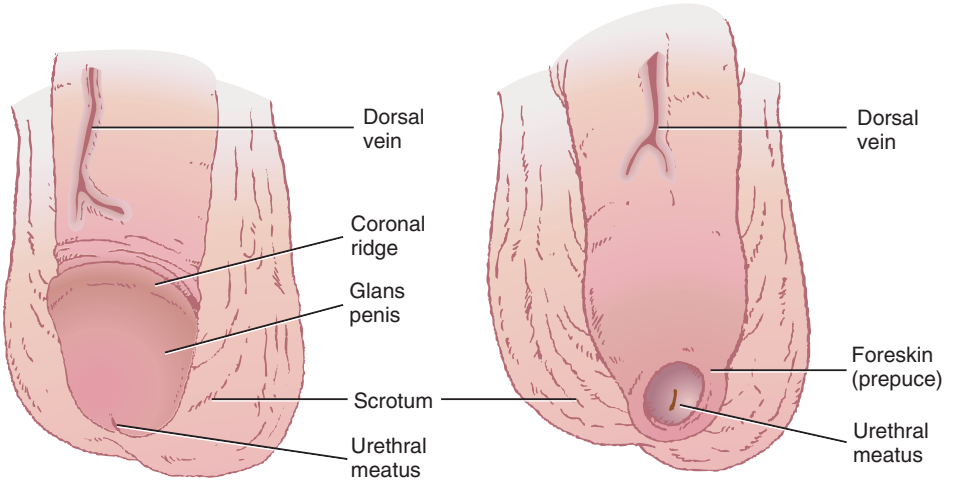

FIGURE 30-10 Appearance of the penis. **A,** Circumcised. **B,** Uncircumcised. (Linton AD: *Introduction to medical surgical nursing,* ed 4, St Louis, 2007, Saunders.)

shaft, near the head of the penis. Paraphimosis occurs most often in children and the elderly. If left untreated, it can disrupt blood flow to the tip of the penis.[13] In severe cases this can lead to damage of the tip of the penis, gangrene, and loss of the penis tip. Emergency care may include gentle compression of the head of the penis while pushing the foreskin forward or wrapping the penis in plastic and applying ice to reduce swelling, allowing the foreskin to return to its extended position. If this fails, the patient may require hospitalization and surgical circumcision.

Priapism

Priapism is a persistent, usually painful, erection that lasts 4 hours or longer and occurs without sexual stimulation. The condition develops when blood in the penis becomes trapped and unable to drain. If the condition is not treated immediately, it can lead to scarring and permanent erectile dysfunction. Priapism can occur in all age groups, including newborns. However, it usually affects male children between 5 and 10 years of age and men between 20 and 50 years of age. Priapism is subcategorized into two types, low flow and high flow.

- *Low-flow priapism* results when blood is trapped in the erection chambers of the penis. It often occurs for unknown reasons in men who are otherwise healthy. This type also affects men with sickle cell disease, leukemia and other cancers, or malaria.
- *High-flow priapism* is less common than the low-flow type and usually less painful. The condition results from a ruptured artery, which occurs because of an injury to the penis or the perineum. The rupture prevents blood in the penis from circulating normally.

NOTE
Sickle cell disease (see Chapter 32) is a common cause of priapism in men. About 42% of men with the disease eventually develop priapism.[2]

Some medications can cause priapism. Examples include antidepressants (e.g., Desyrel), antipsychotics (e.g., Thorazine), injection drugs used to treat erectile dysfunction (ED), and oral ED drugs (e.g., Viagra). Other causes of priapism include trauma to the spinal cord or genital area, black widow spider bites, carbon monoxide poisoning, and illicit drug use (e.g., marijuana and cocaine). Prehospital care for a patient with priapism is primarily supportive. All patients should be transported and evaluated by a physician.

Benign Prostatic Hypertrophy

Benign prostatic hypertrophy (BPH) is enlargement of the prostate gland. As described in Chapter 10, the prostate gland is the male organ that produces prostatic fluid, a component of semen. It sits beneath the bladder and surrounds the urethra. Most men have a period of prostate growth in their middle to late 40s, when cells in the central portion of the gland reproduce rapidly. As tissues in the area enlarge, they often compress the urethra and may partly block the flow of urine.

NOTE
The prostate gland is assessed during a rectal examination. The physician palpates the gland for size, consistency, nodularity, and tenderness. In benign prostatic hypertrophy (BPH), the gland is smooth, symmetrical, and feels slightly rubbery. In contrast, a cancerous prostate may feel asymmetrical and have a stony-hard consistency. Discrete nodules may be palpable. Marked prostatic tenderness suggests **acute prostatitis**. If a patient has signs and symptoms of prostate irregularities, his blood may be tested for prostate-specific antigen (PSA); if this value is elevated, the prostate may be biopsied to rule out cancer.

Not all men with BPH are symptomatic. However, some complain of urinary frequency, a weak urine stream, difficulty starting and stopping urination, overflow

incontinence, hematuria, and urinary tract infection. Treatment of BPH depends on the severity of the signs and symptoms and how they affect daily life. Treatment options include medications, surgery, and nonsurgical therapies. Enlargement of the prostate gland is not related to the development of prostate cancer.

Testicular Masses

A **testicular mass** is an enlargement or growth on one or both testicles. Most masses are benign, but some may be malignant. Three of the most common benign testicular masses are hydroceles, spermatoceles, and varicoceles.

A **hydrocele** is a fluid-filled sack along the spermatic cord in the scrotum (Figure 30-11). A **spermatocele** is a benign cystic accumulation of sperm that arises from the head of the epididymis (Figures 30-12 and 30-13). Both conditions result in collections of fluid in the scrotal sac. These masses are generally soft and painless. Their size can change rapidly as fluid enters or leaves the scrotum. A **varicocele** is an enlargement of the veins that drain the testicles (Figure 30-14). These masses are soft, scrotal swellings that often are more prominent when the man is standing or exercising. Varicoceles sometimes may cause a sensation of heaviness or a dull ache in the genital area.

Ultrasound and transillumination techniques are used to diagnose testicular masses. Most testicular masses require no treatment. If a hydrocele or spermatocele is large or painful (or both), surgery may be needed to drain fluid. A varicocele may require surgery to tie off the affected veins.

Testicular cancer also may present as a testicular mass, with or without pain. The mass usually feels firm and arises from the testicle. The diagnosis is made using blood tests and scrotal ultrasound. Treatment involves surgery to remove the affected testicle, chemotherapy, and/or radiation. Testicular cancer is the most common cause of cancer

TABLE 30-4 Abnormalities in the Scrotum

Disorder	Clinical Findings	Comments
Testicular torsion From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2007, Saunders.	*S:* Sudden onset of excruciating pain in testicle, often during sleep or after trauma; patient may also have lower abdominal pain, nausea and vomiting, no fever *O*: Inspection—Red, swollen scrotum, one testis (usually left) higher because of rotation and shortening Palpation—Cord feels thick, swollen, tender; epididymis may be anterior; cremasteric reflex absent on side of torsion *A*: Testicular torsion	Sudden twisting of the spermatic cord usually occurs in late childhood, early adolescence; it is rare after age 20. Torsion usually occurs on the left side. Faulty anchoring of the testis on the scrotal wall allows the testis to rotate. The anterior part of the testis rotates medially toward the other testis. Blood supply is cut off, resulting in ischemia and engorgement. This is an emergency that requires surgery; the testis can become gangrenous in a few hours.
Epididymitis  From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2007, Saunders.	*S:* Sudden onset of severe pain in scrotum, which is somewhat relieved by elevation (positive Phren's sign); also, rapid swelling, fever *O:* Inspection—Enlarged, reddened scrotum Palpation—Exquisitely tender; epididymis enlarged, indurated, and may be difficult to distinguish from testis; overlying scrotal skin may be thick and edematous Laboratory—White blood cells and bacteria in urine *A:* Tender swelling of epididymis	Acute infection of the epididymis commonly occurs as a result of prostatitis; after prostatectomy because of the trauma of urethral instrumentation; or because of a chlamydial, gonorrheal, or other bacterial infection. Differentiating between epididymitis and testicular torsion often is difficult.
Spermatic cord varicocele From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2007, Saunders.	*S:* Dull pain; constant pulling or dragging feeling; or may be asymptomatic *O:* Inspection—Usually no sign; may show bluish color through light scrotal skin Palpation—When patient is standing, a soft, irregular mass is felt posterior to and above the testis; this mass collapses when the patient is supine and refills when he is upright; mass feels distinctive, like a "bag of worms"; testis on the side of the varicocele may be smaller because of impaired circulation *A:* Soft mass on spermatic cord	A varicocele is dilated, tortuous varicose veins in the spermatic cord resulting from incompetent valves in the vein; this permits the reflux of blood. Varicoceles are found most often on the left side, perhaps because the left spermatic vein is longer and inserts at a right angle into the left renal vein. The condition is common in young men. Screening should be done in early adolescence; early treatment is important to prevent the possibility of infertility in adulthood.

Continued

TABLE 30-4—cont'd

Disorder	Clinical Findings	Comments
Spermatocele  From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2007, Saunders.	*S:* Painless, usually found on examination *O:* Inspection—Transilluminates higher in the scrotum than a hydrocele; sperm may fluoresce Palpation—Round, freely movable mass lying above and behind testis; if large, feels like a third testis *A:* Free cystic mass on epididymis	Retention cyst in the epididymis. The cause is unclear but may be obstruction of tubules. Cyst is filled with thin, milky fluid that contains sperm. Most spermatoceles are small (about 1 cm); occasionally they may be larger, and they then are mistaken for a hydrocele.
Diffuse tumor From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2007, Saunders.	*S:* Enlarging testis (most common symptom); when enlarged, it has the feel of increased weight *O:* Inspection—Enlarged testis, does not transilluminate Palpation—Enlarged, smooth, ovoid, firm Important—Firm palpation does *not* cause usual sickening discomfort seen with normal testis *A:* Nontender swelling of testis	Diffuse tumor maintains the shape of the testis.
Hydrocele  From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2007, Saunders.	*S:* Painless swelling, although the patient may complain of weight and bulk in the scrotum *O:* Inspection—Enlarged; mass transilluminates with a pink or red glow (in contrast to a hernia) Palpation—Nontender mass; able to get fingers above mass (in contrast to scrotal hernia) *A:* Nontender swelling of testis	Cystic, circumscribed collection of serous fluid in the tunica vaginalis, surrounding the testis. It may occur after epididymitis, trauma, hernia, or tumor of the testis, or spontaneously in the newborn.

TABLE 30-4—cont'd

Disorder	Clinical Findings	Comments
Scrotal hernia  From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2007, Saunders.	*S:* Swelling; may have pain with straining *O:* Inspection—Enlarged; may reduce when patient is supine; does not transilluminate Palpation—Soft, mushy mass; palpating fingers cannot get above mass; mass is distinct from normal testicle *A:* Nontender swelling of scrotum	Scrotal hernia usually is due to indirect inguinal hernia (see Table 24-6).
Orchitis From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2007, Saunders.	*S:* Sudden onset of acute or moderate pain; swollen testis; feeling of weight; fever *O:* Inspection—Enlarged, edematous, reddened; does not transilluminate Palpation—Swollen, congested, tense, and tender; difficult to distinguish testis from epididymis *A:* Tender swelling of testis	Acute inflammation of testis. Most common cause is mumps, although it can occur with any infectious disease. Patient may have an associated hydrocele that transilluminates.

From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2007, Saunders.
S, Subjective data; *O,* objective data; *A,* assessment.

in men 15 to 34 years of age; it occurs most often between the ages of 20 and 39. Monthly self-examination of the testicles is recommended for men in this age group. Each year more than 8000 new cases of testicular cancer are diagnosed in the United States, and about 380 men die of the disease.[14]

Testicular Torsion

Testicular torsion is a true urological emergency. In this condition, a testicle (usually the left) twists on its spermatic cord, disrupting the blood supply of the testicle. The condition may result from blunt trauma to the scrotal area, but more often it is spontaneous. The two peak periods in which torsion is likely to occur are the first year of life and puberty[2] (the age range is 5 months to 41 years, and the average age of occurrence is 14 years).

Like epididymitis, testicular torsion results in a tender epididymis and painful swelling of the scrotal sac (Figure 30-15). Unlike in epididymitis, however, the patient usually is afebrile. The pain is sudden in onset and usually severe. It often is preceded by vigorous physical activity or an athletic event. The pain sometimes radiates to the ipsilateral left quadrant; is unrelieved by rest or scrotal elevation; and often is associated with nausea and vomiting. Testicular torsion must be diagnosed and treated within 6 hours to prevent loss of the testis from ischemic infarction.[15] Therapeutic intervention includes the application of ice packs to the scrotum and manual manipulation by a physician to reduce the torsion. The patient must undergo surgical repair within 4 to 6 hours of onset of the torsion. Therefore, rapid transport to the emergency department and early recognition are critical for treatment.

PHYSICAL EXAMINATION OF PATIENTS WITH GENITOURINARY OR RENAL DISORDERS

As described in Chapter 20, assessment of the abdomen and genitalia of either gender can be awkward and uncomfortable for the patient and the paramedic. The paramedic should protect the patient's privacy with proper drapes to ensure privacy. When possible, paramedics of the same gender as the patient should perform these examinations. If this is not possible, a chaperone should be present. The paramedic should proceed with a calm, caring, and competent attitude. The patient and significant others should be informed of all actions. As in the care of a patient with an abdominal complaint (see Chapter 29), the examination should include the following:

- Primary assessment
- Focused history
  - OPQRST (*o*nset/origin, *p*rovokes, *q*uality, *r*egion, *s*everity, *t*ime)
  - Previous history of similar event
  - Nausea or vomiting
  - Change in bowel habits or stool (constipation, diarrhea)
  - Change in urinary voiding pattern
  - Weight loss
  - Last oral intake
  - Last bowel movement
- Physical examination
  - Appearance
  - Posture
  - Level of consciousness
  - Apparent state of health
  - Skin color
  - Vital signs
  - Abdominal examination (inspection, auscultation, percussion, palpation)
  - Examination of the genitalia (if indicated)

FIGURE 30-15 Four-day old torsion of the left testis.

LOOK AGAIN
See Chapter 20: Secondary Assessment, pp. 542-546.

Management and Treatment Plan

The paramedic should manage patients with genitourinary disorders as any other patient with acute pain. This includes providing airway, ventilatory, and circulatory support; administering high-concentration oxygen (if indicated); ECG and vital sign monitoring; and rapid, gentle transportation for evaluation by a physician in the patient's position of comfort. Patients should not be permitted to eat or drink, because surgery may be indicated. All patients who have had persistent genitourinary pain or discomfort for several hours should be transported for evaluation by a physician.

SUMMARY

- The urinary system removes waste products from the blood. It also helps maintain a constant body fluid volume and composition.
- The nephron is the functional unit of the kidney. It filters blood, removes waste products, and produces urine.
- Renal failure may result in uremia, hyperkalemia, acidosis, hypertension, and volume overload with congestive heart failure.
- Acute renal failure occurs when the kidneys are unable to excrete the daily load of toxins in the urine. Its onset may be within hours.
- Prerenal ARF results from poor perfusion of the kidneys. Intrarenal ARF is caused by conditions that damage the tissues of the kidney. Postrenal ARF is caused by obstruction of urine flow from both kidneys.
- Dialysis is a technique used to normalize blood chemistry in patients with acute or chronic renal failure. It also is used to remove blood toxins. The two dialysis techniques are hemodialysis and peritoneal dialysis. Dialysis emergencies may include problems with vascular access, hemorrhage, hypotension, chest pain, severe hyperkalemia, disequilibrium syndrome, air embolism, or cardiac arrest.

- Urinary retention is the inability to urinate.
- Urinary tract infections can involve the upper or lower urinary tract.
- Pyelonephritis is inflammation of the kidney parenchyma. It can lead to chronic renal problems.
- Urinary calculi are stones that originate in the kidney.
- Epididymitis is inflammation of the epididymis. The epididymis is the tube that carries sperm from the testicle to the seminal vesicles.
- Fournier's gangrene is a bacterial infection of the genitals that can lead to death of skin tissue and systemic sepsis.
- Phimosis is tightness of the foreskin of the penis. Paraphimosis occurs when a male is unable to retract the foreskin over the head of the penis.
- Priapism is a painful, sustained erection.
- Benign prostatic hypertrophy is enlargement of the prostate gland. It may be associated with urinary difficulty and urinary tract infections.
- Testicular masses may be benign or cancerous.
- In testicular torsion a testicle twists on its spermatic cord, disrupting the blood supply to the testicle. This is a true emergency
- The physical examination for a patient with a urinary tract problem is similar to that for abdominal pain. Patients with genitourinary pain should be managed in the same way as any other patient with acute pain.

CHAPTER

31 Gynecology

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the physiological processes of menstruation and ovulation.
2. Describe the pathophysiology of the following nontraumatic causes of abdominal pain in females: pelvic inflammatory disease, Bartholin's abscess, vaginitis, ruptured ovarian cyst, ovarian torsion, cystitis, dysmenorrhea, mittelschmerz, endometriosis, ectopic pregnancy, vaginal bleeding, uterine prolapse, and vaginal foreign body.
3. Outline the prehospital assessment and management of a female with abdominal pain or bleeding.
5. Outline the specific assessment and management of a patient who has been sexually assaulted.
6. Describe specific prehospital measures to preserve evidence in sexual assault cases.

KEY TERMS

Bartholin's abscess An accumulation of pus that forms a lump in one of the Bartholin's glands; it results when blockage of the gland's duct allows infection to develop.

cesarean delivery A surgical procedure in which the abdomen and uterus are incised and the baby is delivered transabdominally.

cystitis Inflammation of the urinary bladder and ureters.

date rape Nonconsensual sex between people who are already acquainted (e.g., friends, acquaintances, or people who are dating).

dilation and curettage (D & C) A gynecological procedure in which the uterine cervix is widened and the endometrium of the uterus is scraped away.

dysfunctional uterine bleeding (DUB) Abnormal bleeding that occurs because of changes in hormone levels.

dysmenorrhea Pain associated with menstruation.

dyspareunia Pain with intercourse.

ectopic pregnancy An abnormal pregnancy in which the conceptus implants outside the uterine cavity.

endometriosis An abnormal gynecological condition characterized by ectopic growth and function of endometrial tissue. It is thought to result when fragments of endometrium from the lining of the uterus are regurgitated during menstruation backward through the fallopian tubes into the peritoneal cavity; there, they attach and grow as small cystic structures.

endometritis An inflammatory condition of the endometrium, usually caused by bacterial infection.

endometrium The mucous membrane lining of the uterus, which changes in thickness and structure with the menstrual cycle.

external genital organs The outer parts of the female genitalia; they consist of the labia majora, the labia minora, Bartholin's glands, and the clitoris. Also known as the *vulva*.

fallopian tubes A pair of ducts that open at one end into the uterus and at the other end into the peritoneal cavity, over the ovaries; also known as *uterine tubes*.

hysterectomy The surgical removal of the uterus.

mammary glands External accessory sex organs in females; breasts.

menarche The first menstruation and commencement of the cyclic menstrual function.

menopause The cessation of menses.

menstruation The periodic discharge through the vagina of a blood secretion containing tissue debris from the shedding of the endometrium from the nonpregnant uterus.

mittelschmerz Abdominal pain in the region of the ovary during ovulation; it usually occurs midway through the menstrual cycle.

oocytes Incompletely developed ova.

ovarian torsion Twisting of an ovary around its vascular pedicle.

ovaries A pair of female gonads, one on each side of the lower abdomen beside the uterus.

ovulation The release of an ovum or secondary oocyte from the vesicular follicle.

pelvic inflammatory disease (PID) Any inflammatory condition of the female pelvic organs, especially one caused by bacterial infection.

rape Nonconsensual sex or an attempt to force another person to have sex against his or her will; it includes intercourse in the vagina, anus, or mouth.

ruptured ovarian cyst A ruptured globular sac filled with fluid or semisolid material that develops in or on the ovary.

sexual assault The forcible perpetration of an act of sexual contact on the body of another person, male or female, without his or her consent.

uterine prolapse The falling or sliding of the uterus from its normal position in the pelvic cavity into the vaginal canal.

uterus The hollow, pear-shaped internal female organ of reproduction.

vagina The part of the female genitalia that forms a canal from the orifice through the vestibule to the uterine cervix.

vaginal bleeding The loss of blood from the uterus, cervix, or vagina.

vaginitis Inflammation of the vaginal tissues.

zygote The developing ovum from the time it is fertilized until it is implanted in the uterus as a blastocyst.

A number of disorders can occur in the female reproductive system. Some of these can lead to gynecological emergencies. This chapter discusses the causes of and emergency care for problems associated with the female reproductive system and the treatment of victims of sexual assault.

ORGANS OF THE FEMALE REPRODUCTIVE SYSTEM

The female reproductive organs include the ovaries, fallopian (uterine) tubes, uterus, vagina, external genital organs, and mammary glands (Figure 31-1; also see Chapter 10). The following is a brief review of these structures.

(Courtesy Ray Kemp, St. Charles, Mo.)

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 202-205.

The **ovaries** are small, oval-shaped glands on either side of the uterus. Each ovary consists of a dense outer portion *(cortex)* and a less dense inner portion *(medulla)*. The ovaries produce eggs (ova) and hormones, especially estrogen and progesterone. The **fallopian tubes** are the uterine ducts for the ovaries. An ovum that is fertilized in the fallopian tube normally implants in the lining of the uterus *(endometrium)*. This signals the beginning of pregnancy.

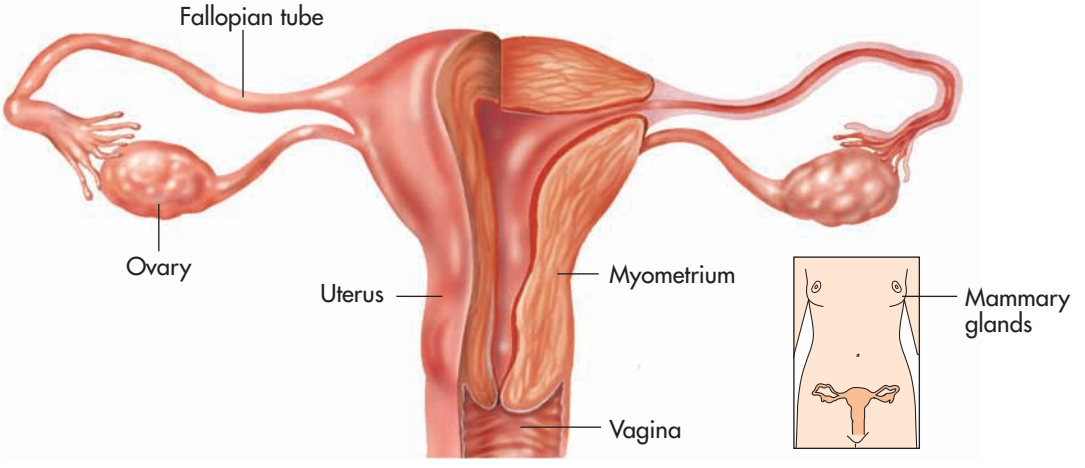

FIGURE 31-1 Female organs.

The **uterus** (womb) is a muscular organ the size and shape of a medium-sized pear. The main function of the uterus is to accept and nourish a fertilized ovum. A fertilized ovum that is not implanted in the uterus is shed from the body through menstruation.

The **vagina** (birth canal) is the female organ of copulation. It is a canal that joins the *cervix* (the lower portion of the uterus) to the outside of the body. It receives the penis during intercourse.

The **external genital organs** *(vulva)* are the outer parts of the female genitalia. They also protect the internal organs from infectious disease. The external genital organs consist of the *labia majora,* the *labia minora, Bartholin's glands.* and the *clitoris.*

The **mammary glands** are the organs of milk production. They are located in the breasts *(mammae).* Under the influence of hormones, the glands secrete milk during nursing.

MENSTRUATION AND OVULATION

Menstruation

In women of reproductive age, the body prepares for a possible pregnancy about once a month. If pregnancy does not occur (i.e., a fertilized ovum does not implant in the uterine wall), menstruation follows. **Menstruation** is the normal, periodic discharge of blood, mucus, and cellular debris from the uterine mucosa. The normal menstrual cycle lasts about 28 days. It occurs at more or less regular intervals from puberty to menopause (except during pregnancy and lactation). The average menstrual flow is 25 to 60 mL. The flow usually lasts 4 to 6 days and is fairly constant from cycle to cycle. The onset of menses **(menarche)** generally begins between ages 12 and 13. Menstruation ends permanently **(menopause)** at an average age of 47 years. However, the normal age for menopause can range from 35 to 60 (Box 31-1). Menstruation occurs in three phases: the follicular phase, the ovulatory phase, and the luteal phase.

NOTE

All phases of the menstrual cycle are affected by the release of hormones. These hormones include follicle-stimulating hormone (FSH), luteinizing hormone (LH), estrogen, and progesterone.

FOLLICULAR PHASE

The follicular phase begins on the first day of the menstrual cycle. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are released from the brain and make contact with the ovaries. This stimulates each ovary to produce about 15 to 20 oocytes (immature ova). Each oocyte is surrounded by a layer of cells (granulosa cells). The structure is known as a *primary follicle.* FSH and LH also cause an increase in the production of estrogen. The rise in estrogen levels stops the production of FSH, limiting the number of primary follicles that mature into *secondary follicles.* A mature secondary follicle continues to enlarge and produce estrogen. Eventually it forms a lump on the surface of the ovary. The fully mature follicle is known as the *vesicular* (or *graafian*) *follicle* (Figure 31-2).

OVULATORY PHASE

Cellular secretions of the graafian follicle cause it to swell more rapidly than can be accommodated by follicular growth. The rise in estrogen during this phase triggers the release of LH. This causes the follicle to expand and rupture and forces a small amount of blood and follicular fluid out of the vesicle. Shortly after this initial burst of fluid, an oocyte escapes from the follicle. The release of this secondary oocyte is called **ovulation.** Ovulation starts about 14 days after the follicular phase. It is the midpoint in the menstrual cycle. The egg is captured in the fallopian tube, where it may or may not be fertilized.

LUTEAL PHASE

After ovulation the empty follicle is transformed into a yellow glandular structure called the *corpus luteum*. The cells of this structure secrete large amounts of progesterone and some estrogen. If pregnancy occurs, the fertilized

BOX 31-1 Hysterectomy

A **hysterectomy** is the surgical removal of the uterus. Hysterectomy is one of the most frequently performed surgeries in the United States. It most often is performed to treat fibroid tumors that have caused symptoms and cancer of the uterus or cervix. Other indications for the surgery include heavy menstrual bleeding, endometriosis, pelvic inflammatory disease, and the removal of a prolapsed uterus. Depending on the type of hysterectomy, the surgery may be performed through the abdomen or vagina or laparoscopically.

In a *subtotal hysterectomy,* only the upper part of the uterus is removed; the cervix is not. (The fallopian tubes and ovaries may or may not be removed.) In a *total hysterectomy* (also called a *complete hysterectomy*), the body of the uterus, the cervix, the fallopian tubes, and the ovaries are removed. If cancer is present or in an advanced stage, a *radical hysterectomy* may be required in which the pelvic lymph nodes and lymph channels also are removed. After a hysterectomy, a woman is unable to bear children, does not menstruate, and needs no contraception.

Serious complications can occur from the surgery. These include blood clots, infection, adhesions, postoperative hemorrhage, bowel obstruction, or injury to the urinary tract. In addition to the direct surgical risks, long-term physical and psychological effects are possible. Examples of these include depression and loss of sexual pleasure. If the ovaries are removed along with the uterus before menopause, the risk of osteoporosis and heart disease may be increased.

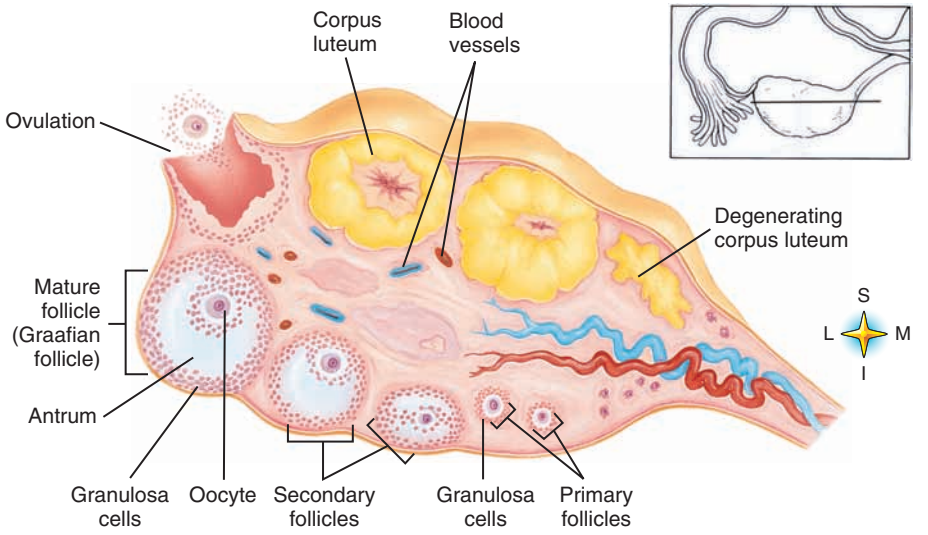

FIGURE 31-2 Diagram of the ovary and oogenesis. A cross section of the mammalian ovary shows successive stages of the ovarian (graafian) follicle and ovum development. The process begins with the first stage, the primary follicle, and (following clockwise) proceeds to the final stage, degeneration of the corpus luteum. (Thibodeau GA, Patton KT: *Structure and function of the body,* ed 13, St Louis, 2008, Mosby.)

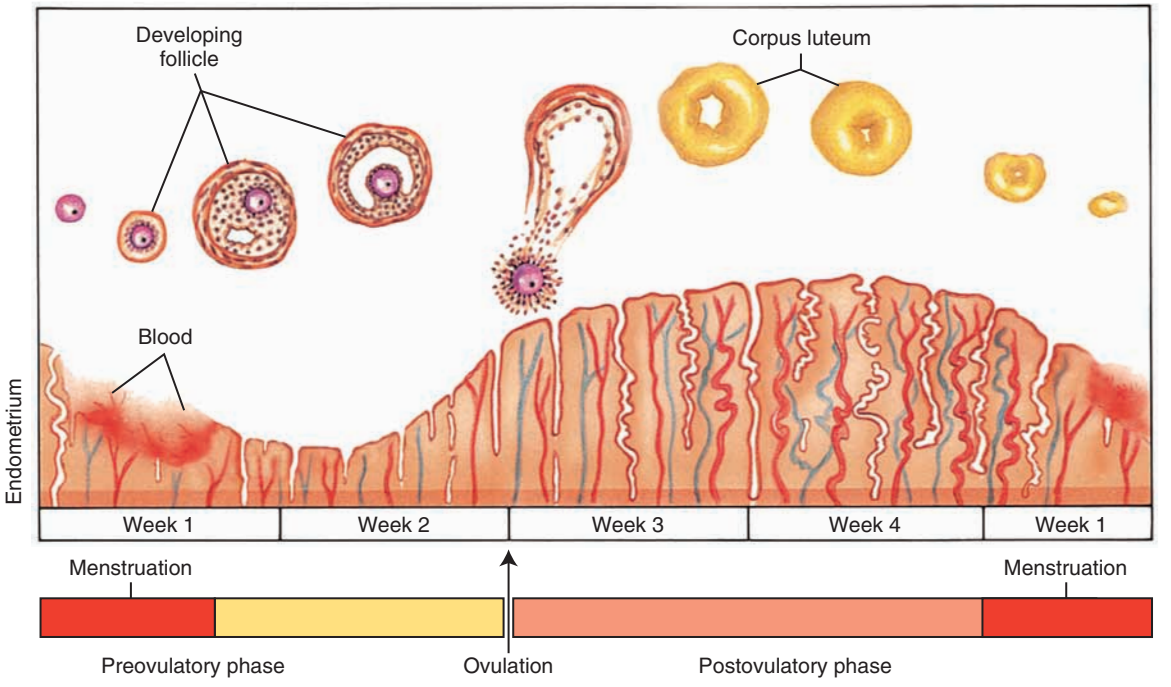

FIGURE 31-3 The female reproductive cycle. (Solomon EP: *Introduction to human anatomy and physiology,* ed 3, St Louis, 2009, Saunders.)

oocyte **(zygote)** travels through the fallopian tube to implant in the uterus. Chorionic gonadotropin is released to prevent the corpus luteum from degenerating. As a result, blood levels of estrogen and progesterone do not decrease and the menstrual period does not occur. If pregnancy does not occur, the corpus luteum degenerates and no longer produces progesterone; the estrogen level decreases, and the top layers of the lining are shed with the menstrual flow.

Hormonal Control of Ovulation and Menses

As described previously, hormones released from the hypothalamus and anterior pituitary control ovulation and menses. Under the influence of the ovarian hormones, the lining of the uterus **(endometrium)** goes through two phases of development: the proliferative phase and the secretory phase (Figure 31-3).

CRITICAL THINKING
What might happen to a woman's menstrual cycle if her hormonal balance were off?

The proliferative phase starts with and is sustained by increasing amounts of estrogen. This estrogen is produced by the maturing follicle. Estrogen stimulates the endometrium to grow and increase in thickness. This prepares the uterus for implantation of a fertilized ovum. The secretory phase begins after ovulation. This phase is under the combined influence of estrogen and progesterone. During this phase, the endometrium is prepared for implantation of the fertilized ovum. Within 7 days after ovulation (about day 21 of the menstrual cycle), the endometrium is ready to receive the developing embryo if fertilization has occurred.

If fertilization does not occur, the ovum can survive only 6 to 24 hours. After this time, the hormone levels drop and the endometrium is shed as menstrual flow. This process usually takes place on day 28 of the cycle. (This is about 14 days after ovulation.) The oocyte can be fertilized for up to 24 hours after ovulation (see Chapter 46).

GYNECOLOGICAL EMERGENCIES

Gynecological emergencies to be discussed in this chapter are medical conditions (Box 31-2) and sexual assault. (Other traumatic injuries are addressed in Chapter 43; genitourinary causes of abdominal pain are described in Chapter 30; and obstetrical emergencies are presented in Chapter 46.)

Acute or chronic infection involving a patient's uterus, ovaries, fallopian tubes, and adjacent structures may be a source of severe abdominal pain. Abdominal pain associated with the female reproductive system can cover a wide range. The pain may mark simply minor episodes of difficult menstruation, or it may indicate potentially life-threatening hemorrhage from a ruptured ovarian cyst or ectopic pregnancy. Regardless of the type of emergency, pregnancy should always be considered in any woman of childbearing age until a physician determines otherwise.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is a general term for infection of the cervix, uterus, fallopian tubes, and ovaries and their supporting structures (Figure 31-4). PID affects about 1 million women annually and is responsible for more than 250,000 hospitalizations each year.[1] Pelvic

BOX 31-2 Gynecological Emergencies

- Gynecological disorders
  - Cystitis
  - Ectopic pregnancy
  - Endometriosis
  - Endometritis
  - Mittelschmerz
  - Pelvic inflammatory disease
  - Ruptured ovarian cyst
  - Vaginal bleeding
  - Bartholin's abscess
  - Vaginitis
  - Ovarian torsion
  - Dysfunctional uterine bleeding
  - Uterine prolapse
  - Vaginal foreign body
- Sexual assault

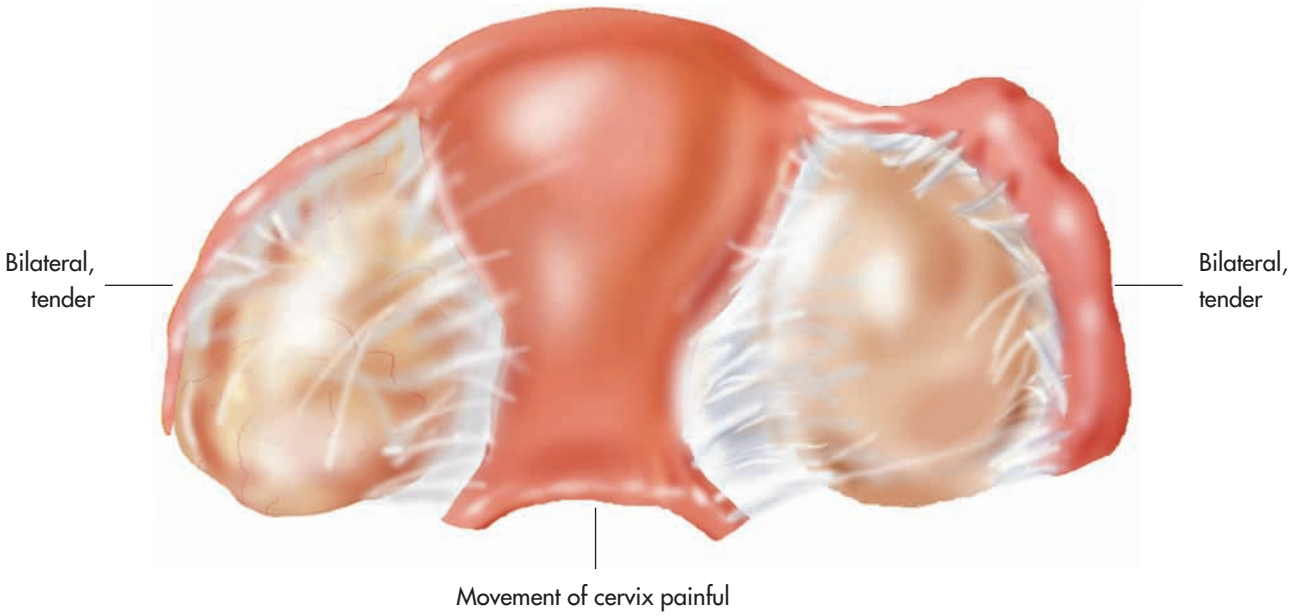

FIGURE 31-4 Symptoms of pelvic inflammatory disease.

inflammatory disease usually is caused by sexually transmitted bacteria, most commonly *Neisseria gonorrhoeae* (gonorrhea) and *Chlamydia trachomatis* (chlamydia). Staphylococci, streptococci, and other pathogens also may cause infection. However, these organisms usually are transmitted by instruments used during medical procedures.

Pathogens ascending from the vaginal area may infect the cervix initially (cervicitis). This may be followed by infection of the uterus proper (endometritis) and the fallopian tubes (salpingitis). Finally, the supporting structures around the uterus and fallopian tubes (parametritis) may become infected. Because the infection is polymicrobial, it can produce diffuse lower abdominal pain associated with low-grade fever (variable), vaginal discharge, and dyspareunia (pain with sexual intercourse). The inflammation often follows the onset of menstrual bleeding by 7 to 10 days. At that time, the reproductive organs are vulnerable to bacterial infection because the lining of the uterus has been shed during menstruation.

PID often is accompanied by pain on ambulation; the patient bends forward and takes short, slow steps, often guarding the abdomen ("PID shuffle"). Consequences of PID include secondary infertility, ectopic pregnancies, and tubo-ovarian abscesses. In severe cases the reproductive organs may need to be removed surgically. Definitive treatment usually consists of antibiotic therapy, which helps control the infection and prevent damage to the fallopian tubes.

Prehospital care is primarily supportive for all infections that affect the female reproductive system. In most cases, evaluation and care by a physician are required.

Bartholin's Abscess

Bartholin's abscess is an accumulation of pus that forms a lump (swelling) in one of the Bartholin glands. It occurs when blockage of the duct of the gland allows an infection to develop. The abscess can take years to form, or it may arise quickly, over several days. Signs and symptoms include swelling and inflammation of the gland and a visible lump on one side of the vaginal opening. Fever also may be present. Any activity that puts pressure on the vulva (including walking, sitting, and sexual intercourse) can cause severe pain and discomfort.

After examination by a physician, treatment may include a biopsy to rule out malignancy; surgical incision to drain the infected gland; and oral antibiotic therapy. About 10% of infections recur. Surgery sometimes is required for recurrent infections.

Vaginitis

Vaginitis *(vulvovaginitis)* is inflammation and infection of the vulva and vagina. It can occur in young girls and women of all ages but is most common in postmenopausal and postpartum women. It is a very common disease that affects millions of women each year. Most cases of vaginitis result from *Candida* (yeast) infections, bacterial infections *(bacterial vaginosis),* and the sexually transmitted disease *trichomoniasis* (see Chapter 28). Vaginitis also can be caused by parasites, viruses, and poor personal hygiene. Regardless of the cause of the infection, patients with vaginitis often complain of irritation and itching of the genital area, in addition to the following:

- Inflammation (redness and swelling) of the labia majora, labia minora, or perineal area
- Vaginal discharge
- Foul vaginal odor
- Discomfort or burning with urination

NOTE

Noninfectious vaginitis usually is caused by an allergic reaction (e.g., to detergents, soaps) or irritation from vaginal sprays, douches, and spermicidal products. This form of vaginitis can cause the same signs and symptoms as the infectious form.

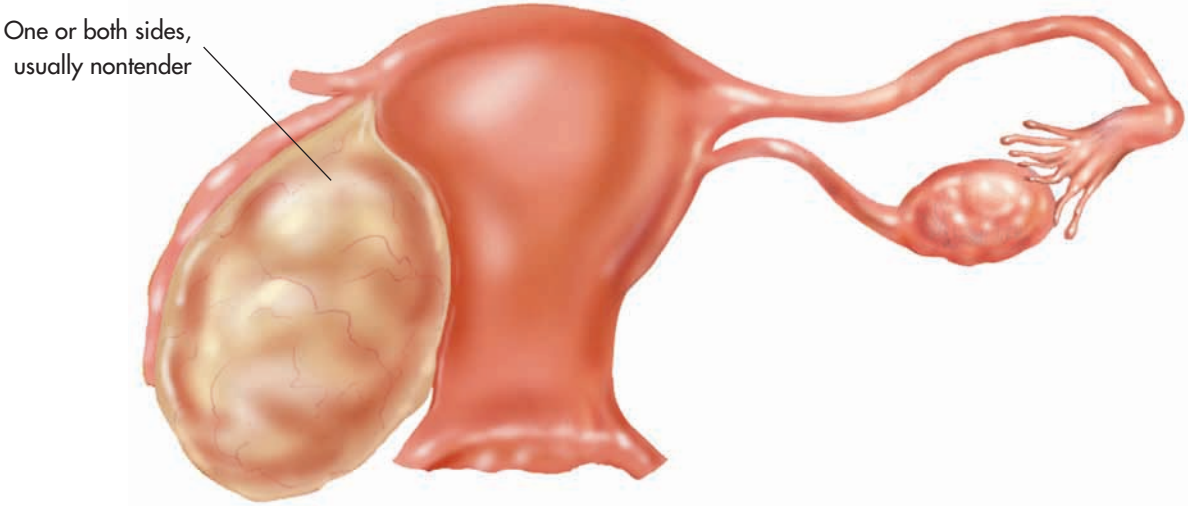

FIGURE 31-5 Ovarian cyst.

Depending on the cause of the infection, treatment for vaginitis may include antiyeast or antifungal creams, vaginal suppositories, and antibiotics. Most patients are advised not to engage in sexual activity until the infection has resolved. Vaginitis can be spread to sexual partners, who also may require treatment.

Ruptured Ovarian Cyst

A **ruptured ovarian cyst** can be a gynecological emergency that may result in significant internal hemorrhage. An ovarian cyst is a thin-walled, fluid-filled sac on the surface of the ovary (Figure 31-5). The abdominal pain caused by an ovarian cyst may result from rapid expansion, torsion that produces ischemia (described later), or acute rupture. The type of cyst most prone to rupture is the *corpus luteum cyst.* This cyst forms as a result of hemorrhage in a mature corpus luteum. The corpus luteum develops after ovulation (day 14 of the 28-day cycle). Therefore, most ruptures occur about 1 week before menstrual bleeding is to begin. However, some patients with a ruptured ovarian cyst have vaginal bleeding or report a late or missed period at the time of rupture.

CRITICAL THINKING

Consider a patient you suspect has a ruptured ovarian cyst. How would you assess for the possibility of bleeding?

A ruptured ovarian cyst can result in localized, one-sided lower abdominal pain. A ruptured cyst also can result in generalized signs of peritonitis if massive hemorrhage has occurred. The onset of pain often is associated with minimal abdominal trauma, sexual intercourse, or exercise.

Ovarian Torsion

Ovarian torsion is the twisting of the ovary. Numerous conditions can cause such torsion, including congenital abnormalities, ovarian cysts or tumors, disease that affects the fallopian tube or ovary, adhesions from previous pelvic surgeries, trauma, and others. As a rule, torsion affects only one ovary and commonly the oviduct (adnexal torsion). Ovarian torsion is the fifth most common gynecological surgical emergency. About 70% of cases occur in women under 30 years of age. About 20% of reported cases involve pregnant women.[2]

Signs and symptoms of ovarian torsion include a sudden onset of lower abdominal pain (usually on the right side) that may radiate to the back, pelvis, or thigh. The pain often begins with exercise. The patient usually describes the pain as sharp or stabbing. Often the patient complains of nausea and vomiting. Fever may be present but is usually a late sign. Care by a physician may include pain management and fluid replacement. Surgery may be indicated to manage vascular compromise, peritonitis, or necrosis.

Cystitis

Cystitis is inflammation of the inner lining of the bladder. It usually is caused by a bacterial infection. Both males and females can develop infection. However, cystitis is more common in women, because the urethra is shorter. The main symptom of cystitis is a frequent urge to pass urine, with only a small amount of urine passed each time. Other signs and symptoms may include painful (burning) urination, fever, chills, and lower abdominal pain. The urine occasionally may be foul smelling or contain blood. Cystitis also can occur as a result of a structural abnormality of the ureters (this is common in children) or compression of the urethra as a result of inflammation. Indwelling urinary catheters are another cause. Prompt treatment of cystitis with a complete course of antibiotics usually settles the infection within 24 hours.

Dysmenorrhea and Mittelschmerz

Dysmenorrhea is pain during menstruation. The condition may include headache, faintness, dizziness, nausea, diarrhea, backache, and leg pain. In severe cases, chills, headache, diarrhea, nausea, vomiting, and syncope can occur. Dysmenorrhea occurs more often in women who are not sexually active and women who have not borne children. The lower abdominal pains associated with dysmenorrhea are thought to be related to muscular contraction of the myometrium (the muscular layer of the uterus). These muscle contractions are mediated by local prostaglandins. Other factors associated with dysmenorrhea include infection, inflammation, and the presence of an intrauterine contraceptive device.

Mittelschmerz is German for "middle pain." This pain may occur from the rupture of the graafian follicle and bleeding from the ovary during the menstrual cycle. Mittelschmerz is characterized by pain in the right or left lower quadrant of the abdomen. The pain occurs in the normal midcycle of a menstrual period (after ovulation) and lasts about 24 to 36 hours. The hormones produced by the ovary also may produce slight endometrial bleeding and low-grade fever. Dysmenorrhea and mittelschmerz do not pose a threat to life. However, evaluation by a physician is required to rule out more serious causes of menstrual pain. Evaluation also is required to differentiate the pain from that of appendicitis and other surgical emergencies.

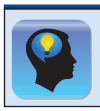
Endometritis

Endometritis is inflammation of the uterine lining. It usually results from infection. Often it occurs after childbirth or abortion and usually is caused by retained placental tissue. (The condition also is a feature of PID and other sexually transmitted infections.) Endometritis may affect the uterus and fallopian tubes. If left untreated, endometritis may result in sterility, sepsis, and death. Signs and symptoms of endometritis include fever, purulent vaginal discharge, and lower abdominal pain. Treatment includes removal of any foreign tissue and antibiotic therapy.

Endometriosis

Endometriosis is an abnormal gynecological condition characterized by the growth of endometrial tissue outside the uterus. This may occur because fragments of endometrium have been regurgitated backward (during menstruation) through the fallopian tubes into the peritoneal cavity, where the fragments attach and grow as small cystic structures. The endometrial tissue of endometriosis functions cyclically and undergoes periodic menstrual breakdown. This can result in bleeding within cysts, stretching of the cyst wall, and pain.

Endometriosis is more common in women who defer pregnancy. The average age of women found to have endometriosis is 37 years. Characteristic symptoms of endometriosis are pain (particularly dysmenorrhea), painful defecation, and suprapubic soreness. Other common symptoms include vaginal spotting of blood before the start of a period and infertility. After evaluation by a physician, treatment may consist of drug therapy with analgesics or hormones and, in some cases, surgery.



CRITICAL THINKING

Why do you think these patients with endometriosis tend to be infertile?

Ectopic Pregnancy

An **ectopic pregnancy** is a pregnancy that develops outside the uterus (Figure 31-6). It is the third leading cause of maternal death and accounts for 6% of maternal mortality.[3] The pregnancy most commonly develops in the fallopian tube or ovary. In rare cases, it develops in the abdominal cavity or cervix. An ectopic pregnancy can be a life-threatening emergency. Most ectopic pregnancies are discovered in the first 2 months, often before the woman realizes she is pregnant. Signs and symptoms include severe abdominal pain that may radiate to the neck or shoulder (and which worsens on inspiration) and vaginal spotting. If rupture occurs, internal hemorrhage, sepsis, and shock may develop.[4] Once an ectopic pregnancy has been confirmed, surgery is performed to remove the developing fetus, placenta, and any damaged tissue at the site of the pregnancy. Ectopic pregnancy is common; it occurs in 2% of all pregnancies.[3] Ectopic pregnancy should be considered in any female of reproductive age who has abdominal pain. (Ectopic pregnancy is described further in Chapter 46.)

Vaginal Bleeding

Vaginal bleeding is the loss of blood from the uterus, cervix, or vagina. The most common source of nontraumatic vaginal bleeding is menstruation. (This bleeding

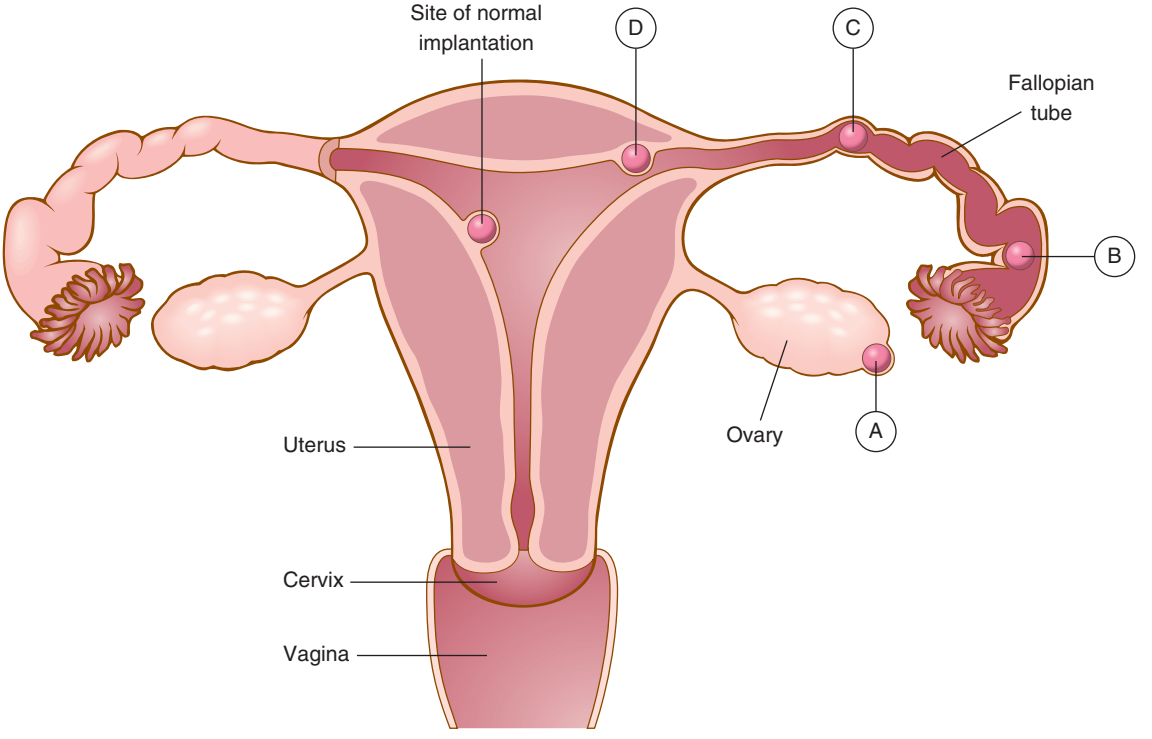


FIGURE 31-6 Ectopic pregnancy. *A, B, C,* and *D* are ectopic sites. The fallopian tube is the most common site for ectopic pregnancies (95%), but they also can occur on the ovary or on the surface of the peritoneum. Normal implantation takes place on the inner lining (endometrium) of the uterus. (Chabner DE: *Medical terminology: a short course,* ed 5, St Louis, 2009, Saunders.)

rarely results in a request for emergency care.) Possible causes of serious nonmenstrual bleeding include the following:

- Spontaneous abortion
- Disorders of the placenta
- Hormonal imbalances (especially menopause)
- Lesions
- PID
- Onset of labor

The paramedic should never assume that vaginal hemorrhage is due to *normal* menstruation. Some causes of vaginal bleeding may be life threatening and can lead to hypovolemic shock and death. (Vaginal passage of clots usually indicates bleeding at a rate greater than menstrual flow.)

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding (DUB) is abnormal bleeding that occurs because of changes in hormone levels. The most common cause of the bleeding is failure of an ovary to release an oocyte *(anovulation);* consequently, ovulation does not take place. This results in continuous, unopposed production of estradiol, which stimulates overgrowth of the endometrium. Without progesterone, the endometrium proliferates and eventually outgrows its blood supply, leading to necrosis. The end result is overproduction of uterine blood flow. With symptoms of DUB, a patient may notice changes in her menstrual cycle, such as the following[5]:

- Vaginal bleeding or spotting that occurs between periods
- Menstrual periods less than 28 days or longer than 35 days apart
- Timing of menstrual periods that changes with each cycle
- Heavier than normal bleeding (passing large clots; changing protection during the night; soaking through a sanitary pad or tampon every hour for 2 to 3 hours in a row)
- Bleeding that lasts for more days than normal or for more than 7 days
- Tenderness and dryness of the vagina

DUB is most common at the extreme ages of a woman's reproductive years, either at the beginning or near the end, but it may occur at any time during reproductive life. Care by a physician may include a pregnancy test, IV hormone therapy, methods to tamponade the bleeding, and sometimes surgery.

Uterine Prolapse

Uterine prolapse is the falling or sliding of the uterus from its normal position in the pelvic cavity into the vaginal canal. As described in Chapter 10, the main portion of the uterus (the body) is positioned between the fundus and the cervix. The uterus is held in place by connective tissue, muscles, and the broad ligament, round ligaments, and uterosacral ligaments. If these muscles and ligaments stretch and weaken, the uterus has inadequate support and descends into the vaginal cavity (Figure 31-7). Factors that may cause uterine prolapse include the following:

- Trauma during vaginal childbirth
- Large babies and difficult vaginal delivery
- Loss of muscle tone associated with aging
- Menopause and reduced amounts of circulating estrogen
- Pelvic cavity tumors

Obesity, chronic constipation, and chronic obstructive pulmonary disease (COPD) can put a strain on the muscles and connective tissue in the pelvis. These conditions may also play a role in the development of uterine prolapse.

If the uterine prolapse is mild and the patient is asymptomatic, treatment may not be necessary. In these cases, patients often are advised to make lifestyle changes to slow progression of the prolapse. These may include losing weight, stopping smoking, and preventing coughing. Heavy lifting and straining also should be avoided. Signs and symptoms of a more severe prolapse include patient

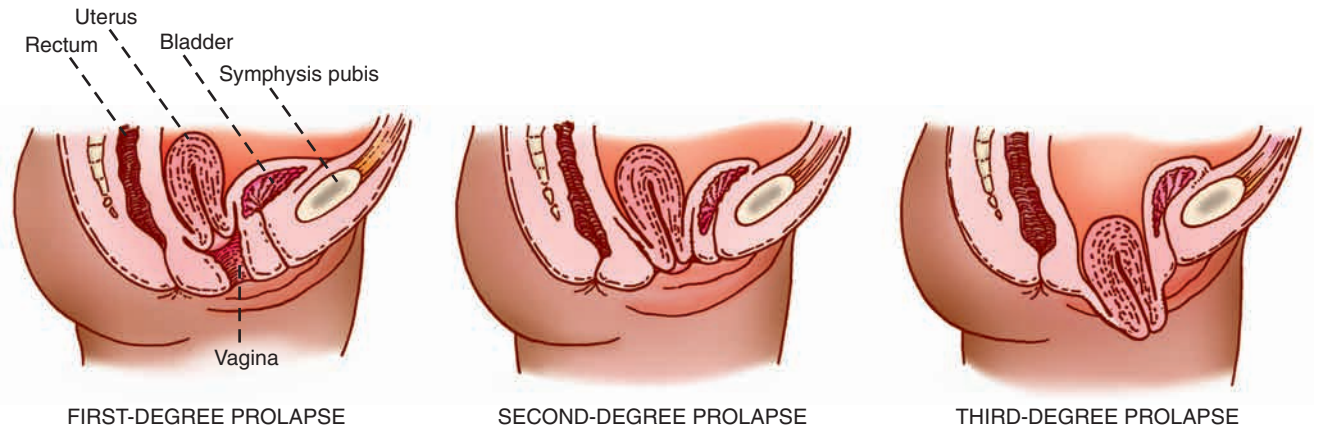

FIGURE 31-7 Degrees of uterine prolapse. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes,* ed 8 Philadelphia, 2009, Saunders, p. 930.)

TABLE 31-1 Characteristics of Abdominal Pain in Gynecological Emergencies

Onset	Location	Quality	Radiation	Vaginal Discharge	Menstrual History
Ruptured Ectopic Pregnancy					
Rapid (can become generalized)	Unilateral (can become generalized)	Cramplike, then steady	Shoulder (may indicate intraperitoneal bleeding)	Vaginal bleeding (75% of cases)	Amenorrhea, 6 weeks or more since last period
Ruptured Ovarian Cyst					
Sudden	Unilateral (can become generalized)	Steady	Shoulder (may indicate intraperitoneal bleeding)	Possible vaginal bleeding	Usually 1 week before period
Pelvic Inflammatory Disease					
Gradual (can become generalized)	Diffuse, bilateral	Steady ache	Right upper quadrant	Watery, foul-smelling discharge	Usually within 1 week after period

complaints of feeling like she is "sitting on a small ball," heaviness in the vaginal area, low back pain, difficult or painful intercourse, and vaginal bleeding. In these cases, placement of a *vaginal pessary* (a device similar to a diaphragm) or surgery may be needed to hold the uterus in place.

Vaginal Foreign Body

It is not uncommon to find a foreign body inserted in the vagina. This is especially true of children, who may insert a foreign body during self-exploration and not tell their parents or caregivers. The foreign body can cause a foul-smelling, purulent discharge with or without vaginal bleeding. Vaginal foreign bodies also may be a result of a psychiatric disorder, unusual sexual practices, or an episode of abuse. Occasionally a tampon, broken portions of condoms, or a pessary is forgotten or lost and causes discomfort and a vaginal discharge. Less common symptoms may include pain or urinary discomfort. No attempt should be made in the prehospital setting to remove a foreign body in the vagina. The patient should be transported for evaluation by a physician.

ASSESSMENT AND MANAGEMENT OF GYNECOLOGICAL EMERGENCIES

Finding the cause of lower abdominal pain is difficult in both men and women. It can be especially challenging in women, because many gynecological conditions produce common characteristics. For example, a ruptured ectopic pregnancy, ruptured ovarian cyst, and PID can have identical presentations (Table 31-1). The goal of prehospital care is to quickly identify the conditions that require aggressive therapy and to rapidly transport the patient for definitive care. Prehospital care includes obtaining a history of the present illness (including a thorough gynecological history); providing airway, ventilatory, and circulatory support as needed; and transporting the patient for evaluation by a physician.

History of Present Illness and Obstetrical History

The paramedic should obtain a history of the present illness to better understand the patient's chief complaint (see Chapter 18). Important associated symptoms include fever, diaphoresis, syncope, diarrhea, constipation, and abdominal cramping. The interview should include a thorough obstetrical history. The obstetrical history includes the following 10 components.[6]

1. *Pregnancy.* The paramedic should determine the total number of pregnancies the patient has had and the number of pregnancies that were carried to term (see Chapter 46).
2. *Previous cesarean deliveries.* A **cesarean delivery** is a surgical procedure in which the abdomen and uterus are incised and the baby then is delivered through the abdomen. Cesarean delivery usually is done when maternal or fetal conditions might make vaginal delivery risky. A history of a previous cesarean delivery may indicate a high-risk pregnancy.
3. *Last menstrual period.* The paramedic should obtain information about the patient's last menstrual period. Questions to ask include the following:
   - When did it start (the date)? When did it end (the duration)? Have your menstrual periods occurred regularly?

- Was your last menstrual period normal for you? Was the menstrual flow heavier or lighter than other periods?
- Did any bleeding occur between periods?

4. *Possibility of pregnancy.* Some patients may hesitate to disclose a possible pregnancy. They may not answer a direct question honestly (e.g., "Could you be pregnant?"). If pregnancy is suspected (but not confirmed by the patient), the paramedic should ask specific questions about missed or late periods, breast tenderness, urinary frequency, morning sickness (nausea and/or vomiting), and unprotected sexual activity to determine the likelihood of a pregnancy.

CRITICAL THINKING

Does a patient always give you accurate information about whether she is pregnant? Why?

5. *History of previous gynecological problems.* The paramedic should identify any previous gynecological problems. Knowledge of these problems can be helpful to others who may be involved in the patient's care. Examples of important previous gynecological problems include infections, bleeding, painful intercourse **(dyspareunia),** miscarriage, abortion, **dilation and curettage (D & C),** and ectopic pregnancy.

NOTE

Dilation and curettage (D & C) is a gynecological procedure. It involves widening of the uterine cervix and scraping away of the endometrium of the uterus. The procedure is used for a variety of conditions. These include diagnosing disease of the uterus, correcting heavy or prolonged vaginal bleeding, and emptying the uterus of the products of conception after delivery or abortion.

6. *Present blood loss.* If the patient is actively bleeding, the paramedic should ask questions about the color (bright versus dark red blood), the amount of blood loss (estimated by the number of pads or tampons soaked per hour), and the duration of the bleeding episode.
7. *Vaginal discharge.* If the patient has a discharge, the paramedic should question her about the color, amount, and odor of the discharge. These findings may indicate the presence of infection, venereal disease, or other illness.
8. *Use and type of contraceptive.* The use and type of contraception is a key part of the obstetrical history. For example, the use of birth control pills has been associated with hypertension and pulmonary embolus. Also, intrauterine devices can cause intrauterine bleeding and infection. Other methods of contraception include the withdrawal or rhythm method (which may increase the likelihood of pregnancy), the use of spermicides and condoms, contraceptive systems (e.g., Norplant and Depo-Provera), and *surgical tubal ligation* (a permanent form of female sterilization in which the fallopian tubes are severed and sealed).
9. *History of trauma to the reproductive system.* The paramedic should question all patients about any injury to the reproductive tract. Such an injury may be responsible for vaginal bleeding or discharge. The paramedic should ask a sexually active patient whether pain or bleeding has occurred during or after intercourse.
10. *Degree of emotional distress.* The paramedic should evaluate the patient's emotional distress. Factors that may be responsible for a patient's emotional distress include personal health issues, depression, an unwanted pregnancy, and financial worries.

PHYSICAL EXAMINATION

The physical examination should be conducted in a comforting, professional manner with consideration shown for the patient's modesty, privacy, and discomfort. When evaluating the potential for serious blood loss, the paramedic should assess the patient's skin and mucous membranes for color, cyanosis, or pallor. Assessment of vital signs should include orthostatic measurements. If indicated, the vaginal area should be inspected for bleeding or discharge, and the color, amount, and presence of clots or tissue (or both) should be noted. The patient's abdomen should be palpated to assess for masses, areas of tenderness, guarding, distention, and rebound tenderness.

PATIENT MANAGEMENT

Management includes support of the patient's vital functions and administration of high-concentration oxygen during transport. Intravenous access usually is not needed unless the patient is showing signs of impending shock or has excessive vaginal bleeding. Many patients prefer to be transported in a left lateral recumbent, knee-chest position. Others may prefer a hips raised, knees bent position for comfort. Vaginal bleeding should be controlled with the application of sanitary pads or trauma dressings. The vagina should never be packed with dressings or tampons. The paramedic should count the number of soaked pads and should record the number on the patient care report.

During transport, the paramedic should monitor the patient for the onset of serious bleeding. If this occurs, or if the patient's condition begins to deteriorate, the

paramedic should establish one or two large-bore intravenous lines with normal saline or lactated Ringer solution. At this point, electrocardiographic (ECG) and pulse oximetry monitoring are indicated. Analgesics should be considered.

SEXUAL ASSAULT

Sexual assault is a crime of violence with serious physical and psychological implications. Anyone of either gender at any age can be sexually assaulted (see Chapter 50). However, women and girls are most often the victims. Estimates indicate that one in six women will experience a completed or attempted rape during their lifetimes and that many of these crimes will go unreported.[7]

Often the paramedic is first to encounter these patients. Tact, kindness, and sensitivity during the patient care episode are essential.

CRITICAL THINKING

How do you feel about rape? How would you manage a patient who has been raped?

DID YOU KNOW?

Rape and Date Rape

Rape occurs when sex is nonconsensual (not agreed upon) or when a person forces or attempts to force another person to have sex against his or her will. Rape includes intercourse in the vagina, anus, or mouth. It is a felony offense that can happen to men, women, and children. Rape can cause physical or emotional harm, or both, to the victim.

Date rape is nonconsensual sex between people who are already acquainted (e.g., friends, acquaintances, people who are dating). The difference between rape and date rape is that in cases of date rape, the victim agreed to spend time with the attacker. Date rape often occurs in the context of domestic violence. It sometimes involves the use of illegal "date rape drugs" that produce amnesia and anesthesia in the victim. These drugs include ketamine, gamma hydroxybutyrate (GHB), and flunitrazepam (Rohypnol). Date rape is still rape. It is a felony offense. A nationally representative survey found that[8]:

- In the first rape experience of female victims, perpetrators were reported to be intimate partners (30.4%), family members (23.7%), and acquaintances (20%).
- In the first rape experience of male victims, perpetrators were reported to be acquaintances (32.3%), family members (17.7%), friends (17.6%), and intimate partners (15.9%).

Initially, paramedics should care for a victim of sexual assault as they would any other injured patient. The first priority is to manage any injury that poses a threat to life. After that, however, the approach should be modified with regard to history taking and the physical examination. Before taking a history or performing an examination, the paramedic should move the patient to a private area. If possible, the patient should be interviewed and examined by a paramedic of the same gender.

SHOW ME THE EVIDENCE

Feldhaus and colleagues interviewed women who reported to the emergency department of an urban level I trauma center for any cause during random periods in 1997. These women were not critically ill. The patients were asked if they had ever been sexually assaulted at any time in their lives. During that time, 360 patients who were eligible for the researchers' study consented to be enrolled in it. Of that group 39% said they had been sexually assaulted at some point in their life, and an additional 12% reported an attempted sexual assault. When the sexual assault occurred during adulthood, 70% of the time the victim knew the perpetrator. Another 8% of the assaults involved multiple attackers. A weapon was used or threatened to be used during the assault 40% of the time. Of this adult assault group, only 45% reported the assault to the police. A report was more likely to be filed if the woman did not know her attacker. Those who were assaulted sought medical aid less than half the time. This study revealed a high lifetime incidence of sexual assault in this group of women.

Feldhaus KM, Houry D, Kaminsky R: Lifetime sexual assault prevalence rates and reporting practices in an emergency department population, *Ann Emerg Med* 36:23-27, 2000.

History Taking

As a rule, victims of sexual assault should not be questioned in detail about the incident in the prehospital setting. The history should be limited to the elements needed to provide emergency care. For example, questions about penetration, sexual history, or sexual practices are irrelevant to prehospital care. They only add to the patient's emotional stress. The patient should be allowed to speak openly, and all information should be recorded accurately and thoroughly. Common reactions to sexual assault include anxiety, withdrawal and silence, denial, anger, and fear.

Assessment

The physical examination should identify any physical trauma, including trauma outside the pelvic area, that needs immediate attention. Facial fractures, human bites of the hands and breasts, long-bone fractures, broken ribs, and trauma to the abdomen are not unusual. The paramedic should examine the genitalia only if a severe injury is present or suspected. When possible, the paramedic should explain all procedures before initiating them. All examination findings should be documented, including the patient's emotional state, the condition of the patient's clothing, obvious injuries, and any patient care provided. A professional attitude is important. Feelings and prejudices

about the victim or the assault should not affect the delivery of care.

Management

After the management of life-threatening injuries, emotional support is the most important patient care procedure paramedics can offer a victim of sexual assault. The paramedic should provide a safe environment for the patient and should respond appropriately to the victim's physical and emotional needs. Paramedics also should be aware of the need to preserve evidence from the crime scene (further described in Chapter 56). Special considerations include the following:

- Handle clothing as little as possible.
- Do not clean wounds unless absolutely necessary.
- Do not allow the patient to drink or brush the teeth.
- Do not use plastic bags for blood-stained articles.
- Bag each clothing item separately.
- Ask the victim not to change clothes or bathe.
- Disturb the crime scene as little as possible.

SUMMARY

- Menstruation is the normal, periodic discharge of blood, mucus, and cellular debris from the uterine mucosa. Ovulation is the release of a secondary oocyte from the ovary.
- Pelvic inflammatory disease results from infection of the cervix, uterus, fallopian tubes, and ovaries and their supporting structures.
- Bartholin's abscess is a buildup of puss in one of Bartholin's glands.
- Vaginitis is inflammation and infection of the vulva and vagina.
- A ruptured ovarian cyst occurs when a thin-walled, fluid-filled sac on the ovary ruptures. This can cause internal hemorrhage.
- Ovarian torsion is twisting of the ovary caused by another condition or disease.
- Cystitis is inflammation of the inner lining of the bladder. It usually is caused by a bacterial infection.
- Dysmenorrhea is characterized by painful menses. It may be associated with headache, faintness, dizziness, nausea, diarrhea, backache, and leg pain.
- Mittelschmerz is German for "middle pain." This pain may occur from the rupture of the graafian follicle and bleeding from the ovary during the menstrual cycle.
- Endometritis is inflammation of the uterine lining. Endometriosis is characterized by endometrial tissue growing outside the uterus.
- An ectopic pregnancy is a pregnancy that develops outside the uterus. Rupture of an ectopic pregnancy can cause life-threatening hemorrhage.
- Vaginal bleeding is the loss of blood from the uterus, cervix, or vagina.
- Uterine prolapse occurs when the uterus descends into the vagina.
- Vaginal foreign bodies can cause vaginal discharge, pain, and urinary discomfort.
- The history obtained from a patient with a gynecological emergency should include the pregnancy history; history of cesarean births; last menstrual period; possibility of pregnancy; history of previous gynecological problems; blood loss; vaginal discharge; contraceptives used; history of trauma to the reproductive system; and degree of emotional distress.
- The goal of prehospital care of lower abdominal pain in the female is to obtain a history (including a gynecological history); provide airway, ventilatory, and circulatory support as needed; and provide transport for evaluation by a physician.
- Sexual assault is a crime of violence. It can have serious physical and psychological effects.
- Paramedics should be aware of the need to preserve evidence from a sexual assault crime scene.

CHAPTER

32 Hematology

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Describe the physiology of blood and its components.
2. Discuss pathophysiology and signs and symptoms of specific hematological disorders.
3. Outline general assessment and management of patients with hematological disorders.

KEY TERMS

acute chest syndrome A new abnormal consolidation on a chest radiograph in a patient with sickle cell disease.

albumin A water-soluble protein containing carbon, hydrogen, oxygen, nitrogen, and sulfur.

anemia A decrease in blood hemoglobin level.

basophil A white blood cell that promotes inflammation.

bilirubin The orange-yellow pigment of bile, formed principally from the breakdown of hemoglobin in red blood cells after termination of their normal life span.

blood clot The end result of the clotting process in blood; a blood clot normally consists of red cells, white cells, and platelets enmeshed in an insoluble fibrin network.

clotting cascade The blood clotting system or coagulation pathway.

clotting factors Substances in the blood that act in sequence to stop bleeding by forming a clot.

differential count A laboratory test that identifies the different types of leukocytes present in blood; also called the *diff.*

disseminated intravascular coagulopathy A grave coagulopathy that results from the overstimulation of the clotting and anticlotting processes in response to disease or injury.

eosinophil A white blood cell that inhibits inflammation; thought to deactivate leukotrienes.

fibrinogen A soluble blood protein converted into insoluble fibrin during clotting.

globulin One of a broad category of simple proteins classified by solubility, mobility, and size.

hematology The scientific study of blood and blood-forming organs.

hemoglobin A complex protein-iron compound in the blood that carries oxygen to the cells from the lungs and carbon dioxide away from the cells to the lungs.

hemolysis The breakdown of red blood cells and the release of hemoglobin.

hemolytic anemia A condition in which delivery of oxygen to tissues is reduced because of an increase in hemolysis of erythrocytes.

hemophilia A group of hereditary bleeding disorders in which one of the factors necessary for blood coagulation is deficient.

hemophilia A A condition caused by a deficiency of coagulation factor VIII; it is considered the classic type of hemophilia.

hemophilia B A condition caused by a deficiency of coagulation factor IX.

hemostasis The cessation of bleeding by mechanical or chemical means or by substances that arrest the blood flow.

Hodgkin's disease A malignant disorder characterized by pain and progressive enlargement of lymphoid tissue.

iron deficiency anemia Anemia caused by inadequate supplies of iron needed to synthesize hemoglobin.

leukemia A malignant neoplasm of blood-forming organs.

leukopenia A decrease in the number of white blood cells (most commonly neutrophils).

lymphocyte A type of white blood cell formed in lymphoid tissue.

lymphoma A group of diseases that range from slowly growing chronic disorders to rapidly evolving acute conditions.

macrophage A phagocytic cell in the immune system.
malignant Very dangerous or virulent; likely to cause death; a cancerous tumor that tends to metastasize.
monocyte A type of white blood cell found in lymph nodes, spleen, bone marrow, and loose connective tissue.
multiple myeloma A malignant neoplasm of the bone marrow.
neutrophil A small, phagocytic white blood cell with a lobed nucleus and small granules in the cytoplasm.
Non-Hodgkin's lymphoma Cancer of the lymphoid tissue, which includes the lymph nodes, spleen, and other organs of the immune system.
pernicious anemia Anemia that results from a vitamin B_{12} deficiency.
plasma The fluid portion of blood.
platelet A fragment of a cell; it contains granules in the central part and clear protoplasm peripherally but has no definite nucleus.
platelet plug A plug consisting of a mass of linked platelets that seals an injured vessel; part of the clotting cascade.
polycythemia A condition characterized by an unusually large number of red cells in the blood as a result of their increased production by the bone marrow.
primary polycythemia A rare disorder of the bone marrow where an increased production of red blood cells (RBCs) causes the blood to thicken; also known as *polycythemia vera*.
prothrombin A chemical that is part of the clotting cascade; the precursor of thrombin.
prothrombin activator A substance that combines with an enzyme to increase its catalytic activity; converts prothrombin to thrombin.
red bone marrow Specialized soft tissue found in many bones of infants and children, in the spongy bone of the proximal epiphyses of the humerus and femur, and in the sternum, ribs, and vertebral bodies of adults. It is essential in the manufacture of red blood cells; also known as *red marrow*.
secondary polycythemia A condition of increased production of RBCs caused by reduced air pressure and low oxygen concentration; may be a natural response to chronic hypoxia.
sickle cell anemia An inherited blood disorder that affects red blood cells; the most common type of sickle cell disease.
sickle cell crisis An acute episodic condition that occurs in individuals with sickle cell anemia.
sickle cell disease A debilitating and unpredictable recessive genetic illness that produces an abnormal type of hemoglobin with an inferior oxygen-carrying capacity.
thrombin An enzyme formed in plasma as part of the clotting process; it causes fibrinogen to change to fibrin, which is essential in the formation of a clot.
thrombocytopenia An abnormal hematological condition in which the number of platelets is reduced; the most common cause is a bleeding disorder.
yellow marrow Specialized soft tissue (mainly adipose) found in the compact bone of most adult epiphyses.

Hematology *is the study of blood and blood-forming organs. Dysfunction in the hematological system can affect other body systems. This can result in a variety of clinical manifestations that characterize hematological disorders. Prehospital care for most patients with hematological disorders is mainly supportive. However, the paramedic's knowledge of these diseases enhances assessment skills. It also provides an understanding of the treatment these patients need.*

BLOOD AND BLOOD COMPONENTS

As described in Chapter 10, blood is composed of cells and formed elements surrounded by plasma. About 95% of the volume of formed elements consists of red blood cells (RBCs; erythrocytes). The remaining 5% consists of white blood cells (WBCs; leukocytes) and cell fragments (platelets) (Figures 32-1 and Table 32-1). The continuous movement of blood keeps the formed elements dispersed throughout the plasma, where they are available to carry out their chief functions[1]: (1) delivery of substances needed for cellular metabolism in the tissues; (2) defense against invading microorganisms and injury; and (3) acid-base balance.

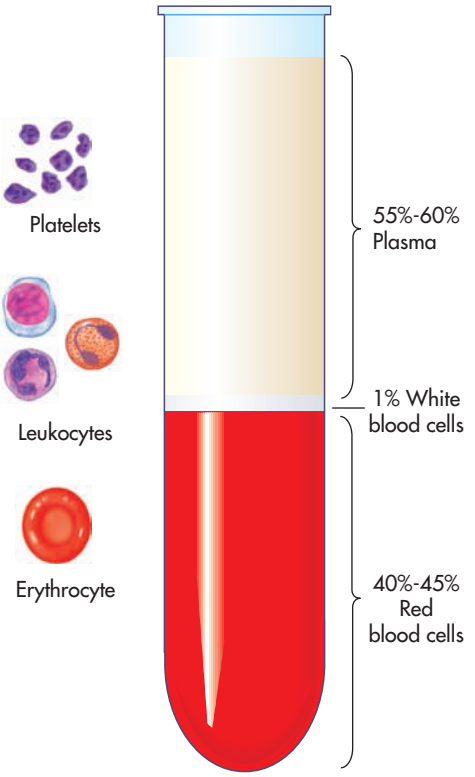

FIGURE 32-1 Blood will settle into three distinct, proportional layers when treated with salt. The transparent yellow layer at the top is plasma—the liquid portion of blood through which solid elements travel. White blood cells (WBCs) settle in the narrow white band in the center, and red blood cells (RBCs), which give blood its crimson color, fall to the bottom of the flask. Red blood cells outnumber white blood cells 600 to 1.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 178-182.

All types of blood cells are formed within the red bone marrow, which is present in all tissues at birth. In the adult the **red bone marrow** primarily is found in membranous bone such as the vertebrae, pelvis, sternum, and ribs. **Yellow marrow** produces some white cells but is composed mainly of connective tissue and fat. Other blood-forming organs include the following:

- Lymph nodes, which produce lymphocytes and antibodies
- The spleen, which stores large quantities of blood and produces lymphocytes, plasma cells, and antibodies
- The liver, a blood-forming organ only during intrauterine life, which plays an important role in the coagulation process

Plasma

Plasma, the clear portion of blood, is about 92% water. It contains three important proteins: albumin, globulins, and fibrinogen. **Albumin** is the most plentiful protein. Albumin is similar to egg white and gives blood its gummy texture. These large proteins keep the water concentration of blood low so that water diffuses readily from tissues into the blood. The **globulins** (alpha, beta, and gamma) transport other proteins and provide immunity to disease. **Fibrinogen** is responsible for blood clotting. Plasma proteins perform various functions that include maintaining blood pH (acting as either an acid or a base); transporting fat-soluble vitamins, hormones, and carbohydrates; and allowing the body to digest them temporarily for food. Plasma also contains salts, metals, and inorganic compounds.

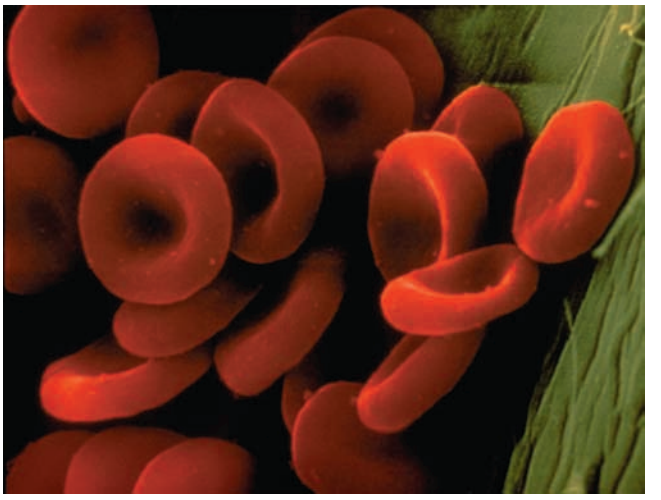

FIGURE 32-2 Mature erythrocytes. (Copyright Dennis Kunkel Microscopy, Inc. From McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children,* ed 6, St Louis, 2010, Mosby.)

Red Blood Cells

Red blood cells are the most abundant cells in the body. They are primarily responsible for tissue oxygenation. They appear as small rounded disks with nearly hollowed-out centers (Figure 32-2). They are composed mainly of water and the red protein **hemoglobin.** Red blood cell production continues throughout life to replace blood cells that grow old and die, are killed by disease, or are lost through bleeding. After RBC production occurs in the bone marrow, the new cell divides until there are 16 RBCs. The cells produce hemoglobin protein until the concentration of the protein becomes 95% of the dry weight of the cell. At this time, the cell expels its nucleus, giving the cell its characteristic pinched look. The new shape of the RBC increases the surface area of the cell and thus its oxygen-carrying potential. Red blood cells have a life span of about 120 days. As the cells age, their internal chemical machinery weakens; they lose elasticity; and they become trapped in small blood vessels in the bone marrow, liver, and spleen. They then are destroyed by specialized WBCs (**macrophages**). Most components of destroyed hemoglobin molecules are used again. However, some are broken down to the waste product **bilirubin.**

TABLE 32-1 Cellular Components of the Blood

Cell	Structural Characteristics	Normal Amounts of Circulating Blood	Function	Life Span
Erythrocyte (red blood cell)	Nonnucleated cytoplasmic disk containing hemoglobin	4.2-6.2 million/mm^3	Gas transport to and from tissue cells and lungs	80-120 days
Leukocyte (white blood cell)	Nucleated cell	5000-10,000/mm^3	Body defense mechanisms	Described below
Lymphocyte	Mononuclear immunocyte	25-33% of leukocyte count (leukocyte differential)	Humoral and cell-mediated immunity	Days or years depending on type
Monocyte and macrophage	Large mononuclear phagocyte	3-7% of leukocyte differential	Phagocytosis; mononuclear phagocyte system	Months or years
Eosinophil	Segmented polymorphonuclear granulocyte	1-4% of leukocyte differential	Phagocytosis, antibody-mediated defense against parasites, allergic reactions, associated with Hodgkin's disease, recovery phase of infection	Unknown
Neutrophil	Segmented polymorphonuclear granulocyte	57-67% of leukocyte differential	Phagocytosis, particularly during early phase of inflammation	4 days
Basophil	Segmented polymorphonuclear granulocyte	0-0.75% of leukocyte differential	Unknown, but associated with allergic reactions and mechanical irritation	Unknown
Platelet	Irregularly shaped cytoplasmic fragment (not a cell)	140,000-340,000/mm^3	Hemostasis after vascular injury; normal coagulation and clot formation/retraction	8-11 days

Adapted from McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children,* ed 7, St Louis, 2006, Mosby.

Each RBC contains about 270 million hemoglobin molecules. Each hemoglobin molecule carries 4 oxygen molecules. The normal amount of hemoglobin in blood is about 15 g/100 mL. This normally is a little higher in males than in females. The number of RBCs is about 4.2 to 6.2 million cells/mm^2 (Box 32-1).

White Blood Cells

As described in Chapter 10, white blood cells arise from the bone marrow and are released into the bloodstream. White blood cells destroy foreign substances (e.g., bacteria and viruses) and clear the bloodstream of debris. Leukocyte production increases in response to infection. This causes an elevated WBC count in the blood. Chapters 27 and 28 provide a discussion of blood groups, the inflammatory process, and the immune response, respectively.

LOOK AGAIN
See Chapter 10: Review of Human Systems, pp. 178-182.

The bone marrow and lymph glands continually produce and maintain a reserve of WBCs. However, there are not many WBCs in the healthy bloodstream. The normal WBC count is about 5000 to 10,000 cells/mm^2. **Monocytes** make up about 5% of the total WBC count and increase with chronic infections. **Lymphocytes** account for about 27.5%, **neutrophils** about 65%, and **eosinophils** and **basophils** together about 2.5% of the total WBC count. A rise in the number of WBCs aids in the diagnosis of some diseases. An increased WBC count is specific for various illnesses such

BOX 32-1 Laboratory Tests

Hematocrit is the fraction of the total volume of blood that consists of red blood cells (RBCs), normally about 45%. For example, a value of 46% implies that there are 46 mL of RBCs in 100 mL of blood. The normal hematocrit for males is 40% to 54%. In females a normal hematocrit is 38% to 47%. A low hematocrit value indicates anemia that may result from trauma, surgery, internal bleeding, nutritional deficiency (e.g., iron or vitamin B_{12}), bone marrow disease, or sickle cell disease. A high hematocrit value may be caused by dehydration, lung disease, certain tumors, and disorders of the bone marrow.

Hemoglobin is reported in grams per 100 mL of blood. The normal hemoglobin level for males is 13.5 to 18 g/100 mL. In women a normal hemoglobin measurement is 12 to 16 g/100 mL.

Reticulocyte count offers details about the rate of RBC production. A reticulocyte count of less than 0.5% of the RBC count usually indicates a deceleration in the process of RBC formation. A reticulocyte count greater than 1.5% usually indicates an acceleration of RBC formation.

as bacterial infection, inflammation, leukemia, trauma, and stress.

The **differential count** (also called the *diff*) identifies the different types of leukocytes (WBCs) present in blood. The test is performed by spreading a drop of blood on a microscope slide, staining the slide, and examining it under a microscope. Cells are identified by the shape and appearance of the nucleus, the color of cytoplasm (the background of the cell), and the presence and color of granules. The percentage of each cell type is reported. At the same time, red cells and platelets are examined for abnormalities in appearance.

Platelets

Platelets (thrombocytes) are small, sticky cell fragments. They play an important role in blood clotting. When a blood vessel is cut, platelets travel to the site and swell into odd, irregular shapes and adhere to the damaged vessel wall. Platelets plug the leak and allow other cells to stick to them and to form a clot. However, if the damage to the vessel is too great, the platelets chemically signal the complex clotting process or **clotting cascade** (described later). Platelets repair millions of ruptured capillaries each day. They often make the rest of the clotting cascade unnecessary (Box 32-2).

CRITICAL THINKING

What body functions are impaired if the white blood cell number or function is diminished?

HEMOSTASIS

Hemostasis is the initial physiological response to wounding that causes bleeding to cease. Hemostasis is initiated when there is a break in the integrity of the vascular endothelium. The vascular reaction or physiology of hemostasis involves vasoconstriction, formation of a platelet plug, coagulation, and the growth of fibrous tissue into the blood clot that permanently closes and seals the injured vessel.

Vasoconstriction resulting from injury is rapid but temporary. In response to injury, severed blood vessels constrict and retract with the aid of the surrounding subcutaneous tissues. This vessel spasm slows blood loss immediately. Vasoconstriction may close the ends of the injured vessels completely. This response usually is sustained for as long as 10 minutes. During this time, blood coagulation mechanisms are activated to produce a blood clot.

Platelets adhere to injured blood vessels and to collagen in the connective tissue that surrounds the injured vessel. As platelets contact collagen, they swell, become sticky, and secrete chemicals that activate other surrounding platelets. This process causes the platelets to adhere to one another. The process creates a **platelet plug** in the injured vessel. If the opening in the vessel wall is small, the plug may be sufficient to stop blood loss completely. If the opening in the vessel is large, however, a **blood clot** is necessary to arrest the flow of blood.

BOX 32-2 Clotting Measurements

Clotting time is normally 7 to 10 minutes. The patient bleeds if the clotting time is prolonged. The patient develops intravascular clots if the clotting time is less than normal. Prothrombin (PT) time measures the clotting time of plasma (the extrinsic clotting cascade). The PT test is used to monitor patients taking certain medications and to diagnose clotting disorders. The PT test specifically evaluates the presence of factors VIIa, V, and X and of prothrombin and fibrinogen. A drop in the concentration of any of these factors will cause the blood to take longer to clot. A prolonged PT time is considered abnormal. The PT test is used in combination with the partial thromboplastin time (PTT) to screen for hemophilia and other hereditary clotting disorders.

The PTT uses blood to which a chemical has been added to prevent clotting before the test begins. The PTT measures the integrity of the extrinsic clotting cascade, which is affected by blood-thinning medications (e.g., heparin and warfarin). The PTT time can help determine a possible cause of abnormal bleeding or bruising. Increased PTT time in a person with a bleeding disorder may indicate that a clotting factor is missing or defective.

Blood coagulation occurs as a result of a chemical process that begins within seconds of a severe vessel injury. Coagulation progresses rapidly; within 3 to 6 minutes after the rupture of a vessel, the entire end of the vessel is filled with a clot. Within 30 minutes the clot retracts and the vessel is sealed further. The blood-clotting mechanism is a complex process and includes the following three mechanisms (Figure 32-3):

1. **Prothrombin activator** is formed in response to rupture or damage of the blood vessel.
2. Prothrombin activator stimulates the conversion of **prothrombin** to **thrombin.**
3. Thrombin in the presence of calcium ions acts as an enzyme to convert fibrinogen into *fibrin threads*. These threads entrap platelets, blood cells, and plasma to form the clot.

The process of hemostasis usually is protective and is required for survival. In some instances, though, hemostasis can result in responses that threaten life and function. Examples include myocardial infarction or stroke.

NOTE

Certain diseases or genetic factors that interrupt the clotting cascade can impair hemostasis. Thus they retard the process of clot formation. Examples include hemophilia, thrombocytopenia (low platelet count), and liver disease, which affects the production of **clotting factors** (substances in the blood that act in sequence to stop bleeding by forming a clot). Various drugs also can impair coagulation. ***Aspirin*** decreases platelet activity. Warfarin suppresses the ability of the liver to make certain clotting factors. In any patient with impaired hemostasis, even minor trauma can result in uncontrollable and life-threatening hemorrhage.

SPECIFIC HEMATOLOGICAL DISORDERS

Hematological disorders presented in this chapter are anemia, leukemia, leukopenia, lymphomas, polycythemia, disseminated intravascular coagulopathy, hemophilia, sickle cell disease, and multiple myeloma (Box 32-3).

Anemia

Anemia is a condition in which the concentration of hemoglobin or erythrocytes in the blood is below normal. Precipitating causes of anemia include chronic or acute blood loss, decreased production of erythrocytes, and increased destruction of erythrocytes. One should note that anemia is not a disease. Rather, anemia is a symptom of a disease. Those at greatest risk are persons with chronic kidney disease, diabetes, heart disease, and cancer; chronic inflammatory conditions such as rheumatoid arthritis or inflammatory bowel disease; and persistent infections such as

BOX 32-3 Hematological Disorders by Cell Type

Disorders of Red Blood Cells
Anemia
Polycythemia
Sickle cell disease

Disorders of White Blood Cells
Hodgkin's disease
Non-Hodgkin's lymphomas
Leukemia
Leukopenia
Multiple myelomas

Disorders of Hemostasis
Disseminated intravascular coagulation
Hemophilia
Thrombocytopenia

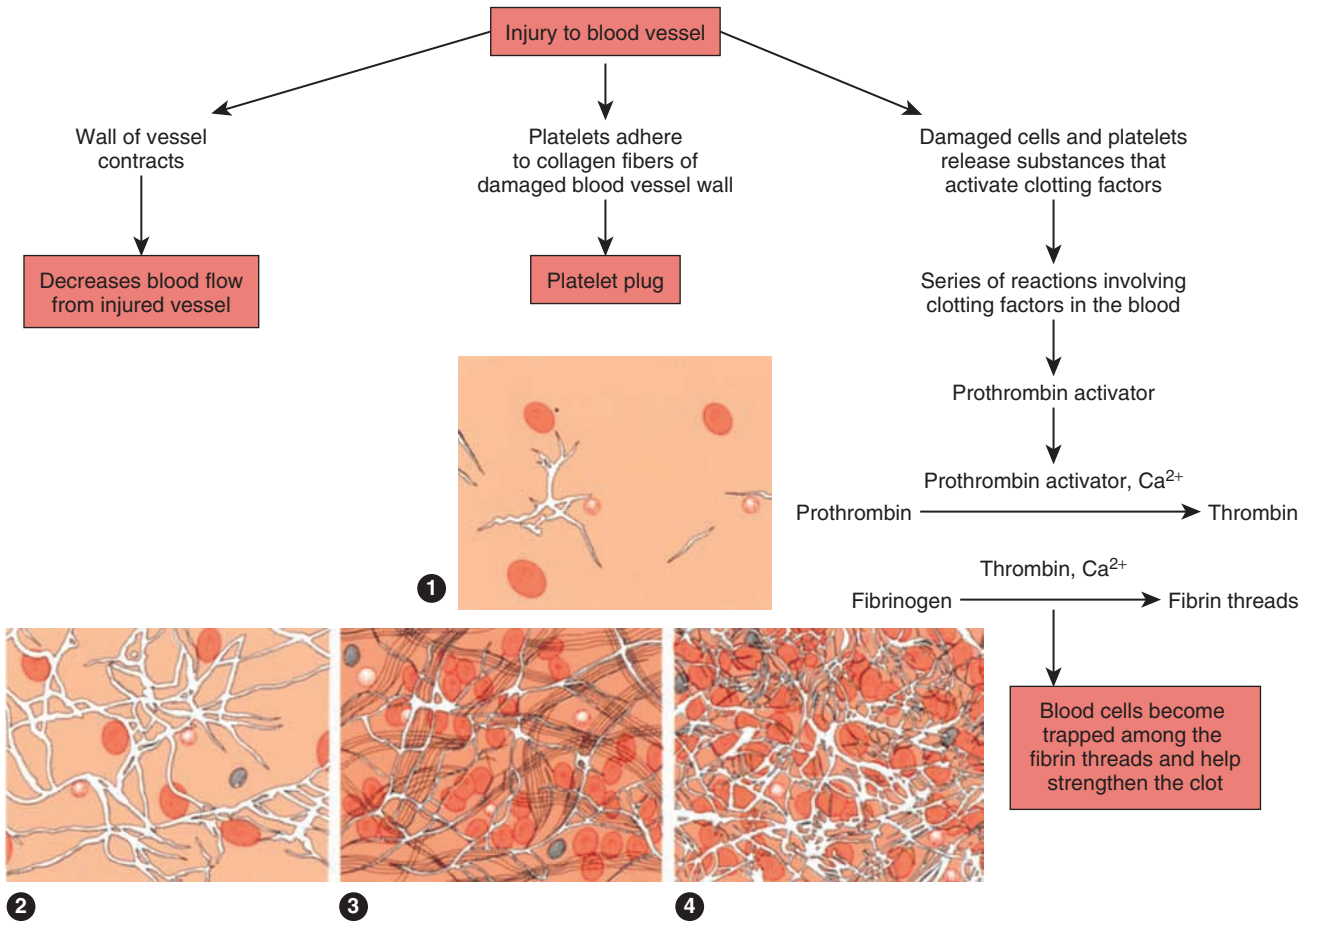

FIGURE 32-3 Overview of blood clotting. Fibrin threads form the webbing of the clot. Blood cells, platelets, and plasma become trapped among the fibrin threads and help strengthen the clot. (From Solomon EP: *Introduction to human anatomy and physiology,* ed 3, St Louis, 2009, Saunders.)

human immunodeficiency virus (HIV). These conditions can cause anemia by interfering with the production of oxygen-carrying RBCs. In the case of cancer and chemotherapy, anemia sometimes can be caused by the treatment itself. Two common forms of anemia are **iron deficiency anemia** and **hemolytic anemia.**

IRON DEFICIENCY ANEMIA

Iron is the critical part of a hemoglobin molecule, giving it the ability to bind oxygen (Figure 32-4). The lack of iron in iron deficiency anemia prevents the bone marrow from making enough hemoglobin for the RBCs. The RBCs produced are small and have a pale center. They also have a reduced oxygen-carrying capacity. The most common cause of iron deficiency anemia in adults is blood loss from menstrual bleeding or intestinal bleeding.[2] A diet that is low in iron usually is the cause of iron deficiency anemia in children. Vitamin deficiencies also can produce anemia. Lack of folic acid (one of the B vitamins) is the most common form of vitamin-deficiency anemia (Box 32-4).

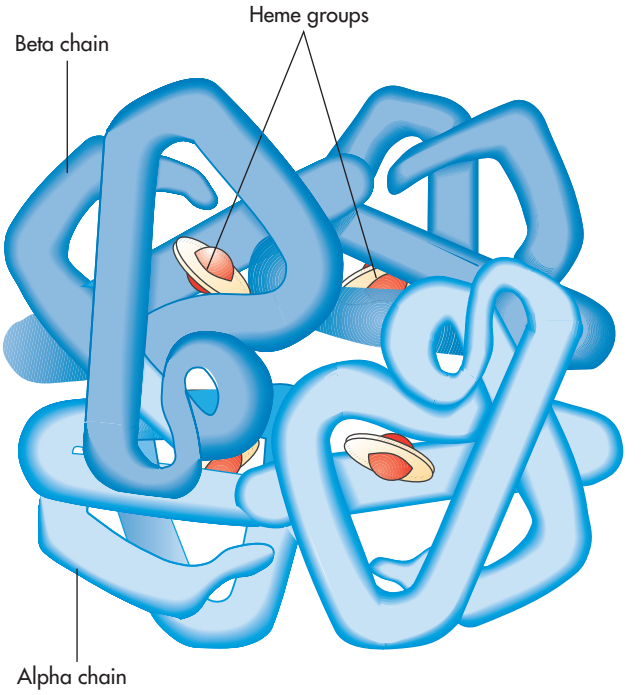

FIGURE 32-4 The 4-chained hemoglobin molecule is made from more than 10,000 atoms. Yet when fully laden, the molecule will carry only 4 pairs of oxygen atoms. Hemoglobin is built around 4 atoms of iron that act like oxygen magnets. Each red blood cell holds 300 million of these vital protein molecules.

CRITICAL THINKING
Can you predict the signs and symptoms of anemia?

HEMOLYTIC ANEMIA

Premature destruction of RBCs in the blood (**hemolysis**) causes hemolytic anemia. This destruction can result from an inherited disorder inside the RBC. It also can result from a disorder outside the cell. The condition usually is acquired later in life.

Inherited Disorders. Hemolysis can occur as a result of abnormal rigidity of the cell membrane. This rigidity causes the cell to become trapped at an early stage of its life span in the smaller blood vessels (usually of the spleen). In these smaller blood vessels the RBC is destroyed by macrophages. This type of anemia can occur from a genetic defect in the hemoglobin within the cell (e.g., sickle cell anemia and thalassemia). It also can occur from a defect in one of the enzymes in the cell that helps protect the cell from chemical damage during infectious illness. A deficiency of one of the enzymes, glucose-6-phosphate dehydrogenase, is common in African Americans.

Acquired Disorders. Acquired hemolytic anemia results from one of three conditions:

1. Disorders in which normal RBCs are disrupted as a result of mechanical forces (e.g., abnormal blood vessel linings or blood clots)
2. Autoimmune disorders, which can destroy RBCs with antibodies that are produced by the immune system (e.g., drug-induced hemolytic anemia, an incompatible blood transfusion, described in Chapter 11).

BOX 32-4 Pernicious Anemia

Pernicious anemia results from a vitamin B_{12} deficiency. Pernicious anemia has a number of causes including surgery, infection, medication use, and poor diet. The condition can also result from a lack of *intrinsic factor* (a protein in the stomach), which is needed for the absorption of vitamin B_{12} from food. The deficiency of vitamin B_{12} prevents the body from making an adequate number of healthy RBCs. Severe vitamin B_{12} deficiency can cause neurological problems, such as confusion, dementia, depression, and memory loss.[3] The condition is usually treated with vitamin B_{12} supplements or injections.

NOTE
Drug-induced hemolytic anemia is a blood disorder that occurs from an autoimmune response. This autoimmune response can be triggered by a number of drugs, including cephalosporins, penicillin and its derivatives, NSAIDs, and others. The immune system attacks RBCs and causes their early breakdown and destruction. The condition usually resolves with good outcome when the drug responsible for the disorder is discontinued.

3. Conditions that can cause hemolytic anemia when RBCs are destroyed by microorganisms in the blood (e.g., malaria)

SIGNS AND SYMPTOMS OF ANEMIA

All forms of anemia share signs and symptoms. These signs and symptoms include fatigue and headaches, sometimes a sore mouth or tongue, brittle nails, and, in severe cases, breathlessness and chest pain (Table 32-2). Other patient complaints are related to an abnormal decrease in the number of WBCs (leukopenia) or a reduction in platelets (thrombocytopenia) and may include the following:

- Bleeding from mucous membranes
- Cutaneous bleeding
- Fatigue
- Fever
- Lethargy

DIAGNOSIS AND TREATMENT

The patient's signs and symptoms, patient history, and examination of the patient's blood through blood tests and bone marrow biopsy indicate a diagnosis of most forms of anemia. For example, iron deficiency anemia usually reveals RBCs that are smaller than normal. Hemolytic anemia shows RBCs that are immature and abnormally shaped. Treatment should be indicated to correct, modify, or diminish the mechanism or process that is leading to defective RBC production or reduced RBC survival.

NOTE

A bone marrow biopsy specimen taken from the sternum or pelvis offers details about the various parts of blood. The specimen also provides information about the presence of cells foreign to the marrow. Bone marrow biopsy is useful in diagnosing many hematological disorders such as anemia, leukemia, and certain infections. A bone marrow transplant sometimes is used to treat these and other diseases.

Leukemia

Leukemia refers to any of several types of cancer in which an abnormal proliferation of WBCs usually occurs in the bone marrow (Figure 32-5). The excess production of leukemic cells crowds and impairs the normal production of RBCs, WBCs, and platelets. Leukemia is more common in males than in females. Leukemia is also more common in Caucasians than in African Americans. In 2008, about 46,000 Americans (2500 of them children) were diagnosed with the disease.[4]

The exact cause of leukemia is not known; however, genetics may play a role. Abnormal chromosomes associated with congenital disorders (e.g., Down syndrome) and human immunodeficiency type (HIV-type) viruses are associated with a rare form of this disease. Other factors that may play a role in the development of leukemia include exposure to radiation, viral infections, immune defects, and exposure to various chemicals in home and work environments.

TABLE 32-2 Causes, Signs and Symptoms, and Treatment for Specific Forms of Anemia

Form of Anemia	Causes	Signs and Symptoms	Treatment
Iron deficiency anemia	Insufficient intake of iron Gastrointestinal disorders (e.g., ulcer disease) External and/or internal bleeding Prolonged aspirin or NSAID therapy Gastrectomy (surgical removal of part or all of stomach)	Those related to underlying cause (e.g., bleeding) Those common to all forms of anemia	Correction of underlying cause Supplemental iron tablets or injections
Hemolytic anemia	Genetic red blood cell disorder Autoimmune disorders Malaria and other infections	Jaundice Those common to all forms of anemia	Splenectomy Immunosuppressant drugs Avoidance of drugs or foods that precipitate hemolysis Antimalarial drugs Blood transfusions

NSAID, Nonsteroidal antiinflammatory drug.

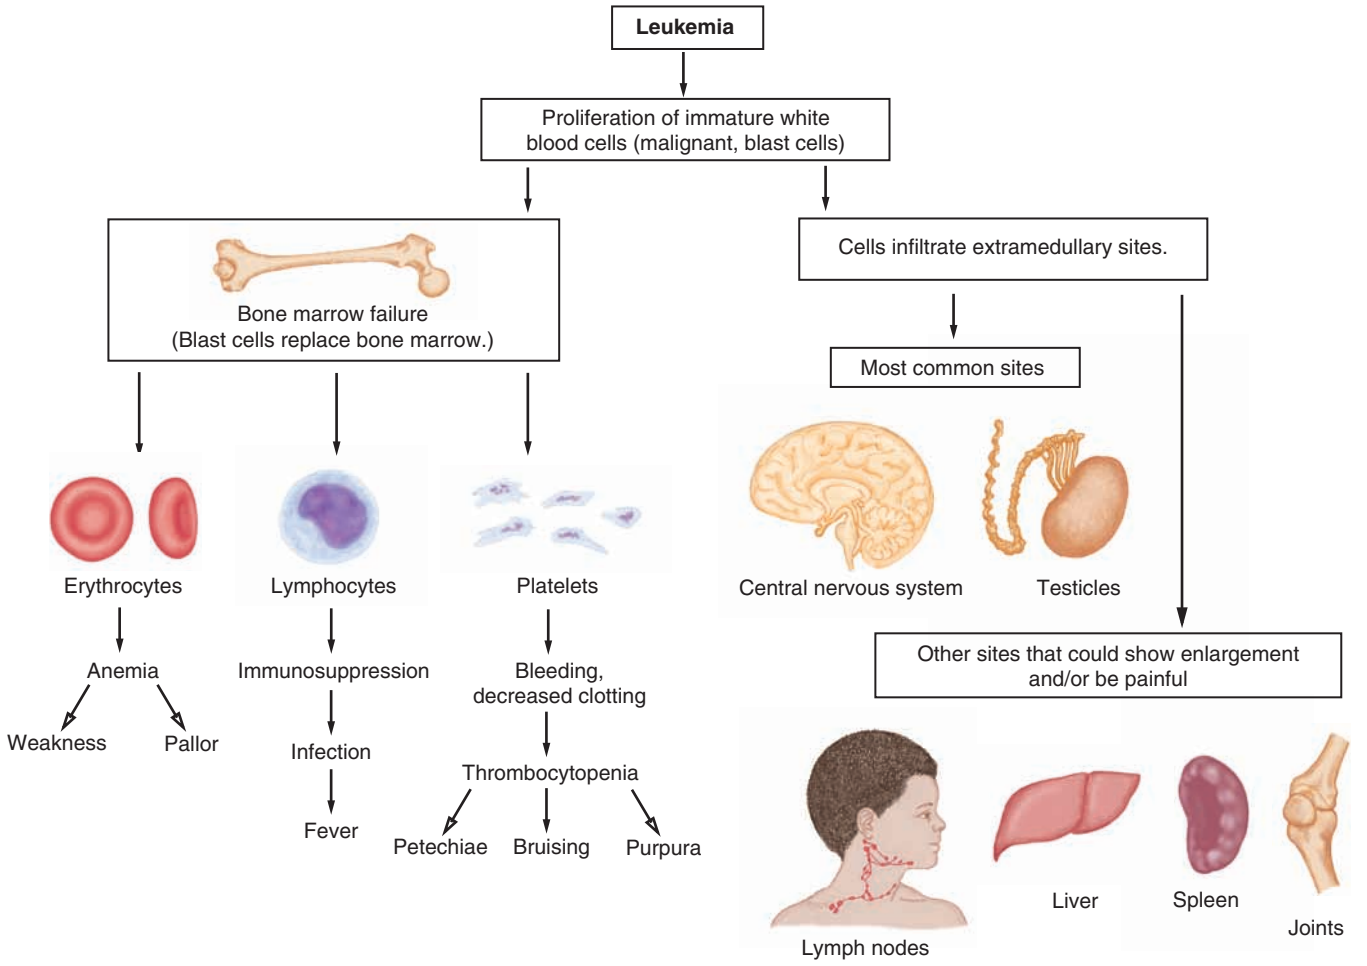

FIGURE 32-5 Pathophysiology of leukemia. (From McKinney ES et al: *Maternal-child nursing,* ed 2, St Louis, 2005, Saunders.)

NOTE

Leukopenia is a decrease in the number of white blood cells (most commonly neutrophils). When white cells are depleted, it weakens the immune system and places the person at risk for developing infection. Leukopenia has many causes including chemotherapy, radiation therapy, posttransplant medications, leukemia, various anemias, and other diseases. The condition is diagnosed with blood testing (complete blood count).

CLASSIFICATIONS

Leukemia is classified as *acute* or *chronic.* Cancer cells in acute leukemia begin proliferating at an early stage of their development (arrested as immature cells). Chronic leukemia implies an abnormal proliferation of more mature but not fully differentiated cells. Leukemias are classified further according to the type of WBC involved (Box 32-5). Two common forms of leukemia are *acute lymphocytic leukemia* and *acute myelogenous leukemia.* The first affects mostly children younger than age 15. (It sometimes is called *childhood leukemia.*) The latter affects mostly middle-aged adults. In both types, abnormal WBCs are produced in such large amounts that they eventually accumulate in the vital organs (liver, spleen, lymph, and brain). This impedes the function of these organs and leads to death. Chronic forms of leukemia can develop slowly, often over many years. Cases of disease often are discovered by chance during routine blood analysis.

BOX 32-5 Types of Leukemia

The terms *lymphocytic* or *lymphoblastic* indicate that the cancerous change takes place in a type of marrow cell that forms lymphocytes. The terms *myelogenous* or *myeloid* indicate that the cell change takes place in a type of marrow cell that normally matures to form red cells, some types of white cells, and platelets.

Acute lymphocytic leukemia and acute myelogenous leukemia are each composed of *blast cells,* respectively known as lymphoblasts or myeloblasts. Acute leukemias progress rapidly without treatment.

Chronic leukemias have few or no blast cells. Chronic lymphocytic leukemia and chronic myelogenous leukemia usually progress slowly compared to acute leukemias.

SIGNS AND SYMPTOMS

The proliferation of leukemic cells or the resulting inadequate production of other normal blood cells makes the patient highly susceptible to serious infections, anemia, and bleeding episodes. Signs and symptoms of leukemia include the following:

- Abdominal fullness
- Bleeding
- Bone pain
- Elevated body temperature and diaphoresis (i.e., sweating)
- Enlargement of lymph nodes
- Enlargement of the liver, spleen, and testes
- Fatigue
- Frequent bruising
- Headache
- Heat intolerance
- Night sweats
- Weight loss

CRITICAL THINKING

If a child has a lot of odd bruises, what would you suspect if a diagnosis of leukemia is not known?

DIAGNOSIS AND TREATMENT

The diagnosis of leukemia is confirmed by bone marrow biopsy. The severity of the disease is assessed by the degree of liver and spleen enlargement, extent of anemia, and lack of platelets in the blood. Treatment for acute leukemia can include the transfusion of blood and platelets, antibiotic therapy to manage anemia and infection, and the use of anticancer drugs and sometimes radiation to destroy the leukemic cells. In some cases the leukemia is treated with a bone marrow transplant (Box 32-6). Patients with chronic leukemia can be managed effectively with medication. Many patients require no treatment in its early stages.

DID YOU KNOW?

Blood Transfusion Complications

Each year, almost 5 million Americans receive a blood transfusion. The transfusion may be of whole blood (containing RBCs, WBCs, platelets, and plasma). More commonly, an individual component of whole blood is transfused (RBCs [most common], plasma, or platelets and clotting factors). Blood is usually obtained through blood banks. These facilities collect, test, and store the blood to ensure its safety and availability. The blood is typed as A, B, AB, or O, and Rh status is determined (described in Chapter 11). The blood is also tested for viral or bacterial infection (HIV, hepatitis B and C, variant Creutzfeldt-Jakob disease). Complications of blood transfusions (if any) are usually mild. Some, however, can be serious and life threatening. Possible complications include[5]:

- Allergic reaction: An allergic reaction to a transfusion may be mild or severe. Signs and symptoms include anxiety, nausea, pain in the chest or back, dyspnea, fever and chills, tachycardia, and hypotension.
- Viral or infectious disease from tainted blood (rare).
- Fever: May occur within 24 hours of the transfusion. This is usually a response to the white blood cells in donated blood. (These cells are sometimes removed by the blood bank to avoid this complication.)
- Circulatory overload: Occurs from a rapid transfusion of a large volume of blood. Risk increases in patients older than 60 years of age and in those who have cardiac or pulmonary failure or anemia. Primary signs and symptoms are dyspnea, orthopnea, peripheral edema, and a rapid rise in blood pressure.
- Iron overload: Often a result of frequent blood transfusions. The iron may accumulate and damage the heart, lung, and other organs.
- Lung injury: Usually a complication only in very ill patients. Although rare, injury usually occurs within 6 hours of the transfusion. Cause is unknown, but may be related to proteins found in the donated plasma of women who have been pregnant. The donated plasma of men is sometimes preferred.
- Acute immune hemolytic reaction: A rare and serious complication that results from type-and-cross-mismatch of patient and donor blood. Signs and symptoms of the reaction are usually sudden in onset and include fever, chills, chest pain, nausea, and dark urine. Hemolytic reactions attack new red blood cells and can lead to kidney damage.
- Delayed hemolytic reaction: A slower version of the acute immune hemolytic reaction that may not be noticed until the patient's RBC count is quite low.
- Graft versus host disease (GVHD): An often fatal illness caused by WBCs in donated blood. The disease causes destruction of host tissue. Symptoms usually begin within 1 month of the transfusion and include fever, rash, and diarrhea. GVHD is most common in patients with immune suppression.

Signs and symptoms of the reactions and complications listed above require that the transfusion be immediately stopped. In-hospital care for these patients will be dictated by the severity and cause of the adverse reaction.

Lymphomas

Lymphoma is a general term applied to any neoplastic disorder of the lymphoid tissue. Hodgkin's disease is one type; all others, despite their diversity, are called *non-Hodgkin's lymphomas.* All lymphomas are **malignant** (cancerous tumors that tend to metastasize).

NOTE

Blood cancers such as leukemia, Hodgkin's lymphoma, non-Hodgkin's lymphoma, myeloma, and myelodysplastic syndromes are cancers that originate in the bone marrow or lymphatic tissues. They are considered to be related cancers because they involve the uncontrolled growth of cells with similar functions and origins. The diseases result from an acquired genetic injury to the DNA of a single cell, which becomes abnormal (malignant) and multiplies continuously. The accumulation of malignant cells interferes with the body's production of healthy blood cells. Every 4 minutes one person is diagnosed with a blood cancer. An estimated 139,860 people in the United States will be diagnosed with leukemia, lymphoma, or myeloma in 2009. New cases of leukemia, Hodgkin's and non-Hodgkin's lymphoma, and myeloma account for 9.5% of the more than 1.4 million new cancer cases diagnosed in the United States each year.[7]

BOX 32-6 Blood and Marrow Stem Cell Transplantation

A stem cell is a cell whose daughter cells may develop into other cell types. Some cells can develop into several different types of mature cells, including lymphocytes, granulocytes, thrombocytes, and erythrocytes. Stem cells reside in marrow and also circulate in the blood. They also circulate in large numbers in fetal blood. They can be recovered from umbilical cord and placental blood after childbirth. Stem cells can be harvested, frozen, and stored for future transplantation.

Stem cell transplantation is standard therapy for selected patients with leukemia, lymphoma, and myeloma. The two major types of stem cell transplants are *autologous* and *allogenic.* An autologous transplant uses the patient's own marrow. The marrow is collected while the patient is in remission. Before it is given back to the patient, the marrow may be treated with chemotherapeutic agents or antibodies to cleanse it of cancer cells that may be present in the marrow. An allogenic transplant uses marrow from a donor. The donor is usually a brother or sister with the same tissue type. If a sibling is not available, a search of bone marrow registries for tissue-typed volunteers can be made for an unrelated donor. In addition to treating some cancers and other blood disorders, stem cells may play a key role in the future in treating diseases such as Alzheimer's, Parkinson's, and heart disease.

Adapted from Leukemia and Lymphoma Society: *Blood and marrow stem cell transplantation,* White Plains, NY, Feb 2008, Author.

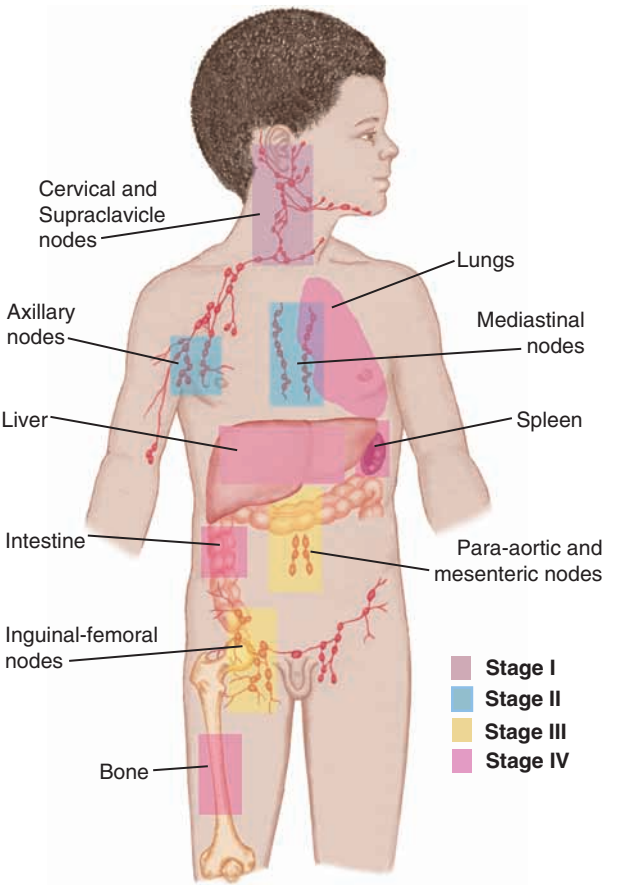

FIGURE 32-6 Pathophysiology of Hodgkin's disease. (From McKinney ES, et al: *Maternal-child nursing,* ed 2, St Louis, 2005, Saunders.)

HODGKIN'S DISEASE

Hodgkin's disease is characterized by painless, progressive enlargement of lymphoid tissue found mainly in the lymph nodes and spleen (Figure 32-6). Left unchecked, these cancer cells multiply and eventually displace healthy lymphocytes, suppressing the immune system. Signs and symptoms include swollen lymph nodes in the neck, axillae, or groin; fatigue; chills; and night sweats. Some patients also experience severe itching, persistent cough, weight loss, shortness of breath, and chest discomfort.

Hodgkin's disease is a rare cancer of unknown cause that may have a heritable component. The disease is more common in males than in females, with a peak incidence at age 20 to 29 as well as in persons between 55 and 70 years of age.[1] The disease is confirmed by the identification of *Reed-Sternberg cells* in lymph nodes or organs affected by the cancer. Treatment depends on the level of lymph node and organ system involvement (the *stage* of the disease) and can consist of radiation and chemotherapy with anticancer drugs. Hodgkin's disease is one of the most curable cancers.

NON-HODGKIN'S LYMPHOMAS

Non-Hodgkin's lymphomas vary in their malignancy according to the nature and activity of the abnormal cells. At least 10 types of non-Hodgkin's lymphoma have been identified. Each type is ranked as low, intermediate, or high grade. This ranking is based on how aggressively the disease behaves. Low-grade diseases usually progress slowly. They also tend not to spread beyond the lymphatic system. High-grade diseases can spread to distant organs within a few months. Signs and symptoms include painless swelling of one or more groups of lymph nodes, enlargement of the liver and spleen, fever, and, in rare cases, abdominal pain and gastrointestinal bleeding.

The cause of these cancers is largely unknown. One form, *Burkitt's lymphoma,* is a childhood cancer. In Africa, it is strongly associated with infection by Epstein-Barr virus. Other types worldwide have been linked to infection by HIV-type viruses and other conditions that affect the immune system (e.g., organ transplantation, radiation and chemotherapy, lupus, and rheumatoid arthritis). Treatment consists of radiation therapy, administration of anticancer drugs, and sometimes bone marrow transplantation.

Polycythemia

Polycythemia is an increase in the total RBC mass of the blood. The condition may be a natural response to chronic hypoxia (*secondary polycythemia*). Polycythemia also may occur for unknown reasons (*primary polycythemia*). Polycythemia also can result from dehydration (*apparent polycythemia*). In this instance, the RBC production does not exceed the upper limits of normal.

DID YOU KNOW?

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is a group of metabolic complications that can occur after treatment of cancer, usually non-Hodgkin's lymphomas and acute leukemias. These complications are caused by the breakdown products of dying cancer cells. Complications include hyperkalemia, hyperphosphatemia, hyperuricemia and hyperuricosuria, hypocalcemia, and consequent acute uric acid nephropathy and acute renal failure. A constellation of clinical symptoms may develop before initiation of chemotherapy or more commonly within 72 hours after administration of cytotoxic therapy. Signs and symptoms may include[6]:

- Nausea and vomiting
- Lethargy
- Edema
- Fluid overload
- Congestive heart failure
- Cardiac dysrhythmias
- Seizures
- Muscle cramps
- Tetany
- Syncope
- Sudden death

Because of the array of complications that may be associated with TLS, prehospital care can range from providing only comfort measures to full cardiac life support. In-hospital care may include the control of hyperuricemia to lower uric acid level, hydration to correct electrolyte imbalance, and administration of sodium bicarbonate to alkalinize the urine. In severe cases, dialysis may be needed.

SECONDARY POLYCYTHEMIA

Secondary polycythemia can be naturally present in persons who live in or visit areas of high altitude. Polycythemia is due to reduced air pressure and low oxygen concentration. When the oxygen supply to the blood is reduced, the kidneys produce the hormone *erythropoietin.* This hormone stimulates RBC production in the bone marrow to compensate for the reduced oxygen supply. The result is an increase in the oxygen-carrying efficiency of the blood. The RBC numbers return to normal when the person returns to sea level. Secondary polycythemia also can be present in heavy smokers. The disease can be caused by chronic bronchitis and conditions that increase erythropoietin production (e.g., liver cancer and some kidney disorders).

PRIMARY POLYCYTHEMIA

Primary polycythemia is also known as *polycythemia vera.* Primary polycythemia is a rare disorder of the bone marrow. In this disorder the increased production of RBCs causes the blood to thicken. This condition primarily develops in persons older than 50 years of age and can lead to several physiological problems that include the following:

- Blurred vision
- Dizziness
- Generalized itching
- Headache
- Hypertension
- Red hands and feet; red-purple complexion
- Splenomegaly

Other complications associated with primary polycythemia include platelet disorders, which cause bleeding or clot formation; stroke; and the development of other bone marrow diseases (e.g., leukemias). Treatment consists of phlebotomy. (This is the slow removal of blood through a vein.) Treatment also consists of anticancer drug therapy. The therapy controls the overproduction of RBCs in the marrow.

Disseminated Intravascular Coagulopathy

Disseminated intravascular coagulopathy (DIC) is a complication of severe injury, trauma, or disease. Disseminated intravascular coagulopathy is a common abnormal clotting disorder. The disease most often is seen in the critical care setting. It disrupts the balance among procoagulants, inhibitors, thrombus formation, and lysis. Signs and symptoms of DIC include dyspnea and bleeding and symptoms associated with hypotension and hypoperfusion.

Disseminated intravascular coagulopathy occurs in two phases.[8] The first phase is characterized by free thrombin in the blood, fibrin deposits, and aggregation of platelets. The second phase is characterized by hemorrhage caused by the depletion of clotting factors. The clinical consequences of these processes predispose the patient to multiple-system organ failure from bleeding and coagulation disorders caused by the following (Figure 32-7):

- Loss of platelets and clotting factors
- Fibrinolysis
- Fibrin degradation interference
- Small vessel obstruction, tissue ischemia, RBC injury, and anemia from fibrin deposits

DIC is confirmed through laboratory tests. Then the treatment is aimed at reversing the underlying illness or injury that triggered the event. In an effort to control the depletion of clotting factors, in-hospital care includes the replacement of platelets, coagulation factors, and blood. At the same time, attempts are made to manage the primary process.

Hemophilia

Hemophilia refers to a medical condition that causes uncontrolled bleeding and involves the loss of bleeding control mechanisms. The disease is a group of inherited bleeding disorders (Box 32-7). Hemophilia A is due to a deficiency in factor VIII. This factor is essential to the process of blood clotting (Table 32-3). Another less common form of hemophilia, caused by a deficiency of factor IX, is known as hemophilia B. This hemophilia also is known as *Christmas disease* (named for a man first diagnosed with the disease in 1952). All types of hemophilia present

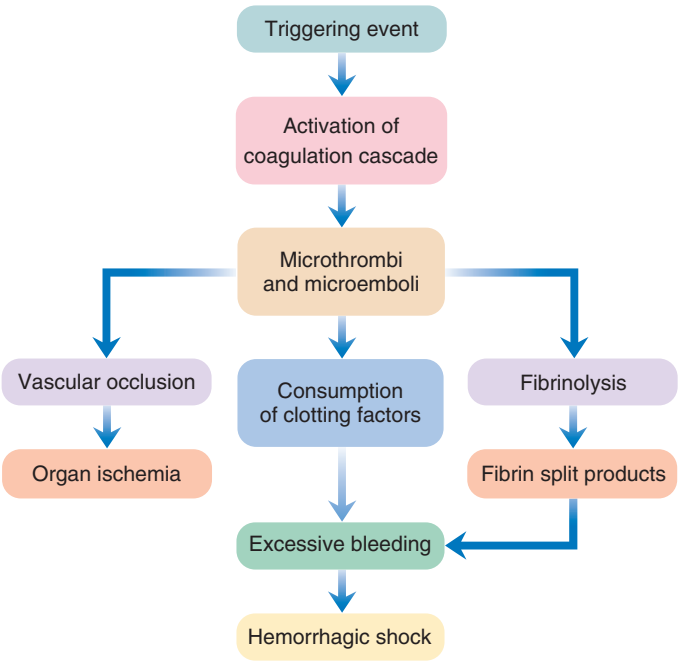

FIGURE 32-7 Pathophysiology of disseminated intravascular coagulation. Clotting and bleeding occur simultaneously, resulting in organ ischemia and hemorrhagic shock. (From Copstead-Kirkhorn LE, Banasik JL: *Pathophysiology,* ed 4, St Louis, 2010, Saunders.)

BOX 32-7 Hereditary Characteristics of Hemophilia

Chromosomes from the mother link with an equal number from the father, and each pair determines the type of information that genes carry. Females have two X chromosomes. Males have an X and a Y chromosome. The mother passes on the X chromosome to her child, and the father passes on an X or a Y. Two X chromosomes produce a female child; an X and a Y produce a male child.

Hemophilia stems from an abnormal gene on the X chromosome. A female with an abnormal X chromosome usually is spared the disease because, although she received one abnormal X chromosome from one parent, the normal X chromosome passed on from her other parent counteracted the abnormal gene. However, she is a carrier of the disease and can pass it on to her children. A woman can have hemophilia only if her mother is a carrier and her father has hemophilia, which is rare. Affected males do not pass the defective gene to sons, but they pass it on to all of their daughters. A male, however, receives only one X chromosome. If his mother is a carrier, the male child will have a 50% chance of having hemophilia.

with similar problems. Yet the specific factor involved determines the severity of bleeding. About 18,000 people in the United States have hemophilia; about 400 are born with the disorder each year.[9]

Bleeding from hemophilia can occur spontaneously, even after minor injury. It also can occur during some medical procedures (e.g., tooth extraction). Hemorrhage

TABLE 32-3 Clotting Factors and Synonyms

Factor	Synonyms
I	Fibrinogen
II	Prothrombin
III	Thromboplastin
IV	Calcium
V	Proaccelerin
VI	None in use
VII	Serum prothrombin conversion accelerator
VIII	Antihemophilic globulin, antihemophilic factor
IX	Plasma thromboplastin component, Christmas factor
X	Stuart factor
XI	Plasma thromboplastin antecedent
XII	Hageman factor
XIII	Fibrin-stabilizing factor

can occur anywhere in the body. However, bleeding into joints, deep muscles, the urinary tract, and intracranial sites is the most common. Head trauma is potentially life threatening in these patients. Central nervous system bleeding is the major cause of death for patients with hemophilia in all age groups.[10]

Hemophilia is controlled by infusions of concentrates of factor VIII. These infusions can be administered by the patient. However, serious or unusual bleeding often requires hospitalization. Persons with hemophilia are advised to avoid activities that may increase their risk of injury. These include, for example, contact sports. Most patients with hemophilia are knowledgeable about their disease. Most seek emergency care only when complicated problems and trauma-related issues arise.

CRITICAL THINKING

Imagine that you are caring for a patient with hemophilia who has fallen 15 feet from a ladder. This patient refuses care and transportation. What should you do?

NOTE

Factor VIII is made from large pools of donor blood. During the first few years of the acquired immunodeficiency syndrome epidemic, many persons with hemophilia and their sexual partners became infected with human immunodeficiency virus through factor VIII infusions. There are careful screening protocols for blood now. However, infusions still carry a minute risk of transmitting hepatitis B virus, hepatitis C virus, and human immunodeficiency virus to factor VIII recipients. Another factor VIII product, recombinant factor VIII (Recombinate), is produced by inserting cloned factor VIII into animal tissues. Recombinate is not made from human plasma, is the purest form of factor VIII, does not transmit viral contamination, and is as effective as plasma-derived factor VIII.[11]

Thrombocytopenia

Thrombocytopenia is a low platelet count. In healthy people, the blood normally contains 150,000 to 450,000 platelets/microliter of blood. At levels of 20,000 to 30,000 platelets/microliter of blood, bleeding can occur with relatively minor trauma. At levels below 20,000 platelets/microliter of blood, spontaneous bleeding can occur, increasing the risk for shock and death. This is especially true if bleeding occurs in the brain. Bleeding on the skin is usually the first sign of a low platelet count. This may appear as:

- Small red or purple spots on the skin (petechiae), often on the lower legs
- Purple, brown, and red bruises (purpura) that happen easily and often
- Prolonged bleeding, even from minor cuts
- Bleeding or oozing from the mouth or nose, especially nosebleeds or bleeding from brushing teeth
- Unusually heavy menstrual flow

Thrombocytopenia can occur if the body does not produce enough or destroys too many platelets, or if the spleen retains too many platelets. The disease is often associated with leukemia or lymphoma, aplastic anemia, vitamin B_{12} or folic acid deficiency anemias, an enlarged spleen, infectious diseases such as HIV/acquired immunodeficiency syndrome (AIDS), and massive blood transfusions. Two diseases that occur because of increased destruction of platelets are[12]:

- Idiopathic thrombocytopenic purpura (ITP)—ITP occurs when antibodies attack and destroy the body's platelets for unknown reasons. In children, ITP can be an acute condition that occurs after infection. Acute ITP is rare in adults. More common is chronic ITP, a condition that may persist for years and most frequently affects women ages 20 to 40 years.
- Thrombotic thrombocytopenic purpura (TTP)—TTP is a life-threatening disease that occurs when small blood clots form suddenly throughout the body. It can result in cardiac hemorrhage and death. It occurs more often in women and is associated with pregnancy, metastatic cancer, chemotherapy, HIV/AIDS, and some prescription drugs. Patients with TTP experience kidney failure or decreased kidney function, fever, and neurological complications.

Treatment for thrombocytopenia depends on cause and severity. Some patients will only require careful monitoring of their platelet counts. Other more serious cases may be treated with administration of corticosteroids (prednisone), transfusion of platelets, and, rarely, surgical removal of the spleen.

Sickle Cell Disease

Sickle cell disease is an inherited blood disorder that affects red blood cells. There are several types of sickle cell disease. The most common type is **sickle cell anemia.** Sickle cell disease is a debilitating and unpredictable genetic illness. It affects persons of African descent and, less commonly, persons of Mediterranean origin. One in 12 African Americans and more than 70,000 Americans of different ethnic origins are estimated to suffer from sickle cell disease. In the United States, about 1000 persons are born with the disease each year. It is estimated that 12.5 million Americans have *sickle cell trait.*[13] (Box 32-8). Signs and symptoms of sickle cell disease include the following:

- Delayed growth, development, and sexual maturation in children
- Jaundice
- Priapism in adolescent and adult males
- Splenomegaly
- Stroke

BOX 32-8 Characteristics of Sickle Cell Trait

A person must inherit two sickle cell genes—one from each parent—to develop sickle cell disease. When only one gene is present, the condition is known as a *sickle cell trait.* Persons with sickle cell trait usually do not experience symptoms except occasionally under low-oxygen conditions (e.g., scuba diving or traveling at high altitudes). However, these persons can pass the gene, and possibly the disease, on to their children. If both parents have sickle cell trait, the child has a 25% chance of developing the disease, a 50% chance of having sickle cell trait, and a 25% chance of having neither. Genetic counseling should be considered for carriers of the disease who plan to become parents. Many states require sickle cell screening of newborns. Some colleges and universities also screen young athletes for the sickle cell trait as part of the athlete's health assessment.

SHOW ME THE EVIDENCE

Researchers asked patients older than 16 years with sickle cell disease to maintain a diary for 6 months that outlined pain incidence and severity, opioid use, and frequency of emergency department (ED) visits. At entry they completed a survey of other pertinent information and blood and urine samples were analyzed. The goal of this study was to describe characteristics of patients who frequently seek emergency care for sickle cell disease versus those who do not. Because it is common for frequent ED users to be labeled as drug seekers these researchers sought to describe their characteristics. Of the patients included in the study 35% were identified as high ED users. These frequent users had more severe disease as evidenced by higher pain levels, lower hematocrit levels, and increased need for transfusions.

From Aisiku IP, Smith WR, McClish DK, et al: Comparisons of high versus low emergency department utilizers in sickle cell disease, *Ann Emerg Med* 53(5):587-593, 2009.

PATHOPHYSIOLOGY

Sickle cell disease produces an abnormal type of hemoglobin called *hemoglobin S.* This abnormal type has an inferior oxygen-carrying capacity. When hemoglobin S is exposed to low oxygen states, it crystallizes. This distorts the RBCs into a sickle shape (Figure 32-8). The sickle-shaped cells are fragile and easily destroyed. They also are unable to pass

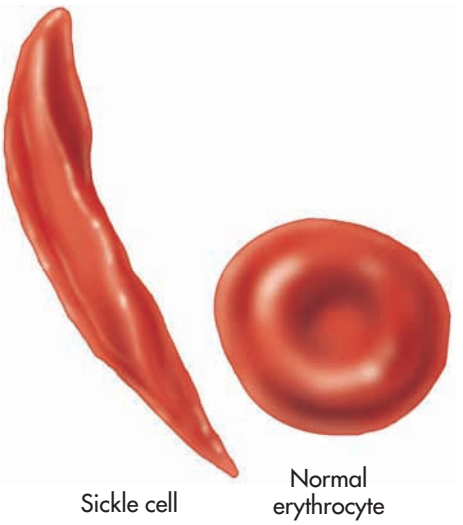

FIGURE 32-8 Sickle cell versus normal erythrocyte. (From McKinney ES, et al: *Maternal-child nursing,* ed 2, St Louis, 2005, Saunders.)

easily through tiny blood vessels and consequently block flow to various organs and tissues. This causes a vasoocclusive **sickle cell crisis** that can be life threatening. As fewer RBCs pass through congested vessels, tissues and joints become starved for oxygen and other nutrients. This causes excruciating pain. Other signs and symptoms of sickle cell disease are increased weakness, aching, chest pain with shortness of breath, sudden and severe abdominal pain, bony deformities, icteric (jaundice) sclera (Figure 32-9), fever, and arthralgia (joint pain) (Figure 32-10).

NOTE

Acute chest syndrome (ACS) is defined as a new abnormal consolidation on a chest radiograph in a patient with sickle cell disease. The condition is usually caused by pulmonary infarction from a sickle crisis in adults, and infection in children. The syndrome may be associated with acute pleuritic chest pain, fever, and leukocytosis. ACS is a common medical emergency for patients with sickle cell disease. It often requires hospitalization.

CRITICAL THINKING

How do you think a patient with such chronic pain must feel at the beginning of a sickle cell crisis?

Sickle cell crisis can occur in any part of the body and can vary in intensity from one person to the next and from one crisis to the next. Over time the crises can destroy the spleen, kidneys, gallbladder, and other organs. Sickle cell crisis may occur for no apparent reason. It also may be triggered by conditions such as the following:

- Dehydration
- Exposure to extremes in temperature
- Infection

FIGURE 32-9 Jaundice of the sclera.

BOX 32-9 Care Objectives for Sickle Cell Crisis

The main care objectives of patients in sickle cell crisis are to provide (1) supplemental oxygen by facemask or nasal cannula to help counter tissue hypoxia and reduce cell clumping; (2) rest to minimize energy expenditure and oxygen use; (3) hydration through oral and IV therapy; (4) electrolyte replacement, because hypoxia results in metabolic acidosis, which also promotes sickling; (5) analgesics for the severe pain from vasoocclusion; and (6) blood replacement to treat anemia and to reduce the viscosity of the sickled blood.[14]

- Lack of oxygen
- Strenuous physical activity
- Stress
- Trauma

Three less common types of sickle cell crisis are aplastic, hemolytic, and splenic sequestration. In *aplastic crisis* the bone marrow temporarily stops producing RBCs. In *hemolytic crisis* the RBCs break down too rapidly to be replaced adequately. *Splenic sequestration* usually is a childhood difficulty that occurs when blood becomes trapped in the spleen. This causes the organ to enlarge and possibly may lead to death.

MANAGEMENT

At this time, no cure exists for sickle cell disease. Because of the eventual damage that occurs to the spleen, patients with sickle cell disease are at increased risk for septicemia if infected by certain types of bacteria. Children with the disease should be current with all immunizations. When in crisis, these patients require prompt treatment with oxygen if hypoxic, intravenous therapy to manage dehydration, antibiotics to manage infection, and analgesics (e.g., ***morphine***) to manage pain (Box 32-9). In severe cases a blood transfusion may be indicated to effect a temporary replacement of hemoglobin S. Blood transfusions also can be advised during pregnancy to reduce the risk of a crisis, which can be fatal to the mother and fetus. Transfusions also may be advised before surgery because anesthesia can be hazardous to those with the disease.

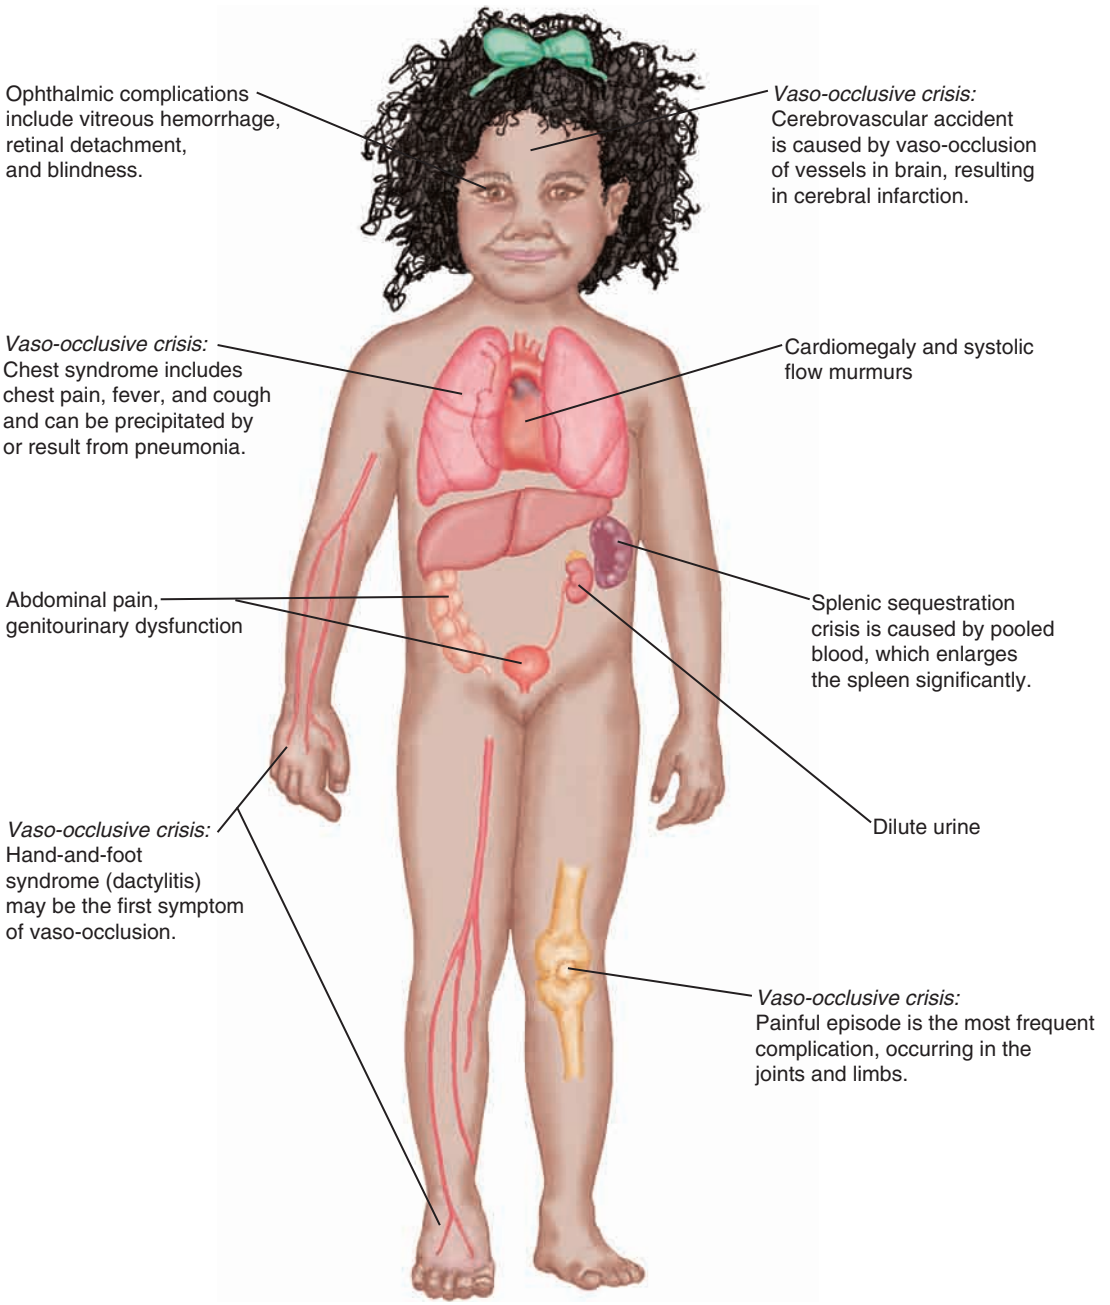

FIGURE 32-10 Pathophysiology of sickle cell disease. (From Ferguson DG, Fodden DI: *Accident and emergency medicine,* London, 1998, Churchill Livingstone.)

Multiple Myeloma

Multiple myeloma is a malignant neoplasm of the bone marrow. The tumor, composed of plasma cells, destroys bone tissue (especially in flat bones). This causes pain, fractures, hypercalcemia, and skeletal deformities. In myeloma the neoplastic cells produce large amounts of protein (*M protein*) that affect the viscosity of the blood. Masses of coagulated protein can accumulate within the tissues and impair function. Some patients with this disease die of kidney failure. The kidneys fail because of the buildup of proteins that infiltrate the kidneys and block the renal tubules. In many ways, multiple myeloma resembles leukemia. However, the plasma cell proliferation generally is confined to the bone marrow.

CRITICAL THINKING
Which are the flat bones?

Other disorders associated with multiple myeloma include proteinuria, anemia, weight loss, pulmonary complications from rib fracture, and recurrent infections from suppression of the immune system. Patient complaints associated with multiple myeloma may include weakness, skeletal pain, hemorrhage, hematuria, lethargy, weight loss, and frequent fractures.

Multiple myeloma occurs rarely before 40 years of age and then occurs increasingly with age. The disease is more common in males than in females and may have a heritable component.[1] Multiple myeloma is diagnosed through x-ray films, blood studies, and tumor biopsy. Treatment consists of chemotherapy with anticancer drugs, radiation therapy, plasma exchange, and bone marrow transplantation.

GENERAL ASSESSMENT AND MANAGEMENT OF PATIENTS WITH HEMATOLOGICAL DISORDERS

As stated previously, most patients with hematological disorders are knowledgeable about their disease. Often they call emergency medical services to help manage a "change" in their condition. They also may call to arrange for transportation to an emergency department for physician evaluation. The situations that invoke a call for emergency care vary by patient and disease. Common chief complaints can be classified by body system (Table 32-4).

Prehospital Care

In many cases the prehospital care for a patient with a hematological disorder will be mainly supportive. As with any other patient care encounter, however, the paramedic should perform a general assessment, a focused history, and focused physical examination. These measures will guide patient care. They also will help to determine the appropriateness of emergency transport. Some patients with hematological disorders will have complex medical histories. When possible, these patients should be transported to the primary hospital where they usually receive their medical care.

As referenced in Table 32-4, a patient with a hematological disorder may have a variety of complaints and physical findings. Some patient complaints may be vague as well. (Examples include fever, fatigue, and headache.) This can further complicate the paramedic's assessment. After ensuring adequate airway, ventilatory, and circulatory status, the paramedic should assess vital signs and perform a physical examination. The patient's skin should be assessed for color and turgor, noting any cyanosis or jaundice, warmth or coolness, bruising, edema, or ulcerations. The paramedic also should ascertain any new onset of fever, weakness, cough, rash, spontaneous bleeding (e.g., bleeding gums, epistaxis), vomiting, or diarrhea. Some hematological disorders can involve the ability of the blood to deliver enough oxygen to tissues. Thus the paramedic should question all patients with hematological disorders specifically about recent dizziness, syncope, difficulty breathing, and heartbeat irregularities.

Other key elements of the patient assessment and history include identifying existing hematological disease (including any family history of hematological disease), any significant medical history or recent injury, the patient's medication use (prescriptions and over-the-counter medications, herbal supplements), allergies, and alcohol or illicit drug use.

Based on the patient's condition, prehospital care measures may include oxygen administration, intravenous fluid replacement, the use of antidysrhythmics, and the administration of analgesics for pain management. Some of these patients will be gravely ill; calming and comfort measures for the patient and family should be provided.

TABLE 32-4 Chief Complaints of Patients with Hematological Disorders Classified by Body System

Body System	Complaints	Possible Causes
Central nervous system	Altered level of consciousness	Anemia, sickle cell disease
	Increased weakness, numbness	Autoimmune disease
	Visual disturbances/ loss of vision	Unilateral sensory deficits
Cardiorespiratory	Dyspnea/crackles	Heart failure
	Anemia	Bleeding disorders
	Pulmonary edema	Hemoptysis
	Chest pain	Tachycardia
Integumentary	Prolonged bleeding	Hemolytic anemia; polycythemia
	Bruising	Sickle cell disease; liver disease
	Itching/petechiae	
	Pallor	Jaundice
Musculoskeletal	Bone or joint pain	Autoimmune disease
	Fracture	Hemophilia
Gastrointestinal	Abdominal pain	Hemolytic anemia, viral disease
	Bleeding of gums/ gingivitis	Blood-clotting abnormalities
	Epistaxis	Autoimmune disease
		Generalized sepsis
	Ulceration	Melena/ hematemesis
Genitourinary	Hematuria	Sickle cell disease, bleeding disorders
	Menorrhagia/ amenorrhagia	
	Priapism	Infection
		Sexually transmitted disease

SUMMARY

- Blood is composed of cells and formed elements surrounded by plasma. About 95% of the volume of formed elements consists of RBCs (erythrocytes). The remaining 5% consists of WBCs (leukocytes) and cell fragments (platelets).
- Anemia is a condition in which the amount of hemoglobin or erythrocytes in the blood is below normal. Two common forms of anemia are iron deficiency anemia and hemolytic anemia. All forms of anemia share signs and symptoms. These signs and symptoms include fatigue and headaches, sometimes a sore mouth or tongue, brittle nails, and, in severe cases, breathlessness and chest pain. Diagnosis is made by history and from blood tests and bone marrow biopsy results.
- Leukemia refers to any of several types of cancer in which an abnormal proliferation of WBCs usually occurs in the bone marrow. The proliferation of leukemic cells crowds and impairs the normal production of RBCs, WBCs, and platelets. Leukemia is classified as acute or chronic. The proliferation of leukemic cells makes the patient highly susceptible to serious infections, anemia, and bleeding episodes. The diagnosis is confirmed by bone marrow biopsy.
- Lymphoma refers to a group of diseases that range from slowly growing chronic disorders to rapidly evolving acute conditions. Hodgkin's disease is one type; all others are called non-Hodgkin's lymphomas.
- Polycythemia is characterized by an unusually large number of RBCs in the blood as a result of their increased production by the bone marrow. Polycythemia may be a natural response to hypoxia. (This is known as secondary polycythemia.) Polycythemia also may occur for unknown reasons. (This is known as primary polycythemia.)
- Disseminated intravascular coagulopathy is a complication of severe injury, trauma, or disease. It disrupts the balance among procoagulants, thrombin formation, inhibitors, and lysis. Signs and symptoms of disseminated intravascular coagulation include dyspnea, bleeding, and symptoms associated with hypotension and hypoperfusion. The treatment is aimed at reversing the underlying illness or injury that triggered the event.
- Hemophilia A is caused by a deficiency of a blood protein called factor VIII. Hemophilia B is caused by a deficiency of factor IX. Bleeding from hemophilia can occur spontaneously, after even minor injury, or during some medical procedures.
- Thrombocytopenia is a low platelet count. It can occur when the body does not produce enough or destroys too many platelets, or if the spleen retains too many platelets. Bleeding is the chief complication of thrombocytopenia.
- Sickle cell disease is a debilitating and unpredictable recessive genetic illness. It affects persons of African descent. Less often, it affects persons of Mediterranean origin. Sickle cell anemia produces an abnormal type of hemoglobin. This is called hemoglobin S. This abnormal type has an inferior oxygen-carrying capacity. Complications of sickle cell disease include episodes of severe pain, fatigue, pallor, jaundice, stroke, delayed growth, hematuria, priapism, and splenomegaly.
- Multiple myeloma is a malignant neoplasm of the bone marrow. The tumor destroys bone tissue (especially flat bones). This causes pain, fractures, hypercalcemia, and skeletal deformities.
- In many cases of hematological disorders, the prehospital treatment is supportive. Treatment includes ensuring adequate airway, ventilatory, and circulatory support.

CHAPTER

33 Nontraumatic Musculoskeletal Disorders

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Outline musculoskeletal structure and function.
2. Describe how to perform a detailed assessment of the extremities and spine.
3. Specify questions in the patient history that help identify musculoskeletal problems.
4. Describe assessment and management of specific nontraumatic musculoskeletal disorders based on an understanding of the pathophysiology.

KEY TERMS

appendicular skeleton The bones of the upper and lower extremities.

arthritis An inflammatory condition of the joints, characterized by pain and swelling.

atrophy Decrease in size (shrinkage) of a cell, which adversely affects cell function.

axial skeleton The bones of the head, neck, and torso.

benign A noncancerous tumor or harmless condition.

bone spurs Bony growths formed on normal bone.

bone tumor An abnormal growth of cells within a bone; may be malignant or benign.

bursa A small sac containing synovial fluid that helps ease friction between a tendon and skin or between a tendon and bone.

bursitis An inflammation of the bursa, the connective tissue structure surrounding a joint.

carpal tunnel syndrome An entrapment neuropathy that occurs when the median nerve becomes pressed or squeezed at the wrist in the carpal tunnel.

cartilaginous joints Joints that are slightly movable.

cauda equina syndrome A rare disorder of the lumbar spine that affects the bundle of nerve roots at the lower end of the spinal cord; a surgical emergency.

chronic fatigue syndrome A debilitating and complex disorder, characterized by profound fatigue that is not improved by bed rest and that may be worsened by physical or mental activity.

dermatomyositis An inflammatory myopathy characterized by a skin rash that precedes or accompanies progressive muscle weakness.

diskectomy The surgical removal of a disk.

epiphyseal plate The site of bone elongation; also known as the *growth plate*.

fascia The loose areolar connective tissue found beneath the skin or dense connective tissue that encloses and separates muscle.

fasciitis Inflammation of the fascia.

fibromyalgia A disorder that causes extreme fatigue; associated with "tender points" on the neck, shoulders, back, hips, arms, and legs.

fibrous joints Joints that are immovable.

flexor tenosynovitis A pathological state that causes a disruption of tendon function in the hand; usually the result of infection.

gait A manner of walking or moving on foot.

gangrene Dead or dying body tissues attributable to blood supply that is lost or inadequate.

gout A disease associated with an inborn error of uric acid metabolism that increases production of or inter-feres with excretion of uric acid; also known as *hyperuricemia*.

herniated disk Occurs when all or part of a spinal disk is forced through a weakened part of the disk.

inflammatory myopathies A group of diseases that involve chronic muscle inflammation accompanied by muscle weakness.

joint Any one of the connections between bones that are classified according to structure and mobility as fibrous, cartilaginous, or synovial. *Fibrous joints* are immovable, *cartilaginous joints* are slightly movable, and *synovial joints* are freely movable.

joint disorder Any disease or injury that affects human joints.

kyphosis An abnormal condition of the vertebral column characterized by increased convexity in the curvature of the thoracic spine as viewed from the side.

ligament A band of white, fibrous tissue that connects bones.
lordosis An inward curvature in the lumbar spine that is normally present to some degree.
malignant Very dangerous or virulent; likely to cause death; a cancerous tumor that tends to metastasize—the ability of cancer cells to move or spread from one organ or tissue to distant locations in the body.
muscle strain A slight tear in a muscle or tendon.
muscle tone The constant tension produced by muscles of the body for long periods of time.
muscular system The body system responsible for execution of movement and postural maintenance.
musculoskeletal system The body system comprises bones, muscles, tendons and ligaments, and articulating surfaces (e.g., joints, bursae, disks).
myalgia Diffuse muscle pain, usually accompanied by malaise; it occurs in many infectious diseases.
myositis A muscular disorder characterized by progressive muscle weakness and wasting; also known as *inclusive body myositis*.
necrotizing fasciitis A rare infection of the deep layers of the skin and subcutaneous tissues.
osteoarthritis A form of arthritis in which one or many joints undergo degenerative changes.
osteomyelitis Local or generalized infection of bone and bone marrow, usually caused by bacteria introduced by trauma or surgery.
paronychia A common skin infection that occurs around the nails and that allows for an invasion of bacteria, yeast, or fungus.
pathological fracture A fracture that results from weakness in the bone caused by trauma, metabolic disease (such as osteoporosis), or tumor.
piriformis syndrome A neuromuscular disorder associated with irritation or compression of the sciatic nerve.
point-to-point movements Refers to methods used to evaluate a patient's coordination.
polymyositis Slow, but progressive muscle weakness that affects skeletal muscle on both sides of the body.
postural maintenance The result of muscle tone responsible for keeping the back and legs straight, the head in an upright position, and the abdomen from bulging; also balances the distribution of body weight.
primary tumor A malignant tumor in the original site where it first arose.
pseudogout Inflammation caused by *calcium pyrophosphate* (CPP) crystals; often clinically indistinguishable from gout.
rheumatoid arthritis A chronic, sometimes deforming destructive collagen disease that has an autoimmune component.
sciatica Inflammation of the sciatic nerve.
scoliosis A lateral curvature of the spine.
secondary tumor A malignant tumor that originates in one area of the body and spreads to another area of the body.
septic arthritis A condition that results from direct invasion of the joint space by various microorganisms; also known as *infectious arthritis*.
skeletal muscle Muscle tissue that appears microscopically to consist of striped myofibrils; also known as *striated muscle* and *voluntary muscle.*
skeletal system The body system comprises bones, muscles, tendons and ligaments, and articulating surfaces (e.g., joints, bursae, disks).
slipped capital femoral epiphysis A separation of the ball of the hip joint from the femur at the upper, growing end (growth plate) of the bone.
spinal stenosis Narrowing of the spinal canal.
sprain A partial tearing of a ligament caused by a sudden twisting or stretching of a joint beyond its normal range of motion.
stance The position of the body while standing.
strain An injury to the muscle or its tendon from overexertion or overextension.
synovial joints Joints that are freely movable.
tendon A band or cord of dense connective tissue that connects muscle to bone or other structures; it is characterized by strength and nonstretchability.
tendonitis An inflammatory condition of a tendon, usually caused by a sprain.
ulnar nerve entrapment An injury that occurs when the ulnar nerve in the arm becomes compressed.

Nontraumatic musculoskeletal disorders are common afflictions. These diseases cause pain in the bones, joints, muscles, and surrounding structures. Although the disorders are often associated with aging, they can affect all age groups and frequently cause impairments, disabilities, and handicaps. Nontraumatic musculoskeletal disorders are rarely life threatening. Paramedics, however, should be familiar with these common ailments and the supportive care required for these patients. Box 33-1 lists the musculoskeletal disorders discussed in this chapter.[1]

(Courtesy Ray Kemp, St. Charles, Mo.)

BOX 33-1 Musculoskeletal Disorders

Bony abnormalities
Disorders of the spine
Joint abnormalities
Muscle abnormalities
Overuse syndromes
Soft tissue infections

NOTE

Approximately 33% of adults in the United States are affected by musculoskeletal disorders that limit range of motion or cause pain in a joint or an extremity.[2]

ANATOMY AND PHYSIOLOGY REVIEW

As described in Chapter 10, the musculoskeletal system comprises bones, muscles, tendons and ligaments, and articulating surfaces (e.g., joints, bursae, disks). This discussion will provide a brief review of the skeletal system and the muscular system.

LOOK AGAIN

See Chapter 10: Review of Human Systems, pp. 158-171.

The Skeletal System

The **skeletal system** contains the bony structures that provide support and protection for the body. It also provides a system of levers on which muscles act to produce body movement. The skeletal system contains 206 individual bones. These bones are divided into two categories: the **axial skeleton** and the **appendicular skeleton**. The axial skeleton contains the skull, hyoid bone, vertebral column, and thoracic cage. The appendicular skeleton contains the bones of the upper and lower extremities and their girdles, by which they are attached to the body (Figure 33-1).

Body movement is made possible by bones that are connected to other bones. With the exception of the hyoid bone, every bone in the body connects to at least one other bone by way of **joints.** The three major classes of joints are fibrous, cartilaginous, and synovial. **Fibrous joints** consist of two bones that have little or no movement and are united by fibrous tissue. An example of a fibrous joint is the suture in skull bones. **Cartilaginous joints** unite two bones by means of hyaline cartilage and fibrocartilage. These types of joints are slightly movable. Examples of cartilaginous joints are the **epiphyseal plate** of a growing bone and junctions of the intervertebral disks. **Synovial joints** contain synovial fluid that allows for considerable movement. Most joints that unite the bones of the appendicular skeleton are synovial. Examples of synovial joints are the hinge joint of the elbow and knee and the ball-and-socket joints of the shoulder and hip. Figure 33-2 illustrates the movement found in different kinds of joints.

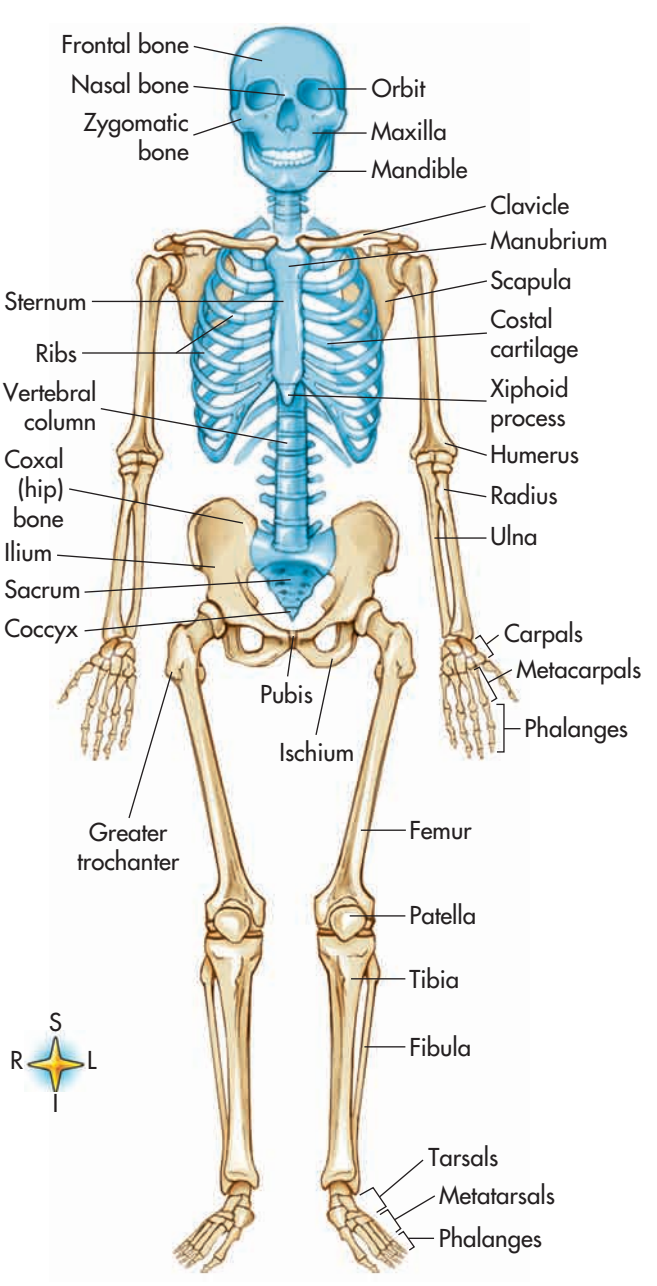

FIGURE 33-1 Skeleton. (From McCance KL, Huether SE: *Pathophysiology: the biologic basis for disease in adults and children,* ed 5, St Louis, 2006, Mosby.)

The Muscular System

The **muscular system** is responsible for execution of movement and postural maintenance. The major types of muscles are skeletal, cardiac, and smooth muscle. Of the three types, skeletal muscle is most common and is the focus of this chapter. It is also the muscle type most involved in musculoskeletal disorders. Skeletal muscles are attached to bones

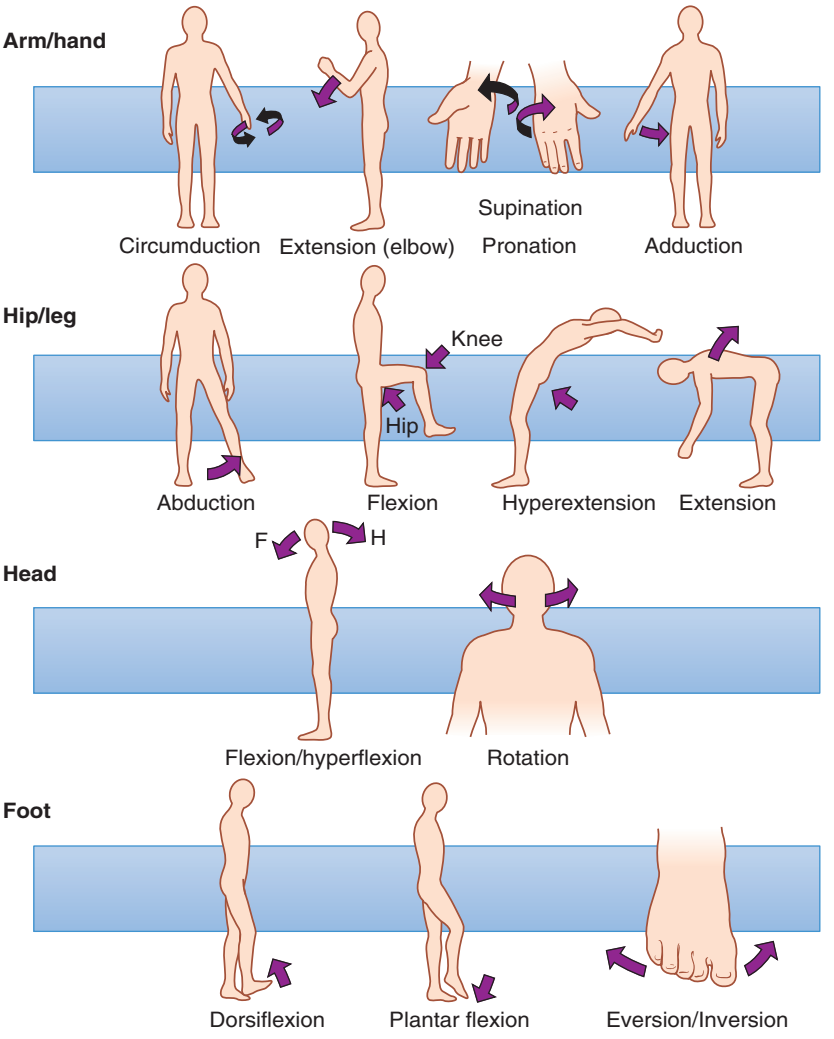

FIGURE 33-2 Joints.

by **tendons**. **Ligaments** connect bone or cartilage and help strengthen and support joints.

Skeletal muscle has specialized contractile cells known as *muscle fibers*. When a nerve impulse passes through the muscle fiber, specialized chemicals cause the muscle to contract. Most skeletal muscles extend from one bone to another and cross at least one joint. The contraction of some muscles and the simultaneous relaxation of other muscles produce body movement. These movements are made possible by pulling one of the bones toward the other across a movable joint.

Postural maintenance is the result of muscle tone. **Muscle tone** is the constant tension produced by muscles of the body for long periods of time. This tone is responsible for keeping the back and legs straight, the head in an upright position, and the abdomen from bulging. Postural maintenance also balances the distribution of body weight. This balance puts less strain on muscles, tendons, ligaments, and bones.

GENERAL ASSESSMENT STRATEGIES

As described in Chapter 20, the general assessment of a patient's musculoskeletal system includes an examination of the extremities, spine, vascular system, and motor system. The purpose of the assessment is to identify abnormal findings, which may include[1]:

- Pain or tenderness
- Swelling
- Abnormal or loss of movement
- Decreased sensation
- Circulatory changes
- Deformity

LOOK AGAIN
See Chapter 20: Secondary Assessment, pp. 546-554.

Extremity Exam

The patient's extremities should be examined for function and structure. General appearance, body proportions, and ease of movement should be noted. Other important observations are limitation in the range of motion, or an unusual increase in the mobility of a joint. Abnormal findings may include signs of inflammation (swelling, tenderness, increased heat, redness, decreased function), asymmetry, crepitus, deformities, decreased muscular strength, and **atrophy** (muscle wasting).

An assessment of the upper and lower extremities should include an evaluation of the skin and tissue overlying the muscles, cartilage, and bones. It should also include an assessment of the joints for soft tissue injury, discoloration, and swelling (Chapter 38). The upper and lower extremities should be reasonably symmetrical in structure and muscularity. Skin color, temperature, sensation, and the presence of distal pulses will help determine the circulatory status of each extremity. The patient's joints should be assessed for full range of motion. All movement should be made without pain, deformity, limitation, or instability.

Hands and wrists: The patient's hands and wrists should be inspected for contour and positional alignment. The hands, wrists, and joints of each finger should be assessed for tenderness, swelling, and deformity.

Elbows: The patient's elbows should be assessed and palpated in both flexed and extended positions. All movement should be made without pain or discomfort.

Shoulders: Both shoulders should be symmetrical and should be palpated for integrity of the clavicles, scapulae, and humeri. In addition, the patient should be able to shrug the shoulders and raise and extend both arms without pain or discomfort.

Pelvis and hips: Structural integrity of the patient's iliac crest and symphysis pubis should be assessed to determine stability. There should be no deformity or point tenderness during palpation.

Knees: The knees should be inspected and palpated for swelling and tenderness. The patella should be nontender and in midline position. The patient should be able to bend and straighten each knee without pain.

Ankles and feet: The ankles and feet should be inspected for contour, position, and size. Tenderness, swelling, and deformity are abnormal findings. The patient's toes should be straight and aligned with each other. The surface of the ankles and feet should be free of deformities, nodules, swelling, and calluses.

Spine Exam

A visual assessment should be made of the patient's cervical, thoracic, and lumbar curves. Abnormal findings may include curvature of the spine from abnormal **lordosis**, **kyphosis**, and **scoliosis**. In addition, there should be no major differences in the height of the shoulders or iliac crest that might result from abnormal spinal curvature.

The patient's neck should be in a midline position. The posterior neck should be free of point tenderness and swelling. In addition, the patient should be able to bend the head forward, backward, and from side to side without pain or discomfort.

The patient's thoracic lumbar spine should be inspected for signs of injury, swelling, or discoloration. In a normal exam, the spine is nontender to palpation.

Vascular Exam

As described in Chapter 10, the peripheral vascular system includes arteries, veins, the lymphatic system, and the fluids exchanged in the capillary beds. An assessment of the vascular system should be part of the general assessment strategy. The patient's upper and lower extremities should be assessed for color and texture and for arterial insufficiency. Lymph nodes should be nonswollen and nontender. Abnormal findings in a vascular exam include:

- Pale or cyanotic skin
- Weak or diminished pulses
- Skin that is cold to the touch
- Absence of hair growth
- Pitting edema

Motor Exam

The patient should be observed while moving and while at rest. Any abnormal or involuntary movements should be noted, as well as the patient's posture, level of activity, and fatigue. Muscle strength should be equal on both sides of the body. Patients should be assessed for agility and tested for flexion, extension, and abduction of the upper and lower extremities.

Coordination can be evaluated for point-to-point movements, gait, and stance. Examples of **point-to-point movements** include touching the finger to the nose and touching each heel to the opposite shin. Methods to evaluate **gait** include asking the patient to walk toe to toe, walk on the toes, and walk on the heels. As described in Chapter 20, **stance** and balance can be evaluated though the *Romberg test* and the *pronator drift test*.

Finally, a healthy patient should be responsive to sensations of pain, temperature, position, vibration, and touch. These are conducted by the sensory pathways of the nervous system. Sensory exams can be performed on conscious patients by using light touch on each hand and each foot. The exam should proceed from head to toe and be symmetrical on both sides of the body.

GENERAL MANAGEMENT STRATEGIES

General management strategies for a patient with a musculoskeletal disorder are the same as those for most other patient care encounters. Prehospital care will be guided by

the patient's chief complaint and the severity of the patient's condition. General management strategies include:

- Scene size-up to ensure personal safety
- A primary survey to ensure airway, ventilation, and circulation
- Secondary assessment and reassessment
- Pharmacological and nonpharmacological measures to ensure comfort
- Transport considerations
- Effective therapeutic communications

The Patient History

The patient history should be thorough and focused on the patient's chief complaint. In addition to the general medical history described in Chapter 18, specific questions to ask a patient with a musculoskeletal disorder are listed in Box 33-2.

Management Guidelines

Prehospital care for most musculoskeletal disorders will be primarily supportive. Management most often is limited to immobilization of the affected area or body part; application of ice and/or elevation of an extremity to reduce pain and swelling; administration of analgesics to relieve pain; and gentle transport for physician evaluation.

BOX 33-2 Questions to Ask for Musculoskeletal Disorders

Complaint: Joint Pain

Where is the specific site of pain?
Does the pain change during the course of the day?
Have you had a recent injury?
How long has there been pain in the joint?
Does the pain get better or worse with movement?

Complaint: Muscle Weakness

Is the weakness widespread or isolated to one area?
Is the weakness related to a painful extremity?
Does the weakness fluctuate or is it constant?
Is the weakness increasing in severity?
Is the weakness associated with sensory changes?
Is there a family history of muscle disease?
Is the weakness the same on both sides of the body?

Complaint: Back Pain

Is the pain confined to the back or does it radiate to the upper or lower limbs?
Is the pain made worse by coughing or sneezing?
Was the pain sudden or gradual in onset?

Complaint: Gait or Balance Issues

Do you trip when walking?
Do you stagger to one particular side?
Do you ever injure yourself when walking?

OSTEOMYELITIS

Osteomyelitis is an acute or chronic bone infection; it affects 2 out of every 10,000 people.[3] The infection can be caused by a number of microbial agents, most commonly *Staphylococcus aureus*. Osteomyelitis also can develop from an open fracture or minor wound infection. It can also result from systemic infection (e.g., urinary tract infection, pneumonia) that allows bacteria to spread in the bloodstream and enter the bone. If left untreated, the infection can become chronic, resulting in a decreased blood supply to the bone and eventual death of the bone tissue. Osteomyelitis affects both children and adults and can affect any bone. In adults the vertebrae and pelvis are most often affected by the disease; in children the long bones are most often involved. Those at increased risk for developing osteomyelitis include:

- People who have undergone recent orthopedic surgery
- The elderly
- Intravenous (IV) drug abusers
- People with sickle cell disease
- People receiving hemodialysis
- People with compromised immune systems

Signs, Symptoms, and Patient Care

Signs and symptoms of osteomyelitis are listed in Box 33-3. The disease is diagnosed using blood tests to confirm infection, and blood cultures to identify the bacteria. Other diagnostic tools include needle aspiration, biopsy, and bone scans. Once the diagnosis has been made, patients are treated with oral or IV antibiotics to manage the infection and to prevent reinfection. Other care may include surgical drainage of a wound or abscess, immobilization of the affected bone or surrounding joints, and sometimes surgery to scrape the infection from the affected bone. In rare cases, amputation of an affected limb may be required.

BONE TUMORS

A **bone tumor** is an abnormal growth of cells within a bone. The tumor can be **malignant** (cancerous) or **benign** (noncancerous). Most bone tumors are benign and not life threatening. Common bone tumors that are benign include *nonossifying fibroma unicameral bone cyst*, *osteochondroma*, *giant cell tumor*, *enchondroma*, and *fibrous dysplasia*.

Malignant tumors can spread cancer cells throughout the body (**metastasize**) via blood or the lymphatic system. A malignant tumor that is in the original site where it first arose is a **primary tumor** (Figure 33-3). A malignant tumor that originates in another area of the body and spreads to the bone is a **secondary tumor.** The four most common types of primary bone tumors are[4]:

Multiple myeloma: Multiple myeloma is the most common primary bone cancer. It is a malignant tumor of bone marrow. Multiple myeloma affects approximately 20 people per million each year. Most cases are seen in patients between the ages of 50 and 70 years old. Any bone can be involved.

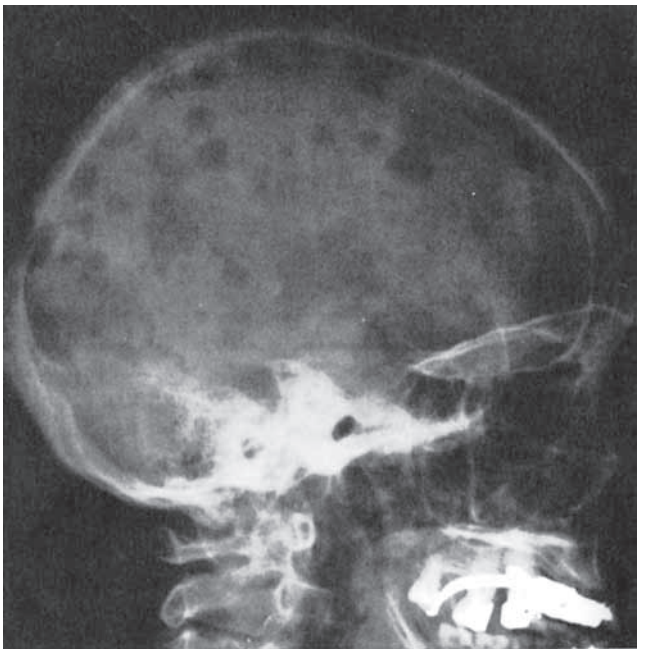

FIGURE 33-3 Multiple myeloma of the skull. Radiograph shows punched-out bone lesions filled with soft tumor. (From Gould BE, Dyer R: *Pathophysiology for the health professional,* ed 4, St Louis, 2011, Saunders.)

BOX 33-3 Signs and Symptoms of Osteomyelitis

- Pain and/or tenderness in the infected area
- Swelling and warmth in the infected area
- Fever, chills
- General malaise
- Drainage of pus through the skin
- Excessive sweating
- Back or neck pain (if the spine is involved)
- Swelling of the ankles, feet, and legs
- Walking that is painful or with a limp

Osteosarcoma: Osteosarcoma is the second most common bone cancer. It occurs in two or three new people per million people each year. Most cases occur in teenagers. Most tumors occur around the knee. Other common locations include the hip and shoulder.

Ewing's sarcoma: Ewing's sarcoma most commonly occurs between 5 and 20 years of age. The most common locations are the upper and lower leg, pelvis, upper arm, and ribs.

Chondrosarcoma: Chondrosarcoma occurs most commonly in patients between 40 and 70 years of age. Most cases occur around the hip and pelvis or the shoulder.

Signs, Symptoms, and Patient Care

Most patients with a bone tumor experience a dull or aching pain in the area of the tumor. The pain is sometimes made worse with physical activity and often awakes the patient at night. Other patients will not complain of pain, but will have discovered a painless mass on self-examination. Pathological fractures are common in these patients. These fractures result from trauma or a metabolic disease, such as osteoporosis, in which the bone weakened by the tumor breaks.

NOTE

A *pathological fracture* is a break at the site of a preexisting abnormality, usually by force that would not fracture a normal bone. Any disease process that weakens a bone (especially the cortex) predisposes the bone to pathological fracture. Pathological fractures are commonly associated with tumors, osteoporosis, infections, and metabolic bone disorders.[5] In some of these patients very minor trauma or even no apparent trauma (e.g., turning over in bed) can cause a pathological fracture.

Benign tumors may or may not require treatment (depending on the specific tumor). Some benign tumors can be aggressive and quickly destroy bone. Malignant tumors may require medication therapy or surgical removal. Still other tumors resolve on their own (especially some bone tumors in children). Most malignant tumors are surgically removed and treated with radiation. If the cancer has metastasized, other treatment may include additional radiation, chemotherapy, and *cryosurgery* (the freezing and killing of cancer cells with liquid nitrogen). In some patients, a bone implant or amputation of an affected limb will be needed. Patient follow-up with regular blood tests and x-ray is required because bone cancer can recur. People who have had bone cancer, particularly children and adolescents, have an increased likelihood of developing another type of cancer, such as leukemia, later in life.[6]

LOW BACK PAIN

Most everyone at some point has back pain that interferes with work, routine daily activities, or recreation. Americans spend at least $50 billion each year on low back pain, the most common cause of job-related disability and a leading contributor to missed work. Back pain is the second most common neurological ailment in the United States. Only headache is more common.[7]

As described in Chapter 10, the vertebral column consists of 26 bones that are divided into 5 regions: 7 cervical vertebrae, 12 thoracic vertebrae, 5 lumbar vertebrae, 1 sacral bone, and 1 coccygeal bone. Together, the vertebrae protect the spinal cord, the rootlets, and the 31 pairs of spinal nerves that convey sensation. The weight-bearing portion of the vertebra is a bony vertebral body. Intervertebral disks are located between the bodies of adjacent vertebrae and serve as shock absorbers (Figure 33-4). The disks allow for

flexibility of the back. They also prevent the vertebral bodies from rubbing against each other.

Low back pain may be classified as *acute* or *chronic*. Acute back pain is usually of short duration, lasting only a few days to a few weeks. Most acute back pain is caused by trauma to the lower back (e.g., a sports injury or heavy lifting). It can also be caused by arthritis or other degenerative joint disease of the spine, viral infections, and congenital abnormalities. Chronic back pain is back pain that persists for 3 or more months. Although the cause of chronic back pain can be difficult to determine, it can be progressive and debilitating. The conditions discussed in this chapter are disorders of the intervertebral disks, cauda equina syndrome, and sprains and strains of the muscles and supporting structures of the back.

NOTE

Prehospital care for patients with low back pain is primarily supportive. Most care is focused on obtaining a thorough history and providing comfort measures and gentle transport for physician evaluation. Physicians investigate most cases of low back pain through x-rays, MRI (magnetic resonance imaging) scans, and CT (computed tomography) scans.

Disorders of the Intervertebral Disks

As stated previously, the intervertebral disks are found between the bodies of the vertebrae. They act as shock absorbers, prevent the bones of the spine from grinding against each other, and allow for flexibility of the back. Each disk has a central area composed of a jelly-like substance, called the *nucleus pulposus*. This structure is surrounded by concentric rings of fibrous tissue (*annulus fibrosus*). Undue stress (along with degenerative disease) on a disk can force the gel against the inner ring and crack it. From there, the gel pushes outward, cracking successive rings in its path. If stress on the back is severe enough, the vertebral disks and fibrous tissues can be damaged, causing the disk to bulge or protrude. If the gel eventually breaks through the outer ring, it can pinch the nerve root leading from the vertebra. This can result in a "slipped" or **herniated disk** (Figure 33-5).

Disk injury most often affects the lumbar spine in patients 25 to 45 years of age. The most common risk factor for developing lumbar disk disease is lack of exercise that allows the muscles of the back to weaken. Symptoms of a herniated disk vary greatly depending on the position of the herniated disk and the size of the herniation. Common signs and symptoms may include:

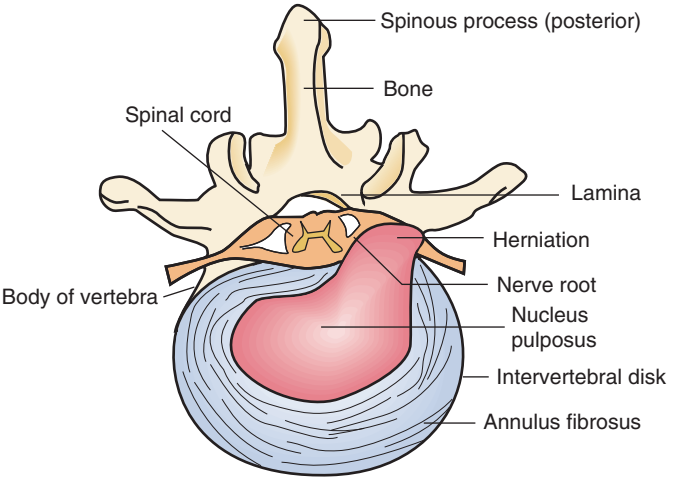

FIGURE 33-5 Herniated intervertebral disk. (From Gould BE, Dyer R: *Pathophysiology for the health professional,* ed 4, St Louis, 2011, Saunders.)

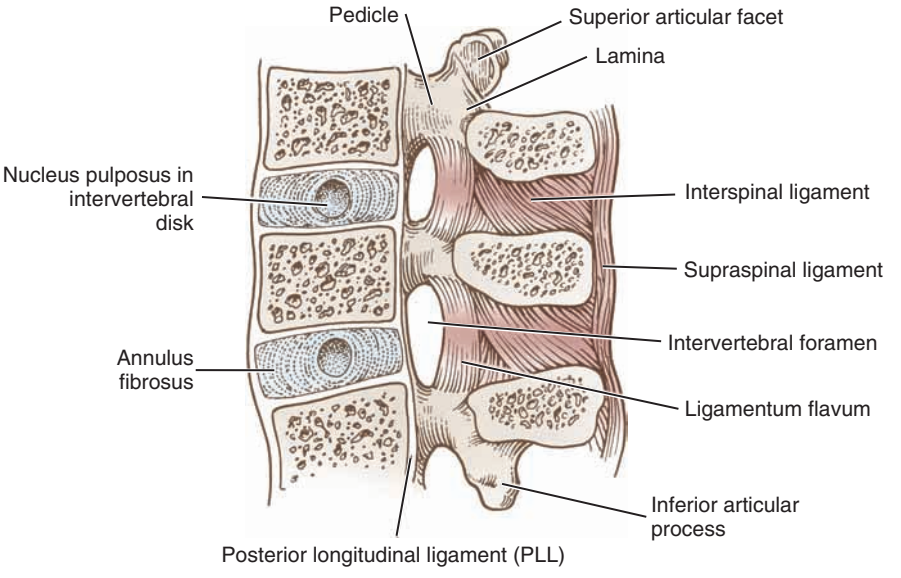

FIGURE 33-4 Median section through three lumbar vertebrae, showing intervertebral disks (nuclei pulposi). (From Rothrock JL: *Alexander's care of the patient in surgery,* ed 13, St Louis, 2007, Mosby.)

- Low back ache
- Numbness or weakness in the lower extremities
- Deep muscle pain and muscle spasms
- Acute or gradual leg pain (usually in only one leg)
- "Shooting" pain in the leg when sneezing, coughing, or straining; may be aggravated by sitting, prolonged standing, bending, or twisting
- Nerve-related symptoms, including muscle weakness in one or both legs, pain in the front of the thigh, and sciatica (Box 33-4)

The goals of treatment for a herniated disk are to relieve pain, weakness, or numbness in the leg caused by pressure on the spinal nerve root or spinal cord. Most patients are first treated with bed rest, analgesics, antiinflammatories, muscle relaxants, and corticosteroids. Physical therapy and exercise programs can help strengthen the back and prevent recurrent injury. Most herniated disks heal without surgery to remove the herniated disk (**diskectomy**).

Cauda Equina Syndrome

Cauda equina syndrome is a rare disorder of the lumbar spine that affects the bundle of nerve roots at the lower end of the spinal cord. It is a surgical emergency that occurs when the nerve roots are compressed and paralyzed, cutting off sensation and movement. If not treated, the syndrome can result in permanent paralysis, impaired bladder and bowel function, and loss of sexual sensation. Even with surgery to relieve the pressure on nerve roots, nerve damage may be irreversible.

Cauda equina syndrome can be caused by a herniated disk, spinal tumor, infection, and **spinal stenosis** (narrowing of the spinal canal). It can also result from spinal trauma, including direct trauma, falls, gunshot wounds, and stabbings. (Children born with spinal abnormalities also can develop the syndrome.) Signs and symptoms of cauda equina syndrome vary in intensity and may evolve slowly over time. These include:

- Bladder and/or bowel dysfunction (loss of control; inability to urinate or defecate)
- Severe or progressive weakness in the lower extremities
- Loss of sensation or an altered sensation between the legs, over the buttocks, the inner thighs and back of the legs (saddle area), and feet and heels
- Pain, numbness, or weakness that spreads to one or both legs and may cause a stumbling gait or difficulty rising from a sitting position

Sprains and Strains of the Lower Back

The lower back carries much of the body's weight during walking, running, lifting, and other activities. Because muscles, ligaments, and bones of the spine provide control and strength for many movements, sprains and strains of the lower back (especially the lumbar spine) are common injuries. They are often caused by twisting or pulling and from improper lifting that puts the back at risk for injury. It is estimated that 50% of all EMS personnel develop back pain every year and that one in four will have a career-ending back injury within the first 4 years of service.[9,10]

BOX 33-4 Sciatica

Sciatica *(sciatic neuralgia)* is a symptom of inflammation of the sciatic nerve. The sciatic nerve is the largest nerve in the body. It runs from the spinal cord to the buttock and hip area and down the back of each leg. This nerve innervates muscles in the back of the knee and lower leg. It also provides sensation to the back of the thigh, lower leg, and sole of the foot. Inflammation of the sciatic nerve causes pain, weakness, numbness, and tingling along its path. Sciatica usually affects only one leg.

Sciatica is a common condition that occurs in about 40% of adults.[8] It is often caused by a herniated disk or spinal stenosis. It can also be caused by injury (e.g., pelvic fracture) or piriformis syndrome (a neuromuscular disorder associated with irritation or compression of the sciatic nerve). Although the discomfort of sciatica can be severe and debilitating, it usually resolves without treatment or surgery in 4 to 8 weeks.

A **strain** is an injury to a muscle or tendon. A **sprain** is the stretching or tearing of a ligament beyond its normal range of movement. Differentiating a sprain from a strain is difficult and unnecessary in the prehospital setting. The signs, symptoms, treatment, and prognosis for both conditions are the same. Signs and symptoms include pain, warmth, muscle spasms, and swelling of the affected area. Most muscle sprains and strains of the lower back are successfully treated with bed rest for 24 to 48 hours to allow the back to heal. Analgesics, muscle relaxants, and antiinflammatories may be prescribed. Physical therapy and exercise programs can help to strengthen the back muscles and prevent future injury. Back pain that does not resolve with these measures will require further evaluation.

JOINT DISORDERS

A **joint disorder** is any disease or injury that affects human joints. These disorders may be short-lived or chronic. The joint disorders discussed in this chapter are those that produce inflammation as a result of disease. These include various forms of arthritis. Joint disorders that result from trauma are discussed in Chapter 44.

Arthritis

Arthritis is an inflammatory condition of the joint, characterized by pain and swelling. The disease limits the activity of nearly 19 million adults and is the most common cause of disability in the United States.[11] Although there are many kinds of arthritis, the disease can be grouped into three general categories: osteoarthritis, rheumatoid arthritis, and gout.

NOTE

Like most other nontraumatic musculoskeletal disorders, prehospital care is primarily supportive. Care is often limited to providing comfort measures and gentle transport for physician evaluation. Physician care for most joint disorders includes a combination of patient education, physical therapy, weight control, and medications to reduce pain and inflammation. In some cases, surgery or joint replacement may be indicated.

OSTEOARTHRITIS

Osteoarthritis is a chronic, degenerative joint disease, most often seen in people more than 40 years old. The onset of the disease is gradual and affects women more often than men. Osteoarthritis is mechanical in nature, resulting from normal wear-and-tear on joints over the course of a person's life. It is marked by the breakdown of cartilage that covers the surfaces of joints, and the formation of **bone spurs** (bony growths formed on normal bone). The wearing away of cartilage and the overgrowth of bone lead to pain and stiffness. As the disease progresses, bone rubs against bone, causing severe pain and reduced mobility. The joints most commonly affected are those in the knees, hips, hands, and the cervical and lumbar spine (Box 33-5).

NOTE

Osteoarthritis and *osteoporosis* have similar names, but are very different conditions. Osteoporosis is a preventable disease characterized by the loss of bone tissue, causing the bones to weaken and easily fracture. Osteoporosis is not a form of arthritis, although the two can occur together. The two diseases develop differently, have different symptoms, and are diagnosed and treated differently. Osteoporosis affects mainly postmenopausal women. It will be described in Chapter 49.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is an inflammatory disease of the joints that causes pain, swelling, stiffness, and loss of function. It is estimated that about 1.3 million people in the United States have the disease.[13] It occurs in all races and ethnic groups. Symptoms of the disease usually become apparent in middle and later life, but can also develop in young adults and children (Box 33-6). RA develops when lymphocytes travel to the synovium in the joints, causing inflammation (**synovitis**). During this process, the normally thin synovium becomes thick and makes the joint swollen and puffy to the touch. As the disease progresses, the inflamed synovium invades and damages the cartilage and bone of the joint. Surrounding muscles, ligaments, and tendons become weakened. Rheumatoid arthritis also can cause more generalized bone loss that may lead to osteoporosis. Unlike other forms of arthritis where only a specific joint is affected, RA generally occurs in a symmetrical pattern (e.g., both hands, both knees). A hallmark of the disease is visible swelling and inflammation of the finger joints closest to the affected hand (Figure 33-6). RA may also affect other areas of the body (neck, shoulder, elbows, feet), and is often associated with fatigue, occasional fever, and general malaise.

NOTE

Juvenile rheumatoid arthritis (JRA) and *juvenile idiopathic arthritis* (JIA) are classification systems for chronic arthritis in children. Most forms of juvenile arthritis are autoimmune disorders. Children with the disease are thought to have a genetic predisposition to it. Development of the disease is then triggered by an environmental factor, such as a virus. The most common symptoms of all types of juvenile arthritis are persistent joint swelling, pain, and stiffness that is typically worse in the morning or after a nap. The pain may limit movement of the affected joint, although many children, especially younger ones, will not complain of pain. Other symptoms include high fever and rash. Children with RA require multidisciplinary treatment and specialty care.

SHOW ME THE EVIDENCE

This retrospective review examined patient records from 1996 to 2005. The researchers reviewed mechanism of injury; prehospital, emergency, and hospital care; and neurological outcome of spinal cord injured (SCI) patients with a history of ankylosing spondylitis. Of the 18 patients identified, SCI in 15 was associated with trauma and the other 3 cases were related to surgery. Four patients died before discharge whereas four were able to walk assisted and seven were in a wheelchair. The researchers concluded that neurological deficits were initially subtle in this group of SCI patients. They also found that extension of the spine during care caused neurological deficits. They recommend cervical alignment in the patient's normal kyphotic flexed position during care.

Thumbikat P, Hariharan R, McClelland M: Spinal cord injury in patients with ankylosing spondylitis: a 10-year review, *Spine* 32(26):2989-2995, 2007.

Patients with RA have varying degrees of the disease. Some patients have only limited bouts, followed by remission and little damage. In other patients the disease is regularly active, lasting many years to a lifetime. This form of RA often leads to severe joint damage and disability. Physician care may include antiinflammatories to reduce pain

BOX 33-5 Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis is a separation of the ball of the hip joint from the femur at the upper, growing end (growth plate) of the bone. It occurs in about 2 of every 100,000 children. It is most common in boys 11 to 15 years of age, in children who are obese, in those who have hormone imbalances, and in those having growth spurts.[12] The condition may affect one or both hips and can occur after even minor trauma (e.g., jumping from a small height). Signs and symptoms include pain and tenderness in the thigh and hip. The affected limb may be slightly rotated in an outward position. A slipped capital femoral epiphysis most often requires surgery to stabilize the hip joint. The condition is associated with early arthritis of the hip joint and a greater risk for osteoarthritis later in life.

BOX 33-6 Ankylosing Spondylitis

Ankylosing spondylitis (AS) is a form of arthritis that primarily affects the spine, although other joints can become involved. It causes inflammation of the vertebrae that can lead to severe, chronic pain and discomfort. In the most advanced cases, this inflammation can lead to new bone formation on the spine, causing the spine to fuse in a fixed, immobile position. This sometimes creates a forward-stooped posture (*kyphosis*). AS can cause inflammation, pain, and stiffness in other areas of the body (e.g., the shoulders, hips, ribs, heels, and small joints of the hands and feet). The eyes can also be involved. Rarely, the lungs and heart can be affected. Unlike other forms of arthritis and rheumatic diseases, general onset of AS commonly occurs in younger people, between the ages of 17 and 35. It also can affect children and the elderly. The disease is more common in men than in women. The severity of the disease varies from person to person and may lead to permanent disability.[14]

Paramedics and other emergency personnel must remember that patients with AS have inflexible spines that cannot be moved. EMS procedures must be modified to accommodate these patients to prevent further injury. These include modifying splinting procedures, airway procedures, and transport considerations. For example, patients with AS will require additional padding with splinting techniques. Airway procedures must be performed without flexing the neck. If possible, advanced airway devices that do not require visualization of the airway (e.g., King L&D, laryngeal mask airway [LMA]) should be used instead of endotracheal intubation. Padding with pillows to support the patient's head, neck, and upper back will need to be applied during transport. Special training is available to EMS personnel for managing patients with this condition.[14]

and inflammation, disease-modifying antirheumatic drugs (DMARDs) to slow the course of the disease, analgesics, and physical therapy. Commonly performed surgical procedures include joint replacement, tendon reconstruction, and synovectomy.

NOTE

Biologic response modifiers are a new class of drugs used for the treatment of rheumatoid arthritis.[15] They help reduce inflammation and damage to the joints by blocking the action of cytokines (proteins of the body's immune system that trigger inflammation during normal immune responses). Examples of these drugs include etanercept (Enbrel), infliximab (Remicade), adalimumab (Humira), and anakinra (Kineret).

CRITICAL THINKING

When caring for a patient with severe rheumatoid arthritis or ankylosing spondylitis, how might you have to modify your care if you suspect spine injury?

SEPTIC ARTHRITIS

Septic arthritis is also known as *infectious arthritis*. The condition results from direct invasion of the joint space by various microorganisms. These include bacteria (most common), viruses, mycobacteria, and fungi. Septic arthritis affects about 20,000 people in the United States each year.[16] It can occur in both children and adults.

FIGURE 33-6 Rheumatoid arthritis of hands. (From Christensen BL et al: *Adult health nursing,* ed 6, St Louis, 2010, Mosby.)

NOTE

In the past, septic arthritis was more frequently caused by the bacterium *Neisseria gonorrhoeae,* which causes the sexually transmitted disease gonorrhea. Safer sex practices have led to a decline in gonorrhea and its complications, including septic arthritis. Still, in younger sexually active people, gonorrhea is a potential cause of septic arthritis.

The disease process begins when the infectious agent (most commonly *Staphylococcus aureus*) enters the joint. This usually occurs from active infection elsewhere in the body, such as a respiratory tract infection or urinary tract infection. Infection also can occur from direct invasion (e.g., an open wound near the joint; joint surgery). When the bacterium reaches the synovium in the joint, the immune system is activated, and cartilage begins to be destroyed. This results in inflammation and reduced blood flow to the joint and surrounding structures. Previously damaged joints, especially from rheumatoid arthritis, are the most susceptible to infection. The most commonly involved joint is the knee, followed by the hip, shoulder, ankle, and wrist. Signs and symptoms of septic arthritis include fever; shaking chills; and severe pain, warmth, and swelling in the affected joint. Septic arthritis is treated with antibiotics to resolve the infection. In severe cases, the joint may need surgical reconstruction or replacement.

SHOW ME THE EVIDENCE

Researchers cultured synovial fluid from 109 patients. Of those that were diagnosed with septic arthritis, 50% grew methicillin-resistant *Staphylococcus aureus* (MRSA). In this patient sample MRSA was the most common causative organism in septic arthritis.

Frazee BW, Fee C, Lambert L: How common is MRSA in adult septic arthritis? *Ann Emerg Med* 54(5):695-700, 2009.

GOUT

Gout is a form of arthritis marked by the deposit of uric acid crystals (monosodium urate) in and around a joint. Gout affects mostly men and is thought to be hereditary. It affects about 2.7 of every 1000 adults. For unknown reasons, gout surfaces most often in the metatarsophalangeal joint of the big toe. Gout may also present anywhere in the lower or upper extremities. In the elderly, many joints may be affected. People with gout may also develop tophi (masses of urate crystals deposited in soft tissue). This usually affects cooler areas of the body such as the elbows, ears, and distal finger joints. The disease is also associated with an increased risk for developing kidney stones.[17]

NOTE

Pseudogout is inflammation caused by *calcium pyrophosphate* (CPP) crystals. It is often clinically indistinguishable from gout. Both conditions are treated the same. Like gout, pseudogout is associated with a variety of metabolic disorders. However, unlike gout, there is no specific therapeutic regimen to treat the underlying cause of the disease. The most common sites for pseudogout are the knees, wrists, and shoulders. The symptoms often occur gradually over several days.

In acute gout, the affected joint and surrounding tissues appear hot, red, and swollen. The pain is usually intense and made worse by stimulation or light touch (e.g., covering the toe with a blanket). Gout may remit for long periods, followed by flares that last days to weeks. Chronic gout can lead to a degenerative form of arthritis called *gouty arthritis*. Risk factors for gout include joint injury, obesity, hypertension, alcohol use, diuretics that lead to hyperuricemia, and diets that are rich in meat and seafood. Of the forms of arthritis discussed here, gout is the most treatable form of the disease. It is managed with pain medicine, antiinflammatories, and intramuscular (IM) and oral corticosteroids. An acute episode usually subsides within 24 hours after treatment begins.

MUSCLE DISORDERS

As described in Chapter 10, the muscles of the body fulfill many purposes, such as movement, postural maintenance, and heat production. Inflammation of skeletal muscle can result from injury, infection, or autoimmune disease. Skeletal muscle disorders discussed in this chapter include myalgia and chronic fatigue syndrome. Trauma-related causes of muscle weakness, such as *rhabdomyolysis* and *compartment syndrome,* are described in Chapter 38.

Myalgia

Myalgia means muscle pain or pain in multiple muscles. There are many causes and various types of myalgia. The condition can be acute and temporary, or it can be chronic. Myalgia most often results from overuse, muscle injury, or stress (described later in this chapter). It can also result from a virus, an infection, and an autoimmune disorder. Myalgia can be an indication of serious illness. Serious illness associated with myalgia includes inflammatory myopathies and chronic fatigue syndrome.

INFLAMMATORY MYOPATHIES

Inflammatory myopathies refer to a group of diseases that involve chronic muscle inflammation accompanied by muscle weakness. Causes of these disorders may include injury, infection, autoimmune disease, alcohol and illicit drug use (e.g., cocaine), and some prescribed medications (e.g., some statins). The three main types of inflammatory myopathies are polymyositis, dermatomyositis, and myositis. These are rare disorders that can affect both children and adults. General symptoms that are common to these disorders include[18]:

- Slow and progressive muscle weakness that begins in the muscles closest to the trunk of the body
- Fatigue after walking or standing
- Frequent trips and falls
- Difficulty swallowing or breathing

Dermatomyositis is characterized by a skin rash that precedes or accompanies progressive muscle weakness. The rash looks patchy, with bluish-purple or red discolorations. It characteristically develops on the eyelids and on muscles used to extend or straighten joints, including knuckles, elbows, heels, and toes. Red rashes and swelling may also occur on the face, neck, shoulders, upper chest, back, and other locations. The rash sometimes occurs without obvious muscle involvement. Dermatomyositis may be associated with collagen-vascular or autoimmune diseases, such as lupus.

Polymyositis affects skeletal muscle on both sides of the body. It is rarely seen in persons younger than age 18; most cases are in adults between the ages of 31 and 60. Slow but progressive muscle weakness leads to difficulties climbing stairs, rising from a sitting position, lifting objects, or reaching overhead. People with polymyositis may also experience arthritis, shortness of breath, difficulty swallowing and speaking, and cardiac dysrhythmias. In some cases of polymyositis, muscles farther away from the trunk of the body, such as those in the forearms and around the ankles and wrists, may be affected as the disease progresses. Polymyositis may be associated with collagen-vascular or autoimmune diseases (e.g., lupus) and with infectious disorders, such as human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS).

Myositis is also known as *inclusive body myositis* (IBM). The disorder is characterized by progressive muscle weakness and wasting. Myositis often begins with weakness in the wrists and fingers that causes difficulty with pinching, buttoning, and gripping objects. There may be weakness of the wrist and finger muscles and atrophy of the muscles in the forearms and legs. Difficulty swallowing occurs in about half of the patients.[19] Symptoms of the disease usually begin after the age of 50, although the disease can occur much earlier.

MANAGEMENT

There is no cure for inflammatory myopathies. Options for dermatomyositis and polymyositis include medications to reduce inflammation, physical therapy, exercise, heat therapy, orthotics, assistive devices, and rest. The standard treatment for these conditions includes oral or IV corticosteroid drugs and immunosuppressant drugs. Periodic treatment using intravenous immunoglobulin may also improve recovery.

There is no standard course of treatment for myositis. The disease is generally unresponsive to corticosteroids and immunosuppressive drugs. Physical therapy may be helpful in maintaining mobility. Other therapy is symptomatic and supportive.

Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS) is a debilitating and complex disorder. It is characterized by profound fatigue that is not improved by bed rest and that may be worsened by physical or mental activity. CFS affects between 1 and 4 million Americans, 25% of whom are unemployed or on disability because of the illness. According to the Centers for Disease Control and Prevention (CDC), about 40% of people in the general population who report symptoms of CFS have a serious, treatable, previously unrecognized medical or psychiatric condition (such as diabetes, thyroid disease, substance abuse)[20] (Box 33-7).

BOX 33-7 Risk Groups for CFS[20]

- CFS occurs up to four times more frequently in women than in men, although people of either gender can develop the disease.
- The illness occurs most often in people between the ages of 40 and 59, but people of all ages can have CFS.
- CFS is less common in children than in adults. Studies suggest that CFS is more prevalent in adolescents than in children.
- CFS occurs in all ethnic and racial groups worldwide. Research indicates that CFS is at least as common among African Americans and Hispanics as it is among Caucasians.
- People of all income levels can develop CFS, although there is evidence that it is more common in lower-income than affluent individuals.
- CFS is sometimes seen in members of the same family, but there is no evidence that it is contagious. Instead, there may be a familial or genetic propensity. Further research is needed to explore this.
- CFS can be as disabling as multiple sclerosis, lupus, rheumatoid arthritis, heart disease, end-stage renal disease, chronic obstructive pulmonary disease, and similar chronic conditions.

NOTE

Fibromyalgia (FM) is another disorder that causes extreme fatigue. In addition to fatigue, FM is associated with "tender points" on the neck, shoulders, back, hips, arms, and legs. The distinction between FM and CFS is not clear. Some experts believe they are one and the same disorder, with slightly different manifestations. The cause of both FM and CFS is unknown, although there may be a viral or heritable component.[21] Both FM and CFS have pain and fatigue as symptoms, and both disorders are treated in the same manner.

SIGNS AND SYMPTOMS OF CFS

The primary signs and symptoms of CFS are difficulties with memory and concentration, problems with sleep, and persistent muscle pain that lasts 6 months or more. In addition, the person may experience joint pain (without redness and swelling), headache, tender lymph nodes, sore throat, and malaise following exertion. Other symptoms may include[22]:

- Irritable bowel
- Depression, irritability, mood swings, anxiety, panic attacks
- Chills and night sweats
- Visual disturbances (blurring, sensitivity to light, eye pain)
- Allergies or sensitivities to foods, odors, chemicals, medications, or noise
- Brain fog (feeling like one is in a mental fog)
- Difficulty maintaining upright position, dizziness, balance problems, or fainting

CFS often follows a cyclical course, alternating between periods of illness and relative well-being. Some patients experience partial or complete remission of symptoms during the course of the illness, but symptoms often reoccur.

MANAGEMENT

Prehospital care is primarily supportive. Diagnosis of CFS and fibromyalgia (FM) is based on history and clinical signs and symptoms. (There is no laboratory marker to confirm the disorders.) Most patients are managed with a combination of therapies tailored to the severity of the illness. These may include counseling and behavioral therapy, drug therapy to relieve symptoms, relaxation therapy to reduce anxiety, and support groups with others who have the illness. There is no cure for the illness.

OVERUSE SYNDROMES

The overuse of muscles, tendons, ligaments, and supporting structures can result in numerous injuries and ailments (**overuse syndromes**). The specific disorders discussed in this chapter are bursitis, muscle strain, and tendonitis.

Bursitis

Bursitis is an inflammation of one or more bursae often caused by excessive use of a joint. A **bursa** is a small sac containing synovial fluid that helps ease friction between a tendon and skin or between a tendon and bone (Figure 33-7). Inflammation from injury, compression, overuse, or

FIGURE 33-7 Bursitis. (From Epstein O, et al: *Clinical examination,* ed 4, St Louis, 2008, Mosby Ltd.)

infection is the most common cause of bursitis. Crystal deposits (uric acids) associated with some diseases such as gout, rheumatoid arthritis, and scleroderma can also lead to bursitis. Areas most commonly affected include the elbow, shoulder, hip, knee, and Achilles tendon. Risk factors for developing bursitis include[23]:

- *Overuse or repetitive use:* Overuse or repetitive actions, such as running, stair climbing, bicycling, or standing for prolonged periods, can cause bursitis.
- *Disease:* Various diseases, such as arthritis, thyroid disease, and diabetes, can lead to bursitis.
- *Leg-length inequality:* When one leg is shorter than the other by 1 inch or more it affects walking and could lead to irritation of hip bursa.
- *Previous surgery:* Surgery around the hip or prosthetic implants in the hip can irritate the bursae.
- *Bone spurs or calcium deposits:* Bone spurs or calcium deposits can develop within the tendons that attach to the trochanter, causing irritation and inflammation to the bursa.
- *Crystal deposits:* Uric acid, a normal byproduct of daily metabolism, may be deposited as crystals in joints, causing bursitis.

Bursitis most commonly affects people more than 40 years of age. The primary symptom of bursitis is pain, which may be sudden and severe. Loss of motion in a joint caused by crystal deposits can also indicate bursitis. Initial self-care for bursitis is listed in Box 33-8. Other treatment options may include corticosteroids, antibiotics, physical therapy, needle aspiration of bursal fluid, and surgical removal or drainage of an infected bursal sac.

Muscle Strains

Muscle strains, or "pulled muscles," are slight tears in muscles or tendons. They usually result from excessive stretching or use. The tiny tears in the damaged muscle cause muscle fibers to spasm. This results in pain that can last for days to weeks. When strained muscles heal, scar tissue replaces the injured muscle fibers. The scar tissue may cause some weakening of the muscle and may allow muscle injury to recur. Two commonly injured muscles in athletes are the *hamstring* and *quadriceps,* both of which cross the hip and knee joints. Another common site for muscle strains is the lower back.

BOX 33-8 Self-Care for Bursitis[24]

A self-care management approach involves **PRICEM,** which is an acronym for:

Protection: Protect the bursae that are close to the skin with padding.

Rest: The affected body part must be given rest until the symptoms improve. Avoid any activities that cause additional pain.

Ice: Ice packs can be effectively used in reducing the symptoms of inflammation and pain.

Compression: Affected joints can be compressed by using elastic bandage or dressing to relieve pain.

Elevation: Elevating the affected body part above the level of the heart may stop the blood from collecting in the bursae and help reduce inflammation.

Medication: Nonsteroidal antiinflammatory drugs or over-the-counter pain medications such as ibuprofen can be effective in relieving the pain and reducing inflammation.

NOTE

A person who experiences a muscle strain in the thigh will frequently describe a "popping" or "snapping" sensation as the muscle tears. Pain is sudden and may be severe. The area around the injury may be tender to the touch, with visible bruising.

Muscle strains are graded according to their severity. A grade 1 strain is mild and usually heals readily, whereas a grade 3 strain is a severe tear of the muscle that may take months to heal.[19] Most muscle strains can be successfully treated using the PRICEM formula, described in Box 33-8. Some injuries may require *therapeutic ultrasound,* a procedure in which torn muscles are broken down to allow them to heal properly. More severe injury may require surgical repair of torn ligaments, muscles, and tendons.

Tendonitis

Tendonitis is inflammation of a tendon. As described in Chapter 10: Review of Human Systems, a tendon is a tough and flexible band of fibrous tissue that connects muscles to bones. Tendons most often become inflamed from overuse. This may result in the tendon and surrounding tissues becoming swollen and tender. Movement may be painful or limited. Almost any tendon can become inflamed. The most common areas affected by tendonitis are the wrist, ankle and heel, knee, and the rotator cuff of the shoulder (Figure 33-8). Risk factors associated with tendonitis include

FIGURE 33-8 Abnormalities of the elbow: tendonitis. (From Jarvis C: *Physical examination and health assessment,* ed 5, St Louis, 2008, Saunders.)

advancing age; occupations that involve repetitive motions, forceful exertion, or awkward positions; and certain sports, such as bowling, swimming, tennis, baseball, and basketball.

Tendonitis is usually diagnosed by a history and physical examination. As a rule, x-rays or other imaging tests are not needed unless there is suspicion of fracture or underlying illness. Treatment usually consists of PRICEM (see Box 33-8). Some patients (for example, those with arthritis and gout) may be prescribed exercise and physical therapy to prevent recurrent injury.

PERIPHERAL NERVE SYNDROMES

As described in Chapter 10, the peripheral nervous system consists of all the nerves that exit the brain and spinal cord. Two common peripheral nerve syndromes are carpal tunnel syndrome and ulnar nerve entrapment. Both of these conditions can cause pain, tingling, and numbness in the arms, wrists, and fingers.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is an *entrapment neuropathy* that occurs when the median nerve becomes pressed or squeezed at the wrist in the carpal tunnel. The *carpal tunnel* is a narrow, rigid passageway of ligament and bones at the base of the hand. This tunnel houses the median nerve and tendons (Figure 33-9). The median nerve controls sensations to the palm side of the thumb and fingers (although not the little finger). This nerve also provides impulses to small muscles in the hand that allow the fingers and thumb to move. Compression of the median nerve can cause pain, weakness, or numbness in the hand and wrist, radiating up the arm. Compression can be caused by any condition that decreases the space in the carpal tunnel (e.g., irritated tendons or other swelling).

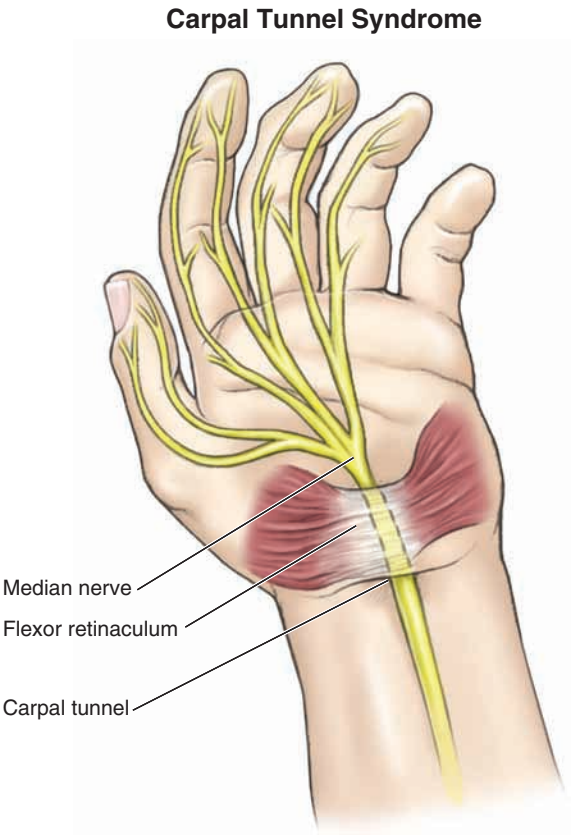

FIGURE 33-9 Carpal tunnel syndrome. (From Herlihy B: *The human body in health and illness,* ed 3, St Louis, 2007, Saunders.)

There are few clinical data to prove whether repetitive and forceful movements of the hand and wrist during work or leisure activities can cause carpal tunnel syndrome.[25] The condition is most likely due to a congenital predisposition; that is, the carpal tunnel is simply smaller in some people than in others. Women are three times more likely than men to develop carpal tunnel syndrome. This is perhaps because the carpal tunnel itself may be smaller in women than in men. Other contributing factors include:

- Trauma or injury to the wrist that causes swelling (e.g., sprain or fracture)
- Overactivity of the pituitary gland
- Hypothyroidism
- Rheumatoid arthritis
- Mechanical problems in the wrist joint
- Repeated use of vibrating hand tools
- Fluid retention during pregnancy or menopause
- Cyst or tumor in the canal

SIGNS AND SYMPTOMS

The symptoms of carpal tunnel syndrome usually begin gradually, often during sleep. Complaints include frequent burning, tingling, or itching numbness in the palm of the hand and the fingers. Sleep is often interrupted with the need to "shake out" the wrist or hand. As symptoms worsen, tingling may occur during the day. The patient may have decreased grip strength, making it difficult to form a fist,

grasp small objects, or perform other manual tasks. Early diagnosis and treatment are important in preventing permanent damage to the median nerve.

MANAGEMENT

Carpal tunnel syndrome is diagnosed through various tests that may include percussion of the median nerve (*Tinel's sign*), wrist-flexion tests (*Phalen's test*), compression tests, and nerve conduction studies.[26] Treatment may include drug therapy to control pain, decrease swelling, and reduce inflammation; wrist splinting to maintain correct wrist position; exercise and physical therapy to restore wrist strength; and sometimes surgery to release pressure in the carpal tunnel.

Ulnar Nerve Entrapment

Ulnar nerve entrapment occurs when the ulnar nerve in the arm becomes compressed. The ulnar nerve (often called the "funny bone") travels from under the clavicle and along the inside of the upper arm. It passes through the cubital tunnel, behind the inside of the elbow, where it can be palpated. Beyond the elbow, the nerve travels under muscles on the inside of the arm and into the hand on the side of the palm with the little finger (Figure 33-10). The ulnar nerve provides sensation to the little finger and the palm half of the ring finger. It also controls most of the small muscles in the hand that help with fine movements, and some larger muscles in the forearm that help a person make strong grips. Entrapment of the ulnar nerve most commonly occurs behind the elbow. The syndrome may be associated with previous injury to the elbow, bone spurs, and swelling. Cysts may also be a cause of the entrapment.

Signs and symptoms of ulnar nerve entrapment are similar to those caused by compression of the medial nerve. They include numbness, pain, and tingling in the elbow, forearm, wrist, and fingers. Often the patient complains that the hand has "fallen asleep." Symptoms frequently occur during sleep when the elbows are commonly flexed, and during daytime activities that involve bending of the elbow. Ulnar nerve entrapment is diagnosed and treated with tests and therapies similar to those for carpal tunnel syndrome. Surgery is sometimes used to reposition the ulnar nerve to avoid compression and entrapment.

SOFT TISSUE INFECTIONS

There are soft tissue infections that can destroy muscles, skin, and underlying tissue. Most are rare and are caused by a bacterial infection. Soft tissue infections specific to nontraumatic musculoskeletal disorders discussed in this chapter include fasciitis, gangrene, paronychia, and flexor tenosynovitis of the hand.

NOTE

The occurrence of serious and rare skin infections is on the rise. This is because of an increase in immunocompromised patients with diabetes, cancer, alcoholism, vascular insufficiencies, organ transplants, and HIV.[19]

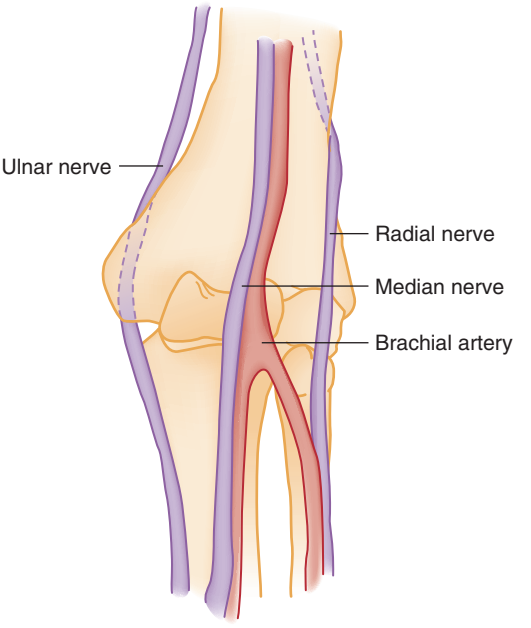

FIGURE 33-10 Ulnar nerve. (From Marx J et al: *Rosen's emergency medicine: concepts and clinical practice,* ed 6, St Louis, 2006, Mosby.)

Fasciitis

Fasciitis refers to inflammation of the fascia. **Fascia** is a strong connective tissue that forms under the skin. The tissue performs a number of functions. It envelops and isolates muscles, and sometimes groups of muscles, in the body. It also provides support and protection for body organs and structures.

Necrotizing fasciitis (also called "flesh-eating bacteria") is a rare infection of the deep layers of the skin and subcutaneous tissues. It rapidly spreads in the deep fascial plane with secondary necrosis (tissue death) in the subcutaneous tissue. Necrotizing fasciitis is most likely to occur in people with compromised immune systems. Many bacteria can cause the disease, some of which are resistant to antibiotics (Box 33-9).

The infection begins slowly, usually at a site of broken skin (minor or major trauma or surgery). Often the patient will complain of intense pain that is out of proportion to

BOX 33-9 Bacteria That Cause Necrotizing Fasciitis*

Streptococcus pyogenes
Staphylococcus aureus
Vibrio vulnificus
Clostridium perfringens
Bacteroides fragilis

**NOTE:* The term *flesh-eating bacteria* is a misnomer. The bacteria do not actually eat the tissue. Skin and muscle are destroyed by the release of toxins, which causes the overproduction of cytokines.

the appearance of the injury. As the disease progresses, the affected area quickly becomes red, hot, and swollen. The skin color may become violet-purple, and blisters may form as necrosis develops in the subcutaneous tissues. Fever, diarrhea, and vomiting are common. If left untreated, the infection may become systemic, leading to death.

NOTE

Since 1883, more than 500 cases of necrotizing fasciitis have been reported in the literature. Overall morbidity and mortality is as high as 75%. The mean age of survivors is 35 years. The mean age of nonsurvivors is 49 years. The disease rarely occurs in children.[27]

Patients with necrotizing fasciitis are managed with surgical debridement of the affected area, IV antibiotics, and support of vital functions. Aggressive surgical removal of the infected tissue is usually necessary. The need for skin grafts is not uncommon. Most patients require intensive care monitoring. Hyperbaric oxygen therapy may be an option in caring for these patients. Hyperbaric oxygen can increase the oxygen within the body's tissues, force oxygen into hypoxic tissue, decrease edema, destroy anaerobic bacteria, and promote the growth of new blood vessels within soft tissue.

DID YOU KNOW?

Hyperbaric Oxygen Therapy

Altering the surrounding air pressure for medical treatment is a practice that dates back to the seventeenth century. At that time, "fevers and inflammations" were treated in crude chambers that were pressurized using hand bellows. Today, hyperbaric oxygen therapy (HBOT) is carried out in single-person chambers. These are monoplace chambers. The treatment also can be done in larger multiplace chambers, which can house several patients and the attending hyperbaric health care workers. HBOT has proved to be effective in the treatment of a wide variety of medical disorders. These include air embolism and decompression sickness; carbon monoxide poisoning and smoke inhalation; carbon monoxide poisoning complicated by cyanide poisoning (controversial); clostridial myonecrosis (gas gangrene); crush injury, compartment syndrome, and other acute traumatic ischemias; intracranial abscesses; and thermal burns. It also has been shown to enhance the healing of certain problem wounds, including tissue necrosis.[28] HBOT works to[29]:

- Greatly increase oxygen concentration in all body tissues, even with reduced or blocked blood flow.
- Stimulate the growth of new blood vessels to locations with reduced circulation, thereby improving blood flow to areas with arterial blockage.
- Cause a rebound arterial dilation after HBOT, resulting in a blood vessel diameter that is greater than that before therapy, improving blood flow to compromised organs.
- Aid in the treatment of infection by enhancing white blood cell action and potentiating germ-killing antibiotics.

Gangrene

Gangrene is a complication of tissue necrosis. It is characterized by the decay and death of body tissue, which becomes black (and/or green) and malodorous (foul smelling) (Figure 33-11). Gangrene results from decreased blood supply to a body part or organ, most commonly the toes, fingers, feet, and hands. It can also result from infection, disease, frostbite, and other soft tissue injury. Two major types of gangrene exist:

1. *Dry gangrene:* Caused by a reduction of blood flow through the arteries (not infection). It appears gradually and progresses slowly. Dry gangrene is associated with arteriosclerosis, diabetes, cigarette smoking, genetics, and other factors. In this type of gangrene, tissues appear dry and discolored and will eventually slough away.
2. *Wet gangrene (moist gangrene):* Develops as a complication of an untreated, infected wound. Swelling results from the bacterial infection that causes a sudden decrease in blood flow. (*Gas gangrene* is a type of wet gangrene caused by the bacteria *Clostridia,* which produce poisonous toxins and gas.) In this type of gangrene, tissues appear moist and produce oozing fluid or pus.

MANAGEMENT

Treatment of gangrene depends upon the type of gangrene (dry versus wet) and upon how much tissue is compromised. Immediate treatment is needed in all cases of wet gangrene and in some cases of dry gangrene. Treatment for both types of gangrene usually involves surgery, antibiotic therapy, anticoagulant therapy, pain management, supportive care, and rehabilitation (especially with surgical or autoamputation). If available, hyperbaric oxygen therapy (HBOT) may be indicated as additional therapy for gas gangrene.

Paronychia

Paronychia is a common skin infection that occurs around the nails. It is usually caused by an injury (e.g., nail biting, pulling a hangnail, trimming a cuticle) that allows for an

FIGURE 33-11 Gangrene of toes. Dry gangrene. (From Damjanov I: *Pathology for the health-related professions,* ed 2, Philadelphia, 2000, Saunders.)

FIGURE 33-12 Paronychia. (From Callen J, Greer K, Hood A, et al: *Color atlas of dermatology,* ed 2, Philadelphia, 2000, Saunders.)

invasion of bacteria, yeast, or fungus (Figure 33-12). The condition is also common in persons with diabetes and in those who have their hands submerged in water for long periods of time. Symptoms include:

- Pain and redness around the nail
- Puss-filled blisters (especially with bacterial infection)
- Nails that are abnormally shaped or have an unusual color

MANAGEMENT

Physician care for patients with paronychia may include incision and drainage of the infection, nail removal, and antibiotic therapy. Warm hand soaks may also relieve discomfort. The condition usually responds well to treatment. Rarely, some infections can be prolonged, requiring additional therapy. Signs of systemic infection from paronychia include chills, red streaks proximal to the infection, fever, malaise, joint pain, and muscle spasm.[30]

Flexor Tenosynovitis

Flexor tenosynovitis is a pathological state that causes a disruption of tendon function in the hand. Most cases are the result of infection. The condition can also be secondary to acute or chronic inflammation as a result of overuse or disease (e.g., diabetes, arthritis). When infectious agents enter the closed space of a tendon sheath, the immune response causes swelling. This interferes with the gliding mechanism of the wrist, hand, and fingers, and can result in disruption of the tendon sheath. It may also lead to tendon necrosis. Flexor tenosynovitis is considered an orthopedic emergency. If left untreated, the infection may become systemic, spreading to fascia, synovial joint spaces, and skin. Subsequent osteomyelitis may result.[19]

The primary cause of infectious flexor tenosynovitis is penetrating trauma that allows native skin flora (both *Staphylococcus* and *Streptococcus*) to invade the tendon sheath. The patient may present with fever and chills. Other signs and symptoms include *Kanavel's sign*:

- Severe pain on passive range of motion
- Swollen digits ("sausage links")
- Fingers that are held slightly flexed
- Swelling and tenderness along the flexor sheath

MANAGEMENT

In most cases of infectious flexor tenosynovitis, surgical drainage is required. Other treatment may include prescribing antibiotics, splinting, and elevating the hand. All patients require physician care and follow-up. Prehospital care is primarily supportive.

SUMMARY

- Although more common in advanced age, nontraumatic musculoskeletal disorders affect patients of all ages.
- The musculoskeletal system is composed of bones, muscles, tendons, ligaments, and articulating surfaces. Three types of joints are fibrous, cartilaginous, and synovial. Muscles are responsible for movement, posture, and heat production.
- The extremities and spine should be examined to determine structure and function. Specific assessments include range of motion, vascular evaluation, and a motor and sensory exam.
- Prehospital management of nontraumatic musculoskeletal disorders includes routine care and pain management.
- Important historical data to gather on a patient with this type of disorder should relate to onset of signs and symptoms, nature and location of pain, presence of weakness or other alteration in motor function, and presence of sensory abnormalities.
- Osteomyelitis is a bone infection. It may result from an open fracture, wound infection, or systemic infection. Signs and symptoms include pain, signs of inflammation, fever, pus, and other functional alterations.
- Bone tumors are benign or malignant abnormal cell growth within a bone. Multiple myeloma is the most common type of primary bone cancer. This disorder is characterized by pain and fractures.
- Acute or chronic low back pain is common. It may be caused by trauma, arthritis, infections, or congenital abnormalities.
- Intervertebral disks can herniate and compress adjacent nerves, causing severe pain and weakness.

- Cauda equina syndrome is caused by compression of the nerve roots at the distal end of the spine. If the compression is not relieved promptly, permanent paralysis and incontinence can occur.
- A strain is an injury to a muscle or tendon. A sprain is stretching or tearing of a ligament. Both conditions cause pain.
- Arthritis is an inflammatory condition of a joint characterized by pain and swelling. Osteoarthritis is a chronic degenerative joint disease that has a gradual onset. Rheumatoid arthritis is an autoimmune disease that affects synovial joints. It causes severe pain, disability, and deformity. Ankylosing spondylitis is a form of arthritis that primarily affects the spine. It requires modifications in prehospital care. Septic arthritis is infection of a joint. Gout is a type of arthritis caused by deposits of uric acid in the joint space.
- Myalgia is pain in one or more muscles. It can be caused by an autoimmune disorder, overuse, or infection.
- Inflammatory myopathies are a group of diseases characterized by muscle inflammation and weakness. They can be caused by autoimmune disease, injury, infection, or drugs.
- Chronic fatigue syndrome is characterized by severe fatigue not improved by rest.
- Fibromyalgia causes fatigue and "tender points" on the neck, shoulders, back, hips, arms, and legs.
- Bursitis is inflammation of one or more bursae. It is often caused by overuse.
- Muscle strains are slight tears in the muscle caused by overuse or by injury.
- Tendonitis is inflammation of a tendon.
- Carpal tunnel syndrome is a type of neuropathy caused by entrapment of the median nerve after repetitive movement. It causes pain, numbness, and weakness.
- Ulnar nerve entrapment occurs when the ulnar nerve (funny bone) is compressed.
- Fasciitis is inflammation of the connective tissue that lies under the skin. Necrotizing fasciitis ("flesh-eating bacteria") is a rare infection that begins in the fascia and can become systemic.
- Gangrene is a complication of tissue necrosis. It occurs when tissue decays.
- Paronychia is a skin infection around the nails.
- Flexor tenosynovitis is often caused by infection. It can lead to dysfunction, necrosis, and systemic infection.

CHAPTER

34 Toxicology

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Define poisoning.
2. Describe general principles for assessment and management of the patient who has ingested poison.
3. Describe the causative agents and pathophysiology of selected ingested poisons and the management of patients who have taken them.
4. Describe how physical and chemical properties influence the effects of inhaled toxins.
5. Distinguish among the three categories of inhaled toxins: simple asphyxiants, chemical asphyxiants and systemic poisons, and irritants or corrosives.
6. Describe general principles of managing the patient who has inhaled poison.
7. Describe the signs, symptoms, and management of patients who have inhaled cyanide, ammonia, or hydrocarbon.
8. Describe the signs, symptoms, and management of patients injected with poison by insects, reptiles, and hazardous aquatic creatures.
9. Describe the signs, symptoms, and management of patients with organophosphate or carbamate poisoning.
10. Outline the general principles of managing patients with drug overdose.
11. Describe the effects, signs and symptoms, and specific management for selected therapeutic and illegal drug overdoses.
12. Describe the short- and long-term physiological effects of ethanol ingestion.
13. Describe signs, symptoms, and management of alcohol-related emergencies.
14. Identify general management principles for the most common toxic syndromes based on a knowledge of the characteristic physical findings associated with each syndrome.

KEY TERMS

adsorb To accumulate on a surface in a condensed layer.

alcohol dependence A disorder characterized by chronic, excessive consumption of alcohol that results in injury to health or in inadequate social function and the development of withdrawal symptoms when the person stops drinking suddenly.

antidote A drug or other substance that opposes the action of a poison.

botulism An often fatal form of food poisoning caused by the bacillus *Clostridium botulinum*.

cathartic A substance that accelerates defecation.

cirrhosis A chronic degenerative disease of the liver.

delirium tremens An acute and sometimes fatal psychotic reaction caused by cessation of excessive intake of alcohol over a long period of time; also known as DTs.

disulfiram-ethanol reaction A potentially life-threatening physiological response caused by disulfiram and ethanol that produces ill effects on the gastrointestinal (GI), cardiovascular, and autonomic nervous systems; disulfiram is prescribed to some alcoholic patients to help them maintain abstinence.

drug abuse Self-medication or self-administration of a drug in chronically excessive amounts, resulting in psychological or physical dependence (or both), functional impairment, and deviation from approved social norms.

envenomation The injection of snake, arachnid, or insect venom into the body.

food poisoning Poisoning that results from food contaminated by toxic substances or by bacteria containing toxins.

gastric lavage Irrigation of the stomach with sterile water or normal saline.

gastrointestinal decontamination The use of medical methods to empty the stomach of ingested toxins to prevent absorption.

Korsakoff's psychosis A form of amnesia often seen in alcoholics, characterized by a loss of short-term memory and an inability to learn new skills.

liquefaction Conversion of solid tissues to a fluid or semi-fluid state.

Lyme disease An acute, recurrent inflammatory infection transmitted by a tick.

mediastinitis Inflammation of the mediastinum.
methemoglobin Hemoglobin with ferrous iron in the oxidized (Fe^{3+}) state.
methemoglobinemia The presence of methemoglobin in the blood, causing cyanosis as a result of the inability of the red blood cells to release oxygen.
nematocyst A capsule containing threadlike, venomous stinging cells found in some coelenterates.
nystagmus Involuntary rhythmic movements of the eyes.
pneumoperitoneum The presence of air or gas within the peritoneal cavity of the abdomen.
poison Any substance that produces harmful physiological or psychological effects.
Rocky Mountain spotted fever A serious tick-borne infectious disease, characterized by chills, fever, severe headache, mental confusion, and rash.
serotonin syndrome A potentially life-threatening drug reaction; most often occurs when two or more drugs that affect serotonin levels are taken together.
surface tension The tendency of the surface of a liquid to minimize the area of its surface by contracting.
tick paralysis A rare, progressive, reversible disorder caused by several species of ticks that release a neurotoxin that causes weakness, incoordination, and paralysis.
toxidromes Clinical syndromes grouped together for the successful recognition of poisoning patterns.
volatility The ability of a liquid to vaporize.
Wernicke-Korsakoff syndrome A disease that results from chronic thiamine deficiency combined with an inability to use thiamine because of a heritable disorder or because of a reduction in intestinal absorption and metabolism of thiamine by alcohol.
Wernicke's encephalopathy A stage of Wernicke-Korsakoff syndrome that usually develops suddenly with the clinical manifestations of ataxia, nystagmus, disturbances of speech and gait, signs of neuropathy, stupor, or coma.
West Nile virus A potentially serious mosquito-borne illness that affects the central nervous system.
whole-bowel irrigation An in-hospital method of GI decontamination; involves the rapid administration of large amounts of a specially balanced fluid to flush the GI tract.

Our environment contains a large number of potentially harmful substances that are both natural and synthetic. These substances can be accidentally or deliberately introduced into the body. These include animal and plant toxins, industrial and household chemicals, prescription medications, and drugs of abuse. Early identification of these agents and rapid transport for definitive care are crucial in managing patients with toxicological emergencies.

(Courtesy Monroe Yancey, St. Louis, Mo.)

SECTION ONE
Poisonings

A poison can be defined as any substance that produces harmful physiological or psychological effects. Emergencies that involve poisons are a major cause of morbidity and mortality in the United States. In 2006, there were more than 2 million unintentional poisonings reported by poison control centers, resulting in more than 700,000 emergency department visits. An additional 200,000 emergency department visits were caused by intentional poisoning; 75% of these patients had to be hospitalized or transferred to another medical facility.[1] According to the National Safety Council, poisoning by solids and liquids was the second leading cause of unintentional death in the United States in 2005, and the second leading cause of unintentional death for all persons ages 17 to 39.[2]

NOTE
Unintentional poisoning is poisoning that occurs when a person takes or gives a substance without the intent to harm. *Intentional poisoning* results when there is intent to cause harm.

CRITICAL THINKING
How many substances that fit the definition of a poison are there in or around your home?

POISON CONTROL CENTERS

More than 60 poison control centers exist across the United States to help treat poisoning emergencies. Most centers are based in major medical centers or teaching hospitals. Each one belongs to regional centers designated by the American Association of Poison Control Centers. Medical professionals staff regional centers. They offer 24-hour telephone access (1-800-222-1222) to population bases of at least 1 million. In 2007, an estimated 4.2 million poisonings were reported to poison control centers throughout the United States. More than 90% of these poisonings happen in the home; 51.2% of poisoning victims are children younger than 6 years of age.[3] By helping persons manage emergencies at home, these centers prevent about 1.6 million hospitalizations and visits to physicians' offices each year.

By request, information and treatment advice is given immediately by the poison control center. They provide this information through a large database of references on more than 350,000 toxic substances. These substances include drugs (legal, illicit, foreign, and veterinary), chemicals, plants, animals, insects, fish, snakes, cosmetics, and hazardous materials. Each request for information is followed up to determine the effectiveness and outcome of the treatment. In addition, the centers are responsible for the following elements of an organized poison system[4]:

1. Treatment information and toxicological consultation with health care providers (e.g., hospitals, physicians, EMS agencies) and the public, using a toll-free number with linkage into various 911 systems
2. Professional education to train those involved in care of poisoned patients
3. Data collection on all poisonings in the region for epidemiological and evaluation purposes
4. Public education and prevention
5. Research
6. Regional EMS poison system development (e.g., patient classification criteria, triage and management protocols, and regional transfer agreements)

Use by Emergency Medical Services Agencies

Regional poison control centers are a ready source of information for any toxicological emergency. Depending on local communications' protocol, poison control centers may be contacted directly by EMS and other public service agencies through telephone, cellular phone, a dispatching center, or medical direction. The immediate determination of potential toxicity is based on the specific agent or agents. It also is based on the amount ingested, the time of exposure, the patient's weight and medical condition, and any treatment given before EMS arrival. The poison center also can coordinate treatment protocol by notifying the receiving hospital while the patient is en route to the emergency department.

GENERAL GUIDELINES FOR MANAGING A POISONED PATIENT

Poisons may enter the body through ingestion, inhalation, injection, and absorption. Box 34-1 lists three types of toxicological emergencies that may result in poisoning. With the exception of administering lifesaving antidotes for specific poisons described later in this chapter, most poisoned patients require only supportive therapy to recover. The poisoned patient often can be managed properly in the prehospital setting using the following guidelines:

1. Ensure adequate airway, ventilation, and circulation. Take action to prevent or reduce the risk of aspiration by carefully monitoring the patient's airway.
2. Obtain a thorough history, and perform a focused physical examination.
3. Consider hypoglycemia in a patient who has an altered level of consciousness or is convulsing. Confirm through serum glucose testing.
4. Administer ***naloxone*** or ***nalmefene*** to a patient with respiratory depression.
5. If overdose is suspected, obtain an overdose history from the patient, family, or friends.
6. Consult with medical direction or a poison control center for specific management to prevent further absorption of the toxin or antidote therapy.
7. Frequently reassess the patient; monitor vital signs and electrocardiogram (ECG).
8. Safely obtain any substance or substance container of a suspected poison. Transport it along with the patient. The paramedic should collect a sample of the patient's vomitus (if present) for laboratory analysis.
9. Employ universal precautions for personal protection, especially if the substance can be absorbed through the skin.
10. Transport the patient for physician examination.

When caring for a patient who has been poisoned, personal safety remains the top priority. A toxicological emergency response may involve hazardous materials. It also may involve patient behavior that is unpredictable or violent. If the scene is not safe, the paramedic crew should retreat to a safe staging area and wait there until the scene has been secured by the proper personnel.

POISONING BY INGESTION

About 80% of all accidental ingestion of poisons occurs in children 1 to 3 years of age.[2] The most common poison exposures in this group result from household products. Such products include petroleum-based agents, cleaning agents, and cosmetics; medications; toxic plants; and contaminated foods. Poisoning in adults, however, usually is intentional. Deliberate poisonings may occur from:

- Attempts at suicide
- Recreational or experimental drug use
- Chemical warfare or acts of terrorism
- Assault and homicide

BOX 34-1 Types of Toxicological Emergencies

Unintentional Poisoning
- Childhood poisoning
- Dosage errors
- Environmental exposure
- Idiosyncratic reactions
- Occupational exposure

Drug and Alcohol Abuse
Intentional Poisoning/Overdose
- Assault/homicide
- Chemical warfare
- Suicide attempts

The toxic effects of ingested poisons may be immediate or delayed, depending on the substance that was ingested. For example, corrosive substances such as strong acids and alkalis may produce immediate tissue damage. This is evidenced by burns to the lips, tongue, throat, and upper gastrointestinal tract. Other substances, such as medications and toxic plants, usually require absorption and distribution through the bloodstream. They also may require alterations by different organs to produce toxic effects. Because only minimal absorption occurs in the stomach, poisons may take several hours to enter the bloodstream through the small intestine. Therefore early management of the ingested poisoning is focused on treating the patient's symptoms and providing supportive care.

Assessment and Management

The primary survey and initial management of a poisoned patient begins with ensuring scene safety. Then the paramedic should manage immediate threats to the patient's life. During scene size-up, the paramedic crew should be alert for specific clues or details that suggest a toxicological emergency. Examples include open medication bottles, scattered pills, vomitus, and open containers of household products. Patient findings that may suggest poisoning include a decreased level of consciousness, airway compromise/injury (e.g., vomitus or pills in the mouth, burns in the oral cavity), abnormal respiratory patterns, and dysrhythmias such as tachycardia and bradycardia.

NOTE

The paramedic must consider the possibility of poisoning whenever the patient's signs and symptoms cannot be attributed to other explainable conditions (e.g., hypoglycemia/hyperglycemia or cardiac dysfunction).

The primary goal of physical assessment of poisoned patients is to identify effects on the three vital organ systems most likely to produce morbidity or death. These organ systems are the respiratory system, the cardiovascular system, and the central nervous system. Obtaining a detailed history of the event and any significant medical or psychiatric history also is important. This information may help to direct treatment in the field or in the emergency department. For example, preexisting cardiac, liver, or renal disease and some psychiatric illnesses may be worsened by a toxic ingestion. These conditions may require care in addition to managing the toxic ingestion.

RESPIRATORY COMPLICATIONS

The first priority in managing a poisoned patient after ensuring scene safety is to secure a patent airway. The paramedic should provide adequate ventilatory support as needed. This includes providing high-concentration oxygen, monitoring pulse oximetry, and possibly implementing advanced airway management to protect the airway and prevent aspiration. Other respiratory complications that may be associated with poisoning include the early development of noncardiogenic pulmonary edema or the later development of adult respiratory distress syndrome (see Chapter 24). Bronchospasm may result from direct or indirect toxic effects.

LOOK AGAIN

See Chapter 24: Respiratory, pp. 757-758.

CARDIOVASCULAR COMPLICATIONS

The most common cardiovascular complication of poisoning by ingestion is the development of cardiac dysrhythmias. Thus the paramedic should assess the patient's circulatory status and continually monitor it by electrocardiogram and frequent blood pressure measurements. The presence of tachydysrhythmias or bradydysrhythmias may indicate serious metabolic disorders such as hypoxia and acidosis. Another cardiovascular complication is the development of hypotension associated with decreased vascular tone.

NEUROLOGICAL COMPLICATIONS

The paramedic should perform and document a baseline neurological examination. Deviations from a normal level of consciousness may range from mild drowsiness and agitation to hallucinations, seizures, coma, and death. Neurological complications may result from the toxin itself, such as lead poisoning in children who have ingested paint chips. Alternatively, the complications may result from a metabolic or perfusion disorder, such as poor cardiac output from dysrhythmias.

HISTORY

A thorough history of the exposure and any significant medical history should be obtained from the patient, family members, or bystanders. Although this information may be unreliable (as in cases involving pediatric patients, drug abuse, or suicide attempts), the following should be ascertained if possible:

- What was ingested? Obtain the poison container and remaining contents unless doing so poses a threat to rescuer safety.
- When was (were) the substance(s) ingested? This may affect the decision to use ***activated charcoal*** or gastric lavage, or to administer an antidote.
- How much of the substance was ingested?
- Was an attempt made to induce vomiting? Did the patient vomit?
- Has an antidote or ***activated charcoal*** been administered?
- Does the patient have a psychiatric history pertinent to suicide attempts? Has the patient had episodes of recent depression?

Gastrointestinal Decontamination

Gastrointestinal (GI) decontamination is the use of medical methods to empty the stomach of ingested toxins to prevent absorption. These methods include the administration of ***activated charcoal,*** gastric lavage, and whole-bowel irrigation. Before attempting to remove poison from the gastrointestinal tract, the paramedic should consult with medical direction or a poison control center. Although once a mainstay in the management of ingested toxins, GI decontamination plays a less important role in poison treatment today. With rare exceptions, gastric lavage and whole bowel irrigation are no longer recommended.[5,6]

NOTE
It should be noted that gastric decontamination rarely affects the clinical outcome of poisoned patients.[5] GI decontamination is only useful for patients who have ingested a poison within 1 hour of being seen. After 1 hour, the toxin most likely will have passed from the stomach into the small intestine where it will be absorbed. Therefore, care for most poisoned patients is primarily supportive. Decisions regarding the use of gastric decontamination are made by medical direction or a poison control center on a case-by-case and drug-by-drug basis.

ACTIVATED CHARCOAL

Activated charcoal is an inert, nontoxic product of wood material that has been heated to an extremely high temperature. Single-dose ***activated charcoal*** is generally recommended for patients who have ingested a life-threatening poison when no antidotes are available and when the charcoal can be administered within one hour of poisoning. The surface characteristics of ***activated charcoal*** enable it to **adsorb** (collect in a condensed form) molecules of chemical toxins while in the intestinal tract. ***Activated charcoal*** is indicated for some toxic ingestions, or for drugs that have delayed emptying. It should be given only when directed by medical direction or a poison control center.[5] It should not be given in cases where strong acid, strong alkali, or ethanol is the toxicant. It also should not be given when specific oral antidotes (e.g., *N*-acetylcysteine [Mucomyst] for acetaminophen overdose) are available. Box 34-2 lists the agents for which activated charcoal generally should and should not be given.[7]

Activated charcoal comes mixed in an aqueous solution with or without a **cathartic** (most commonly sorbitol). A cathartic is an agent that causes bowel evacuation. It decreases the transit time and expels the charcoal within a short period (Box 34-3). Complications of ***activated charcoal*** are poor patient acceptance in consuming the charcoal and vomiting. EMS personnel should protect themselves, the patient, and the immediate area from the staining properties of the charcoal. Personal protective measures also should be taken when administering this agent.

BOX 34-2 Activated Charcoal: Indications and Contraindications

Agents for Which Activated Charcoal Generally Should Be Given*
- Carbamazepine
- Dapsone
- Drugs with anticholinergic effects
- Opioids
- Phenobarbital
- Quinine
- Sustained-release drugs
- Theophylline
- Drug packets in "body stuffers"

Agents for Which Activated Charcoal Generally Should Not Be Given†
- Cyanide
- Ethanol intoxication
- Ferrous sulfate or other iron salts
- Lithium
- Mineral acid ingestion
- Methanol
- Strong acids or alkalis

*When drugs have a delayed emptying.
†When specific antidotes are available.

BOX 34-3 Dosage of Activated Charcoal

1 to 2 g/kg body mass
30 to 100 g in adults
15 to 30 g in children
Prepared in a slurry and administered orally or by gastric tube

CRITICAL THINKING
Why might a patient be reluctant to take activated charcoal?

GASTRIC LAVAGE

Gastric lavage is a method of gastrointestinal decontamination that can immediately recover a portion of gastric contents. It sometimes is used in the emergency department when a highly toxic substance, such as a calcium channel blocker or tricyclic antidepressant (TCA), has been ingested within the past hour. To perform gastric lavage, a large-bore orogastric tube is inserted through the patient's mouth into the stomach. This is followed by instillation of normal saline through the tube, lavaging the stomach of gastric contents until the fluid returned is clear. Gastric lavage is contraindicated in patients who cannot protect their airway and who have an altered level of consciousness. The procedure also is contraindicated in those who have ingested low-viscosity hydrocarbons (e.g., gasoline,

kerosene, furniture polish, mineral spirits) where the risk of aspiration is increased.

WHOLE-BOWEL IRRIGATION

Whole-bowel irrigation is another in-hospital method of GI decontamination. It involves the rapid administration of large amounts of a specially balanced fluid to flush the GI tract. It is administered either orally or via a nasogastric tube. Although rarely indicated, the procedure may be useful in cases of severe, recent ingestion of lithium or metals, such as iron or lead, and in patients who have ingested large amounts of sustained-release formulations of highly toxic drugs. Whole-bowel irrigation also may be useful in the evacuation of drug packets from "body packers."

NOTE

Syrup of ipecac is an over-the-counter liquid medication used to induce vomiting. It was once the treatment of choice in preventing the absorption of poisons. However, studies showed that ipecac-induced emesis reduced drug absorption by only about 30%. The drug also may interfere with the effectiveness of other methods of decontamination and can increase the risk of aspiration. In 2004 the Federal Drug Administration withdrew approval of syrup of ipecac because of its abuse by patients with bulimia (see Chapter 35). Although the drug may be found in a patient's home, it should not be administered to manage an ingested poison. Patients should be advised to remove syrup of ipecac from their home and to call 9-1-1 or a poison control center if needed.[7]

Antidotes

An antidote is an agent used to neutralize or counteract the effects of a specific poison. Some antidotes work by aiding the elimination of the toxin. Others reactivate enzymes that have been altered by the poison. With a few exceptions described in this chapter, most antidotes are given under physician supervision in the hospital setting (Table 34-1).

Management of Specific Ingested Poisons

Specific ingested poisons discussed in this section include strong acids and alkalis, hydrocarbons, methanol, ethylene glycol, isopropanol, metals (iron, lead, and mercury), and poisons from food and plants. Few effective antidotes are available for ingested poisons. Thus managing the patient's symptoms is the main goal in caring for the poisoned patient.

STRONG ACIDS AND ALKALIS

Strong acids and alkalis include those found in toilet-bowl cleaners, rust remover, ammonia, and most liquid drain cleaners (Box 34-4). These acids and alkalis may cause burns to the mouth, pharynx, esophagus, and sometimes the upper respiratory and gastrointestinal tracts. Perforation of the esophagus or stomach may result in vascular collapse, **mediastinitis** (inflammation of the mediastinum), or **pneumoperitoneum** (air or gas in the peritoneal cavity of the abdomen). The frequency of caustic ingestions (most commonly lye) is highest in small children, accounting for 5000 to 8000 accidental exposures each year.[2]

The ingestion of caustic and corrosive substances generally produces immediate damage to the mucous membrane and the intestinal tract. Acids generally complete their damage within 1 to 2 minutes. Alkalis, however, may continue to cause **liquefaction** of tissue and damage for minutes to hours. (Liquefaction is the conversion of solid tissue to a fluid or semifluid state.) Thus the prehospital care usually is limited to airway and ventilatory support, intravenous (IV) fluid replacement, and rapid transport to an appropriate medical facility.

TABLE 34-1 Antidotes to Common Toxins*

Toxin	Antidote
Acetaminophen	*N*-Acetylcysteine
Anticholinergic agents	Physostigmine
Benzodiazepines	Flumazenil
Beta blockers	Glucagon
Calcium channel blockers	Calcium
Cyanide	Amyl nitrate, sodium nitrate, hydroxocobalamin; sodium thiosulfate
Tricyclic antidepressants	Bicarbonate
Digoxin	Digoxin immune Fab
Iron	Deferoxamine
Methanol	Ethanol
Opioids	Naloxone
Organophosphates	Atropine, pralidoxime

*See the *Emergency Drug Index*.

BOX 34-4 Common Acid and Alkali Substances

Acids	Alkalis
Acetic acid	Ammonia
Battery acid	Bleach
Bleach disinfectants	Disk (button) batteries
Hydrochloric acid	Drain pipe and toilet-bowl cleaners
Metal cleaners	Hair dyes and tints
Phenol	Jewelry cleaners
Sulfuric acid	Metal cleaners or polishes
Swimming pool cleaners	Paint removers
Toilet bowl cleaners	Sodium or potassium hydroxide (lye)
	Washing powders

In some cases, medical direction or poison control may recommend diluting the acid or alkali if the patient is conscious. This is done with the oral administration of milk or water: 200 to 300 mL for an adult, 15 mL/kg maximum for a child.[8] Efforts to neutralize the ingested agent with other fluids such as fruit juice, lemon juice, or vinegar are contraindicated. These fluids have the potential to induce intense heat-releasing reactions that can cause severe thermal burns.

CRITICAL THINKING

What is a risk of administering milk or water to a patient with this type of ingestion?

HYDROCARBONS

Hydrocarbons are a group of compounds that are derived mainly from crude oil, coal, or plant sources. Mixtures vary in their viscosity, surface tension, and volatility. **Viscosity** is the resistance of a liquid to flow; **surface tension** is the ability of a liquid to be attracted to another surface; **volatility** is the ability of a liquid to vaporize. These attributes determine the toxic effects of these agents. Other contributing factors include the presence of other chemicals in the product, total amount of product, and route of exposure.

Hydrocarbons are found in many household products. Examples include cleaning and polishing agents, spot removers, paints, cosmetics, pesticides, and hobby and craft materials. Baby oil is a hydrocarbon that is particularly dangerous if ingested. Hydrocarbons also are found in petroleum distillates, such as turpentine, kerosene, gasoline, lighter fluids, and pine oil products. In addition, a large group of halogenated hydrocarbons and aromatic hydrocarbons exists. Examples of halogenated hydrocarbons include carbon tetrachloride, trichloromethane, trichloroethylene, and methyl chloride. Examples of aromatic hydrocarbons are toluene, xylene, and benzene. Hydrocarbon poisonings are common, accounting for 7% of all ingestions in children younger than 5 years of age.[2] Most ingestions occur between May and September. It is during these months when home use of petroleum products allows children the greatest opportunity for exposure (e.g., cleaning and yard machinery).

The most important physical characteristic in the potential toxicity of ingested hydrocarbons is its viscosity. The lower the viscosity, the higher is the risk of aspiration and associated complications. For example, an ingested hydrocarbon product with a low viscosity, such as gasoline or turpentine, rapidly spreads over the surface of the mouth and throat. The more volatile components become gases on contact with the warm mucous membranes. This exposure causes irritation, coughing, and possible aspiration. If aspiration occurs, it may allow a toxic amount of hydrocarbons to enter the lungs. Hydrocarbons with high viscosity (e.g., asphalt, grease, tar) are not aspirated or absorbed in the gastrointestinal tract. Thus they do not have significant toxicity.

NOTE

A mnemonic for remembering hydrocarbons is CHAMP: *c*amphor, *h*alogenated hydrocarbons, *aromatic* hydrocarbons, (heavy) *metal*-containing hydrocarbons, and *pesticide*-containing hydrocarbons.

The clinical features of hydrocarbon ingestion vary widely, depending on the type of agent involved (Box 34-5). If the patient is not displaying symptoms on EMS arrival, the chances of serious complications usually are low. These patients generally are observed in the emergency department for several hours. They often require no treatment. However, any patient suspected of hydrocarbon ingestion who coughs, chokes, cries, or has spontaneous emesis on swallowing should be assumed to have aspirated the hydrocarbon until proven otherwise. Hydrocarbon ingestion may involve the patient's respiratory, gastrointestinal, and neurological systems. The clinical features may be immediate or delayed. Emergency care for symptomatic patients who have ingested hydrocarbon products includes the following:

1. Ensure a patent airway. Provide adequate ventilatory and circulatory support as needed.
2. Identify the substance. Contact medical direction or a poison control center.
3. Decontamination of the stomach generally is avoided in these patients because of the risk of aspiration. The use of ***activated charcoal*** or diluents has not been shown to be effective in managing hydrocarbon ingestion.[7]
4. Initiate intravenous fluid therapy.

BOX 34-5 Clinical Features of Hydrocarbon Ingestion

Immediate: Up to 6 Hours

Gastrointestinal System
- Abdominal pain
- Belching
- Irritation
- Mucous membrane hyperemia
- Nausea and vomiting

Respiratory System
- Cough and choking
- Cyanosis
- Dyspnea
- Inspiratory stridor
- Tachypnea

Neurological System
- Coma
- Fever
- Lethargy
- Malaise
- Seizures
- Systemic factors

Delayed: Days to Weeks

Gastrointestinal System
- Diarrhea
- Hepatic toxicity

Respiratory System
- Atelectasis
- Bacterial pneumonia
- Dyspnea
- Hemolytic and aplastic anemias
- Pulmonary edema
- Spontaneous hemorrhage
- Sputum production
- Systemic factors

5. Monitor cardiac rhythm.
6. Transport the patient for physician evaluation.

CRITICAL THINKING
Will the potential lethal effects of this ingestion always be visible on the scene?

METHANOL

Methanol (wood alcohol) is a poisonous alcohol found in a variety of products. Some of these include gas line antifreeze, windshield washer fluid, paints, paint removers, varnishes, canned fuels such as Sterno, and many shellacs. Methanol is a colorless liquid. It has an odor that is distinct from that of ethanol, the form of alcohol in alcoholic beverages. Poisonings may result from intentional or unintentional ingestions, absorption through the skin, or inhalation. Examples include deliberate use of the agent by chronic alcoholics to maintain an inebriated state, unintentional ingestion resulting from misuse or distribution of methanol for ethanol (as in contraband liquor), and accidental ingestions in children.

The metabolites of methanol are extremely toxic. As methanol is absorbed, it rapidly is converted in the liver to formaldehyde and then to formic acid. The accumulation of formic acid in the blood affects the central nervous system (lethargy, confusion, seizure) and the gastrointestinal tract (abdominal pain, nausea and vomiting) and leads to the development of metabolic acidosis (shock, multisystem failure, death). The patient's vision also may be affected (blurred vision, photophobia). The ingestion of as little as 4 mL can cause blindness.[9] The symptoms of methanol poisoning correlate with the degree of acidosis. The onset of symptoms after ingestion ranges from 40 minutes to 72 hours.

CRITICAL THINKING
Do you think this could have been the origin of the expression "blind drunk"?

Emergency care for methanol poisoning is as follows:

1. *Supportive care:* Secure a patent airway and monitor pulse oximetry. Provide adequate ventilatory and circulatory support as needed. Adequate ventilation is essential to ensure adequate oxygenation, to help correct the profound metabolic acidosis, and to maximize respiratory excretion. Establish an intravenous line. The patient should be placed on a cardiac monitor to detect rhythm disturbances.
2. *Gastrointestinal decontamination:* If the patient is seen within 1 hour after ingestion, gastric lavage may be indicated. ***Activated charcoal*** is ineffective and should not be given. Consult with medical direction or a poison control center.
3. *Correction of metabolic acidosis:* Medical direction may recommend an attempt to correct the metabolic acidosis with ***sodium bicarbonate.*** Large or repeated doses may be necessary. Serum formic acid may be neutralized with bicarbonate administration. However, hemodialysis will likely be necessary to remove toxic levels of methanol and formate.
4. *Prevention of the conversion of methanol to formic acid:* The conversion of methanol to formic acid may be prevented by the administration of ethanol. (Ethanol has 9 times greater affinity for the enzyme that converts methanol to formic acid.[10] If authorized by online medical direction or protocol, give the conscious patient 30 to 60 mL of 80-proof ethanol by mouth or gastric lavage tube. Unconscious patients should have their airway protected with an endotracheal tube before gastric tube administration of ethanol.
5. *Transport:* Rapidly transport the patient to a proper medical facility for definitive treatment.

ETHYLENE GLYCOL

Ethylene glycol is a colorless, odorless, water-soluble liquid. It is commonly used in windshield deicers, detergents, paints, radiator antifreeze, and coolants. The accidental ingestion of ethylene glycol is common in young children because of the brilliant colors added to these preparations. Ingestion also is due to the widespread availability of products containing ethylene glycol and the warm, sweet taste. The agent also is sometimes consumed by alcoholics as a substitute for ethanol. Without treatment, ingestion of as little as 0.2 mL/kg has been reported to be lethal to an adult.[7]

Early signs and symptoms of central nervous system (CNS) depression usually are caused by the ethanol-like effects of ethylene glycol. However, toxicity from ethylene glycol, as from methanol, is caused by the accumulation of glycolic and oxalic acids after metabolism. This occurs primarily in the liver and kidneys. The metabolic molecules may affect the CNS and cardiopulmonary and renal systems. The initial signs and symptoms of ethylene glycol poisoning may include slurred speech, nausea and vomiting, hallucinations, seizure, stupor, and coma. This can be followed by pulmonary edema and cardiac failure.

Emergency care for ethylene glycol poisoning is similar to that used for methanol poisoning. In addition, the paramedic should anticipate orders from medical direction or a poison control center for the following medications:

- ***Thiamine*** to degrade glycolic acid to nontoxic metabolites
- ***Calcium gluconate*** or ***calcium chloride*** to manage hypocalcemia
- ***Diazepam*** or ***lorazepam*** to control seizure activity

CRITICAL THINKING
The effects in stage one of ethylene glycol poisoning could be mistaken for what condition?

ISOPROPANOL

Isopropanol (isopropyl alcohol) is a volatile, flammable, colorless liquid. It has a characteristic odor and bittersweet taste. Rubbing alcohol is the most common household source of this agent. It also is used in disinfectants, degreasers, cosmetics, industrial solvents, and cleaning agents. Common routes of toxic exposure to isopropanol include intentional ingestion as a substitute for ethanol, accidental ingestion, and inhalation of high concentrations of local vapor. Isopropanol is more toxic than ethanol, but less toxic than methanol or ethylene glycol. A lethal dose in adults is rare.[8] In children, any amount of ingestion should be considered potentially toxic.

Isopropanol poisoning affects several body systems, including the central nervous, gastrointestinal, and renal systems. The signs and symptoms often occur within 30 minutes after ingestion. They include CNS and respiratory depression, abdominal pain, gastritis, hematemesis, and hypovolemia. Isopropanol poisoning causes acids to accumulate in the blood (*acetonemia*) and ketones to accumulate in the urine (*ketonuria*). However, associated metabolic acidosis usually does not occur unless the patient develops hypotension.

Emergency care for isopropanol poisoning mainly is supportive. Care includes airway and ventilatory support to ensure adequate respiratory elimination of acetone, fluid resuscitation as needed, and rapid transport to an appropriate medical facility, where dialysis may be necessary. Gastric lavage and ***activated charcoal*** are not effective.[8] Administration of ethanol has not proven to inhibit the toxic metabolite to the same degree as in methanol or ethylene glycol poisoning.

METALS

Infants and children are high-risk groups for unintentional iron, lead, and mercury poisoning. Their immature immune systems and increased absorption as a function of age contribute to this risk.

Iron Poisoning. About 10% of ingested iron (mainly ferrous sulfate) is absorbed each day from the small intestine. After absorption, the iron is converted and is stored in iron storage protein. Then the iron is transported to the liver, spleen, and bone marrow for incorporation into hemoglobin. When ingested iron exceeds the ability of the body to store it, the free iron circulates in the blood. The iron then is deposited into other tissues. Most iron poisonings result from the ingestion of pediatric multivitamins by children younger than 6 years of age.[3]

Unintentional or intentional ingestion of iron may be fatal. Ingested iron is corrosive to the lining of the gastrointestinal tract. Iron may produce gastrointestinal hemorrhage, bloody vomitus, painless bloody diarrhea, and dark stools. Severe cases involve the ingestion of more than 20 mg/kg. Ingestion of more than 60 mg/kg can produce cardiovascular collapse and death.[7] Prehospital care includes supportive measures and rapid transport for physician evaluation and possible gastric decontamination to prevent further absorption. The use of ***activated charcoal*** generally is not recommended because it adsorbs iron poorly. Most patients with iron poisoning survive the episode. The long-term prognosis is favorable.

Lead Poisoning. Metallic lead has been used by human beings for thousands of years. In 1978 lead-based paint was recognized as a major health hazard and was banned from household paints in the United States (Box 34-6). Children are the most common victims of lead poisoning; an estimated 250,000 children in the United States have levels of lead in their bloodstream of 10 mg/dL or greater.[11] Most pediatric poisonings result from ingestion of lead-based paint chips and contaminated house dust. Lead toxicity in adults most commonly results from exposure by inhalation. If not detected early, children with high levels of lead in their bodies can suffer from damage to the brain and nervous system. This can result in behavioral and learning problems, hyperactivity, slowed growth, hearing problems, and headaches. Even children who appear healthy can have dangerous levels of lead in their bodies. Adults with high levels of lead in their systems can experience difficult pregnancies, reproductive problems, hypertension, nerve disorders, muscle and joint pain, and problems with memory and concentration.

Most lead poisoning is slow in onset and results from chronic ingestion or inhalation. This eventually results in toxicity. The metal is excreted by the body slowly and tends to accumulate in body tissues (mainly bone). Lead exposure that results in acute intoxication may lead to paralysis, seizures, coma, and death. Patients who survive are likely to sustain brain damage. Prehospital care is focused on recognizing the potential for lead poisoning and transporting the patient for physician evaluation. If lead poisoning is

BOX 34-6 Places Where Lead Can Be Found

- Homes in the city, country, or suburbs
- Apartments, single-family homes, and private and public housing painted before 1978
- Soil around a home (soil contaminated from exterior paint, or other sources such as past use of leaded gasoline in cars)
- Painted windows and window sills
- Doors and door frames
- Stairs, railings, and banisters
- Porches and fences
- Paint surfaces that have been scraped, dry-sanded, or heated (lead dust)
- Old painted toys and furniture
- The air after vacuuming or sweeping contaminated surfaces
- Food and liquid stored in lead crystal or lead-glazed pottery or porcelain
- Lead smelters or other industries
- Hobbies that use lead (e.g., making pottery or stained glass)
- Folk remedies (greta or azarcon used to treat an upset stomach)

confirmed through x-ray and laboratory testing, care may include gastric decontamination or whole-bowel irrigation. Following treatment, all patients must be discharged to a lead-free environment. Outpatient *chelation therapy* may be indicated to detoxify the lead and excrete the metal from the body.

CRITICAL THINKING

Paramedics play a key role in the emergency management of lead poisoning. What other role can they play in the management of this problem?

Mercury Poisoning. Mercury is the only metal that is liquid at room temperature. It has been used in thermometers, sphygmomanometers, and dental fillings. Various compounds of mercury also are used in some paints, pesticides, cosmetics, drugs, and in certain industrial processes. All forms of mercury (except those in dental fillings) are poisonous.

Inhalation of mercury vapor is the most common route of mercury poisoning. It may cause shortness of breath and lung damage. Mercury also may be absorbed through the skin, causing severe inflammation, and through the intestines after ingestion. After mercury enters the body, it passes into the bloodstream. It later accumulates in various organs, mainly the brain and kidneys. This causes a wide range of symptoms that may include the following:

- Malaise
- Incoordination
- Excitability
- Tremors
- Numbness in the limbs
- Vision impairment
- Nausea and emesis (symptoms of renal failure)
- Mental status changes

Prehospital care mainly is supportive. Following physician evaluation, patients are managed with gastrointestinal decontamination if the ingestion was recent, and with chelating agents. In severe cases, hemodialysis may be indicated.

FOOD POISONING

Food poisoning is a term used for any illness of sudden onset suspected of being caused by food eaten within the previous 48 hours. It is usually associated with stomach pain, vomiting, and diarrhea. Food poisoning can be classified as infectious (bacterial and viral) or noninfectious.

Infectious (Bacterial) Types. One of the common types of bacteria responsible for food poisoning is *Salmonella*. This organism is found in many animals (especially poultry) and in human beings. *Salmonella* bacteria also may be transferred to food from the excrement of infected animals or humans, and by an infected person handling food. Other bacteria (e.g., strains of staphylococcal bacteria) cause formation of toxins. These toxins may be difficult to destroy even with thorough cooking of the food. Other bacteria that commonly cause diarrhea are certain strains of *Escherichia coli* (traveler's diarrhea) and *Campylobacter* and *Shigella* organisms.

Botulism is a rare but life-threatening form of food poisoning. It may result from eating improperly canned or preserved food that is contaminated with the bacterium *Clostridium botulinum*. This organism is found in soil and untreated water in most parts of the world. It also is harmlessly present in the intestinal tracts of many animals, including fish. Its spore-forming properties resist boiling, salting, smoking, and some forms of pickling. This allows the bacterium to thrive in improperly preserved or canned foods. Although foodborne botulism is rare, the disease is more common in the United States because of the popularity of preserving food in the home. Botulism is associated with severe CNS symptoms. These symptoms appear in a characteristic head-to-toe progression: headache, blurred or double vision, dysphagia, respiratory paralysis, and quadriplegia. Respiratory failure occurs in 50% of patients.[8] Death, however, is rare with treatment.

NOTE

Infant botulism is the most common form of illness in the United States, accounting for 72% of all cases.[8] It occurs in children younger than 1 year of age, with a peak incidence between 2 and 6 months of age. The illness often is caused by consuming infected spores from honey and, to a lesser degree, corn syrup.

Infectious (Viral) Types. The viruses that most often cause food poisoning are the Norwalk virus (a common contaminant of shellfish) and rotavirus. Both agents may be responsible for illness when raw or partly cooked foodstuffs have been in contact with water contaminated by human excrement.

Noninfectious Types. Noninfectious types of food poisoning may result from consuming mushrooms and toadstools. Food poisoning also can result from eating fresh foods and vegetables that are accidentally contaminated with large amounts of insecticide. Chemical food poisoning may result from eating food stored in a contaminated container (e.g., a container that previously was used to store poison). It also can result from improperly preparing and cooking various exotic foods.

Management Guidelines. The onset of signs and symptoms from food poisoning varies by cause and by how heavily the food was contaminated. As a rule, symptoms usually develop within 30 minutes in the case of chemical poisoning; in 1 to 12 hours in the case of bacterial toxins; and in 12 to 48 hours with viral and bacterial infections.[8] General principles of the management for patients with suspected food poisoning include the following:

- Use precautions to avoid contamination of self and equipment. Wear gloves, a gown, or both if appropriate.
- Ensure adequate airway, ventilatory, and circulatory support.
- Gather a complete history. This should include time and onset of symptoms, recent travel, the relation of symptoms to ingestion of a particular food, and effects on others who ate the same food. In addition, the paramedic should obtain information on the consistency, frequency, and odor of stool (including the presence of mucus or blood). Fever should be noted as well. Any patient history also should include significant medical history, allergies, and use of medications.
- Initiate intravenous therapy with a crystalloid solution. This will help to manage dehydration and electrolyte disturbances resulting from vomiting and diarrhea.
- Transport the patient for physician evaluation.

PLANT POISONING

Toxic plant ingestion is a frequently reported category of poisonings, second only to ingestion of cleaning substances.[2] The majority of these exposures occur in children less than 6 years of age.

CRITICAL THINKING

What features of a plant would make it attractive for children to eat?

Signs and Symptoms. The signs of toxicity following the ingestion of major poisonous plants are predictable. They are categorized by the chemical and physical properties of the plant. Most signs and symptoms tend to be consistent with the type of major toxic chemical component in the plant. They usually appear within several hours after ingestion, but may be delayed 1 to 3 days. Box 34-7 lists common poisonous plants. Paramedics should be familiar with common poisonous plant life in their response area.

Management. Several hundred species of green plants and more than 100 varieties of mushrooms in the United States contain toxic compounds. These plants and mushrooms have widely varying potencies and combinations of toxins. In addition, such factors as the age of the plant and soil conditions may influence the severity of toxic symptoms. Thus management guidelines should be customized to the patient's symptoms rather than to one type of ingestion. Identification of the plant is important if possible. However, the inability to do so should not delay patient care. The paramedic should consult with medical direction or a poison control center regarding appropriate management. Emergency care for toxic plant ingestion generally includes gastrointestinal decontamination and/or the administration of ***activated charcoal*** in conscious patients, IV fluids, and ensuring adequate airway, ventilatory, and circulatory support. Most patients are hospitalized for observation and treatment as indicated for the toxin involved. Dialysis has not been shown to be effective in removing most plant toxins.[12]

BOX 34-7 Common Poisonous Plants, Trees, and Shrubs

House Plants
Dieffenbachia
Hyacinth
Mistletoe
Narcissus
Oleander
Poinsettia

Flower-Garden Plants
Daffodil
Foxglove
Iris
Larkspur
Lily of the valley

Ornamental Plants

Jack-in-the-pulpit
Mayapple
Nightshade
Water and poison hemlock

Trees and Shrubs
Elderberry
Oaks
Wild and cultivated cherries

POISONING BY INHALATION

The unintentional or intentional inhalation of poisons can lead to a life-threatening emergency. The type and location of injury caused by toxic inhalation depend on the specific actions and behaviors of the chemical involved.[13] Respiratory difficulty may not appear for several hours after exposure to toxic fumes and smoke. All patients should be encouraged to seek physician evaluation. This includes even those who are asymptomatic.

CRITICAL THINKING

Do you think that situations involving toxic gas inhalation are likely to involve one patient or multiple patients? Why?

Classifications

Toxic gases can be classified in three categories: simple asphyxiants, chemical asphyxiants, and irritants/corrosives. **Simple asphyxiants** (e.g., methane, propane, inert gases) cause toxicity by displacing or lowering the amount of oxygen in the air. **Chemical asphyxiants** (e.g., carbon monoxide, cyanide) can cause a number of local and pulmonary reactions when inhaled. Their toxic systemic effects prevent the uptake of oxygen by the blood and can interfere with tissue oxygenation. **Irritants/corrosives** (e.g., chlorine, ammonia) cause cellular destruction and inflammation as they come into contact with moisture. Table 34-2 provides an overview of toxic gases and their clinical features.

TABLE 34-2 Clinical Features of Toxic Gases and Fumes

Class of Toxin	Toxin	Source	Clinical Features	Management
Simple asphyxiants	Propane Methane Carbon dioxide Inert gases (nitrogen, argon)	Cooking gas Cooking gas All fires Industry (especially welding)	Displacement of normal air and lower fractional inspired oxygen concentration, symptoms of hypoxemia without airway irritation	Remove patient from source; give oxygen.
Chemical asphyxiants	Carbon monoxide	Fires	Formation of carboxyhemoglobin; inhibition of oxygen transport (headache is earliest symptom)	Give 100% oxygen.
	Hydrocyanic acid	Industry, burning plastics, furniture, fabrics	Highly toxic cellular asphyxiant	Use cyanide antidote.
	Hydrogen sulfide	Liquid manure pits, decaying organic materials	Highly toxic cellular asphyxiant similar to cyanide; sudden collapse; ability to smell characteristic odor of rotten eggs; rapid fatigue	Use sodium nitrite for cyanide (makes sulfmethemoglobin). Do not use thiosulfate.
Irritants: high solubility in water	Chlorine gas Hydrochloric acid	Industry, swimming pool chemicals, bleach mixed with acid at home	Early onset of lacrimation, sore throat, stridor, tracheobronchitis; with heavy exposure, pulmonary edema in 2-6 hr	Use humidified oxygen, bronchodilators, and airway management.
Irritants: low solubility in water	Ammonia Nitrogen dioxide	Industry, burning fabrics Burning cellulose, fabrics	Sweet "electric" smell; delayed onset (12-24 hr) of tracheobronchitis, pneumonitis, and pulmonary edema; late chronic bronchitis	Give oxygen: observe for 24-48 hr; give steroids (controversial).
	Ozone	Grain silos (acrid red gas) Inert gas arc welding, industry		
	Phosgene	Burning of chlorinated organic material		
Allergenic	Toluene diisocyanate	Manufacture of polyurethanes	Reactive bronchoconstriction; possible long-term effects (chronic obstructive pulmonary disease) in susceptible persons	Use bronchodilators.
Metal fumes	Zinc Copper Tin Teflon	Welding (especially galvanized metal welding)	"Metal fumes fever"; chills, fever, myalgias, headache, nonproductive cough, leukocytosis 4-8 hr after exposure	Is self-limited (12-24 hr).
	Arsine	Burning arsenic-containing ores, electronics industry	Highly toxic effect; hemolysis, pulmonary edema, renal failure; chronic arsenic toxicity	Perform exchange transfusion; use dimercaprol (BAL) for chronic arsenic toxicity only.
	Mercury Lead	Industry, welding	See specific metals	

From Ho MT: *Current emergency diagnosis and treatment,* ed 3, Norwalk, Conn, 1990, Appleton & Lange.

General Management

The general principles of managing patients who have inhaled poisons are the same as those for any other hazardous materials incident (see Chapters 57and 58). These principles include the following:

1. Scene safety
2. Personal protective measures (protective clothing and appropriate respiratory protective apparatus)
3. Rapid removal of the patient from the poison environment

4. Surface decontamination
5. Adequate airway, ventilatory, and circulatory support
6. Initial assessment and physical examination
7. Irrigation of the eyes (as needed)
8. Intravenous line with a saline solution
9. Regular monitoring of vital signs, ECG, and pulse oximetry
10. Rapid transport to an appropriate medical facility

Management of Specific Inhaled Poisons

The specific inhaled poisons discussed in this section include cyanide, ammonia, and hydrocarbons. Carbon monoxide poisoning is described in Chapter 39. Other gases associated with atmospheres with low oxygen levels and chemical and biological warfare are discussed in Chapters 57 and 58.

CYANIDE

Cyanide refers to any of a number of highly toxic substances that contain the cyanogen chemical group. Because of its toxicity, cyanide has few applications. The agent sometimes is used in industry in electroplating ore extraction, fumigation of buildings, and as a fertilizer. Cyanide has been used in gas chambers as a means of execution. It is one of the byproducts of combustion from burning many substances, including nylon and polyurethane. Thus cyanide is a hazard in fire environments.

Cyanide poisoning may result from the inhalation of cyanide gas; the ingestion of cyanide salts, nitriles, or cyanogenic glycosides (e.g., amygdalin, a substance found in the seeds of cherries, apples, pears, and apricots, and the principal constituent of Laetrile); or the infusion of nitroprusside. Cyanide also can be absorbed across the skin. Regardless of the route of entry, cyanide is a rapidly acting poison. It combines and reacts with ferric ions (Fe^{3+}) of the respiratory enzyme cytochrome oxidase to inhibit cellular oxygenation. The cytotoxic hypoxia produces a rapid progression of symptoms from dyspnea to paralysis, unconsciousness, and death (Box 34-8). Large doses usually are fatal within minutes from respiratory arrest.

BOX 34-8 Early and Advanced Signs and Symptoms of Cyanide Poisoning

Early Effects	Advanced Effects
Agitation	Acidosis
Anxiety	Dysrhythmias
Confusion	Hypotension
Dyspnea	Intractable hypotension
Hypertension with reflex bradycardia	Lactic acidosis
	Pulmonary edema
	Seizures
	Coma

After ensuring personal safety, emergency care for a patient with cyanide poisoning begins with securing an open airway and providing adequate ventilatory support with high-concentration oxygen. Oxygen displaces cyanide from cytochrome oxidase and increases the effectiveness of drug administration. After these measures, one type of treatment of cyanide poisoning converts (oxidizes) ferrous ions in hemoglobin (Fe^{2+}) to ferric ions (Fe^{3+}). This forms **methemoglobin:** hemoglobin with ferrous ion in the oxidized (Fe^{3+}) state. Cyanide, which has a greater attraction to iron in the ferric state, is released from the cytochrome oxidase and combines with methemoglobin. This allows cytochrome oxidase to resume its function in normal cellular respiration. Cyanide antidotes (Box 34-9), such as those found in the Pasadena cyanide antidote kit (also known as the *Lilly Cyanide Poison Kit* and *Taylor Kit*), are thought to be effective because they induce methemoglobin production.

DID YOU KNOW?

Methemoglobin (MetHb) is a dysfunctional form of hemoglobin that cannot transport oxygen. An increased level of methemoglobin in the blood is known as **methemoglobinemia**. This condition reduces blood oxygenation and produces a "functional anemia." Methemoglobinemia causes a leftward shift of the oxyhemoglobin dissociation curve. This impedes the unloading of oxygen from normal hemoglobin, reduces the amount of oxygen available to tissues, and leads to tissue hypoxia.

Methemoglobinemia may be congenital. It also may be acquired from exposure to industrial toxins (e.g., nitrites in grain silos) and the ingestion and overuse of some medications such as nitrates, nitrites, and sulfonamides. Signs and symptoms of methemoglobinemia include shortness of breath, cyanosis, mental status changes, headache, fatigue, dizziness, and loss of consciousness. The Rad 57 is an oximetry device that can be used in the prehospital setting to measure SaO_2, carboxyhemoglobinemia, and, in some cases, methemoglobin levels. In the emergency setting, methemoglobinemia is treated with oxygen and in-hospital administration of methylene blue. Methylene blue restores the iron in hemoglobin to its normal (reduced) oxygen-carrying state.

Because methemoglobin cannot transport oxygen, it must be reconverted to hemoglobin. This is accomplished in a three-part process. The goal of the first two steps is the formation of methemoglobin through the administration of ***amyl nitrate*** by inhalation, and IV sodium nitrite. These drugs convert ferrous hemoglobin into methemoglobin. The goal of the third part of the process is to detoxify the cyanide so that it can be eliminated. This is accomplished by giving IV ***hydroxocobalamin***, with or without sodium thiosulfate (See the Emergency Drug Index). These drugs help detoxify cyanide so that it can be eliminated by the kidneys.[8] Prehospital care for patients with cyanide poisoning includes the following:

BOX 34-9 Three-Step Cyanide Antidote

Two Amyl Nitrite Inhalants in Gauze

Administer by inhalation for 15 to 30 seconds; may be repeated as necessary.

3% Sodium Nitrite (Stop Amyl Nitrite)

Adults: 10-mL slow intravenous administration over 2 to 4 minutes

Children: 0.2 mL/kg (up to 10 mL) slow intravenous administration over 5 minutes

Note: If hypotension develops, stop nitrite, treat for shock, and consider administration of *dopamine* (per medical direction).

Hydroxocobalamin

- Adults: 5 g IV
- Children: 70 mg/kg IV (do not exceed adult dose)
- Dilute in 100 mL normal saline; infuse over 15 minutes; may follow with sodium thiosulfate (separate IV)

25% Sodium Thiosulfate

Adults: 12.5 g (50 mL of 25% solution) IV over 10 minutes

Children: 400 mg/kg (1.65 mL/kg of 25% solution) IV over 10 minutes (do not exceed adult dose)

NOTE

The cyanide antidote described in Box 34-9 should not be given to patients with cyanide poisoning that resulted from smoke inhalation. Carbon monoxide limits the amount of oxygen that hemoglobin can carry. This, coupled with formation of methemoglobin from the antidote, leaves little hemoglobin that can carry oxygen to sustain life. The patient may die from anoxia.

Hydroxocobalamin (Cyanokit) is a vitamin B_{12} precursor that can be used to treat cyanide poisoning. It has a central cobalt atom that binds to cyanide in the blood and forms cyanocobalamin (vitamin B_{12}). Detoxification with hydroxocobalamin does not create methemoglobin, so it does not lower the oxygen-carrying capacity of the blood. Rare cases of allergic reaction have been reported. It does not cause hypotension.[14] This makes it possible to use hydroxocobalamin to treat all types of cyanide poisoning, including smoke inhalation (see the *Emergency Drug Index*).

1. Don personal protective equipment as needed. This will help to prevent rescuer contamination.
2. Remove the patient from the cyanide source. Rapid decontamination and removal of the patient's contaminated clothing is essential.
3. Ensure a patent airway and provide adequate ventilatory support.
4. Administer high-concentration oxygen and monitor pulse oximetry.
5. Administer the cyanide antidote. Consult with medical direction or a poison control center and follow the instructions provided by the manufacturer.
6. Initiate intravenous fluid therapy with a volume-expanding solution.
7. Monitor cardiac rhythm by electrocardiogram.
8. Rapidly transport the patient for physician evaluation.

Hypotension should be anticipated as a side effect of antidote therapy. The patient should remain lying down, if possible, and blood pressure must be monitored closely. If hypotension develops, medical direction may recommend the administration of vasopressors.

AMMONIA INHALATION

Ammonia is a toxic irritant that causes local pulmonary complications after inhalation. These complications include inflammation and irritation and, in severe cases, destruction of the mucosal tissue of all respiratory structures. Injury occurs as the ammonia vapor combines with water, producing a highly caustic alkaline compound. Patients usually develop coughing, choking, congestion, burning, and tightness in the chest and a feeling of suffocation. These respiratory symptoms often are associated with burning eyes and tearing. In severe cases, bronchospasm and pulmonary edema may develop. In addition to the general management principles, emergency care may include positive-pressure ventilation and the administration of diuretics and bronchodilators.

HYDROCARBON INHALATION

The hydrocarbons that pose the greatest risk for injury have low viscosity, high volatility, and high surface tension or adhesion of molecules along a surface. These characteristics allow hydrocarbons to enter the pulmonary tree. This causes aspiration pneumonitis and creates the potential for systemic effects as well. Examples of such effects include CNS depression and liver, kidney, or bone marrow toxicity.

Most hydrocarbon inhalations result from "recreational use" of halogenated hydrocarbons (e.g., carbon tetrachloride and methylene chloride) or aromatic hydrocarbons (e.g., benzene and toluene). These agents may produce a state of inebriation or euphoria through "sniffing" or "huffing." (This involves placing the solvent on a rag and inhaling the vapors through a plastic bag.) The onset of these effects usually is rapid, typically occurring within seconds. It may be followed by CNS depression, respiratory failure, or cardiac dysrhythmias. Other signs and symptoms of hydrocarbon inhalation include the following:

- Burning sensation on swallowing
- Nausea and vomiting
- Abdominal cramps
- Weakness
- Anesthesia
- Hallucinations
- Changes in color perception
- Blindness
- Seizures
- Coma

Emergency care for hydrocarbon inhalation generally is supportive and includes airway, ventilatory, and circulatory support; intravenous fluid therapy; vital sign and electrocardiogram monitoring; and transport for physician evaluation.

POISONING BY INJECTION

In addition to poisoning from the injection of drug misuse or abuse (described earlier), poisoning by injection also may result from bites and stings from arthropods, reptiles, and hazardous aquatic life. In contrast to most chemical compounds described previously, poisons from envenomation are mixtures of many different substances. These mixtures may produce several different toxic reactions in human beings. Thus the paramedic must be prepared to manage reactions in many organ systems at the same time. General management guidelines for most poisonings from bites and stings include the following:

1. Ensure personal safety.
2. Provide adequate airway, ventilatory, and circulatory support as needed. Watch for signs of a serious allergic reaction.
3. Clean the affected area with saline. Cover it with a sterile dressing. Intermittently apply ice to it. Obstruction tourniquets or suction devices do not help to delay absorption and should not be used. Commercially prepared antivenin (if available) sometimes is given in the emergency department after appropriate sensitivity testing.
4. Moderate to severe symptoms may require aggressive management. According to medical direction, muscle spasm, severe headache, vomiting, and paresthesia may be managed with benzodiazepines, antiemetics, and pain medication.
5. Transport the patient for physician evaluation. Most patients recover fully. Those at greatest risk for morbidity are the very young, older adults, and those with underlying hypertension or other medical problems.

Arthropod Bites and Stings

Arthropods are invertebrates with segmented bodies and jointed limbs. Some arthropods bite, some sting, and a few bite and sting. Arthropod venoms are complex and diverse in their chemistry and pharmacology. They may produce major toxic reactions in sensitized persons. Such reactions include anaphylaxis and upper airway obstruction. The various reactions to venoms are classified as local, toxic, systemic, and delayed[15-17] (Boxes 34-10 and 34-11).

HYMENOPTERA (WASPS, BEES, ANTS)

Hymenoptera is the name of a large, highly specialized order of insects that includes wasps, bees, and ants. Their venom contains mixtures of toxins, enzymes, and other compounds such as histamines, serotonin, acetylcholine, and dopamine. A single wasp, bee, or ant sting in an unsensitized person usually causes instant pain. This is followed by a wheal-and-flare reaction with variable edema. Anaphylaxis is the most serious complication of Hymenoptera stings. An estimated 0.4% of the U.S. population has some degree of chemical allergy to insect venoms; 40 to 100 deaths caused by anaphylaxis from Hymenoptera stings are reported annually.[7] Persons with a history of allergic reactions to stings often wear medical alert identification. These persons also often carry an emergency kit that contains a preloaded syringe of ***epinephrine*** (EpiPen). The ant species of greatest concern in the United States is the imported fire ant. Stings or bites from fire ants may produce systemic reactions, including anaphylaxis.

Honey bees (and other Hymenoptera) often leave their stingers in the wound. If a stinger is present, it should be scraped or brushed off the skin. Stingers should not be removed with forceps. This is because squeezing the attached venom sac may worsen the injury. Severe allergic reactions should be managed as described in Chapter 27. Hypovolemia (if present) should be treated in the conventional manner with a volume-expanding crystalloid infusion.

LOOK AGAIN
See Chapter 27: Immune System Disorders, pp. 835-836.

ARACHNIDA (SPIDERS, SCORPIONS, TICKS)

Arachnida is a large class of arthropods. These organisms usually have four pairs of legs and a body divided into a cephalothorax (a combined head and thorax) and abdomen. This discussion will be limited to spiders, scorpions, and ticks.

Spider Bites. Most spiders have venom glands. Two major types of reactions occur from spider venom. These are neurotoxic reactions resulting from the black widow bite and local tissue necrosis resulting from the bites of most other spiders.

Black Widow Spider. The female black widow spider is shiny and black with a red hourglass marking on the undersurface of the abdomen (Figure 34-1). The male is about half the size of the female, brown, and nonvenomous to human beings. The spider generally is found in undisturbed areas (under stones, logs, and clumps of vegetation). They rarely inhabit occupied dwellings. Most black widow bites occur in rural and suburban areas of southern and western states between April and October.

The bite of a black widow generally is described by patients as a slight pinprick that is initially painless. As a rule, the only physical findings are two small fang marks. These are about 1 mm apart and surrounded by a small papule. Multiple bites usually rule out any type of spider envenomation because spiders rarely bite more than once. Within 1 hour of envenomation, the neurotoxin produces characteristic muscle spasms and cramps. These may result in abdominal rigidity and intense pain. Associated symptoms include paresthesia (frequently described as a burning

BOX 34-10 Types of Reactions to Venoms

Local Reaction
- Marked and prolonged edema at the sting site
- Possible involvement of one or more neighboring joints
- Possible occurrence in the mouth or throat, producing airway obstruction
- Severe local reactions that may increase the likelihood of future systemic reactions
- Symptoms that usually subside within 24 hours

Toxic Reaction*
- Gastrointestinal disturbances
  - Diarrhea
  - Light-headedness
  - Vomiting
- Other symptoms
  - Convulsions (rare)
  - Edema without urticaria (hives)
  - Fever
  - Headache
  - Involuntary muscle spasms
  - Symptoms that usually subside within 48 hours
  - Syncope (common finding)

Systemic (Anaphylactic) Reaction†
- Reactions that can progress to death within minutes
- Immediate symptoms
  - Facial flushing
  - Generalized urticaria
  - Itching eyes or generalized itching
- Subsequent symptoms
  - Bloody and frothy sputum production
  - Chest or throat constriction, or both
  - Chills and fever
  - Cyanosis
  - Dyspnea
  - Hypotension
  - Laryngeal stridor
  - Loss of bowel or bladder control
  - Loss of consciousness
  - Nausea and vomiting
  - Respiratory failure, cardiovascular collapse, or both
  - Shock
  - Wheezing

Delayed Reaction‡
- Serum sickness symptoms
  - Fever
  - Headache
  - Malaise
  - Polyarthritis
  - Urticaria

*Should be considered with a history of 10 or more stings.
†May occur in response to single or multiple stings.
‡Usually occurs 10 to 14 days after a sting.

FIGURE 34-1 Black widow spider. (Courtesy Michael Cardwell and Associates, 1993. From Auerbach PS: *Wilderness medicine,* ed 5, Philadelphia, 2007, Mosby.)

sensation in the soles of the feet or entire body); pain in the muscles of the shoulders, back, and chest; headache; dizziness; nausea and vomiting; edema of the eyelids; and increased perspiration and salivation. Most patients recover fully within 36 to 72 hours.

Brown Recluse Spider. The brown recluse spider is also known as the fiddle-back spider. The spider is most prevalent in the Mississippi-Ohio-Missouri river basin and the southwestern United States. The species prefers hot, dry, and abandoned environments such as vacant buildings. The spider often is found in clothing closets. The spider is fawn to dark brown and is between 1 and 2 cm long (Figure 34-2). Identifying characteristics of the brown recluse are six white eyes arranged in a semicircle on the head (versus the usual eight eyes of most other spiders) and the presence of a dark, violin-shaped marking on the top of the cephalothorax. The brown recluse is considered shy. It generally does not attack unless threatened. Like black widows, these spiders are most active from April to October.

NOTE
Abdominal rigidity in the absence of palpable tenderness is a crucial finding. This helps to distinguish envenomation from an acute abdominal condition.

The venom of the brown recluse initially causes little pain and often is overlooked by the victim. Approximately 1 to 2 hours later, localized pain and erythema develop (Figure 34-3). This often is followed within 2 days by a blister or vesicle. The lesion may be surrounded by an ischemic ring that is outlined further by an irregular red halo, producing the classic bull's-eye appearance seen with this bite. Over the next 72 hours, the area often becomes larger and the center of the lesion may become purple or develop

BOX 34-11 West Nile Virus*

Mosquitoes are insects of the order Diptera (two-winged flies). Although they have long been associated with the spread of some diseases (e.g., malaria), some species recently have gained notoriety for spreading the West Nile virus. Mosquitoes become carriers of West Nile virus when they feed on infected birds. The mosquitoes then spread the virus to human beings and other animals when they bite.

West Nile virus was first isolated in Uganda in 1937. The virus was first reported in the United States (in Queens, New York) in 1999. In 2008 there were more than 1400 cases reported in the United States, none of which resulted in death.[16]

West Nile virus is a potentially serious illness. It affects the central nervous system. The virus was a major cause of illness in the United States. The symptoms (if present) usually develop within 3 to 14 days after being bitten by an infected mosquito. Most patients (about 80%) are asymptomatic after being bitten. About 20% of infected patients develop mild symptoms that include fever, headache, body aches, nausea and vomiting, and skin rash that lasts from a few days to several weeks. About 1 in 150 infected persons develops serious illness that can lead to seizures, coma, vision loss, numbness, paralysis, and other clinical manifestations such as West Nile fever, West Nile encephalitis, and West Nile meningitis. The neurological effects of the disease may be permanent.[17]

*No specific treatment exists for West Nile virus. Care is mainly supportive. Prevention of the disease is best achieved by avoiding mosquito bites, applying insect repellent containing *N,N*-diethyl-*meta*-toluamide (DEET) to exposed skin when outdoors during peak mosquito hours (evening and early morning), and participating in community mosquito control programs.

FIGURE 34-2 Brown recluse spider. (From Auerbach PS: *Wilderness medicine,* ed 5, Philadelphia, 2007, Mosby.)

a black eschar (dead tissue). The eschar eventually sloughs, leaving an ulcer of variable size and depth. The wound typically is slow to heal and may be visible for months to years after the bite. Occasionally, excision and skin grafting are necessary. Systemic involvement may occur with signs and symptoms that include fever, chills, malaise, nausea and vomiting, generalized rash, and the development of hemolytic anemia, hemoglobinuria, and hypotension. Death occasionally occurs, usually from disturbance of the coagulation system or hepatic injury.

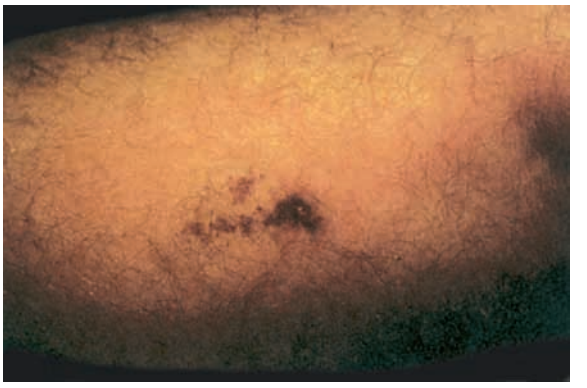

FIGURE 34-3 Brown recluse spider bite at about 6 hours with central hemorrhagic vesicle and gravitational pattern of venom spread. (From Auerbach PS: *Wilderness medicine,* ed 5, Philadelphia, 2007, Mosby.)

FIGURE 34-4 The sculptured scorpion commonly found in the deserts of Arizona, New Mexico, and California. (From Auerbach PS: *Wilderness medicine,* ed 5, Philadelphia, 2007, Mosby.)

CRITICAL THINKING

For which type of spider bite is a patient most likely to call an ambulance? Why?

Scorpion Stings. Only a few of the more than 650 species of scorpions produce human envenomation. In North America the sculptured or bark scorpion is the only species that is dangerous to human beings. This scorpion is found in the southwestern United States and Mexico. The scorpion is nocturnal and favors wooded areas along the edges of desert washes. Occasionally the scorpion invades homes, especially adobe houses. The sculptured scorpion is small and yellow to brown, and some have tail stripes (Figure 34-4). The species is most active from April to August, hibernating during the winter.

The venom of the scorpion is delivered by a stinger on the telson. The venom is a mixture of proteins that causes the release of acetylcholine. It also stimulates sympathetic nerves and directly stimulates the CNS, causing hyper-activity. This particular scorpion venom does not contain enzymes that cause tissue destruction. Thus local

inflammation is not a feature. If swelling, ecchymosis, or redness is present, the scorpion was not of the neurotoxic type. Box 34-12 lists the signs and symptoms of sculptured scorpion stings. Despite the potential for life-threatening systemic effects, mild analgesics, cool compresses, and in-hospital observation are all that are required for these patients.

Tick Bites. Tick bites seldom require emergency care. However, they are capable of causing human disease. They can transmit microorganisms or secrete toxins or venoms. In North America, hard ticks are the most familiar type, although soft ticks also are common to Western states. Local reactions to tick bites vary from the formation of a small pruritic nodule to the development of extensive areas of ulceration. Some of the more important diseases for which ticks are vectors include Rocky Mountain spotted fever, Lyme disease, and tick paralysis.

Rocky Mountain Spotted Fever. **Rocky Mountain spotted fever** is an infectious disease transmitted from rabbits and other small mammals to human beings by the bites of the wood tick and dog tick. The disease occurs more commonly on the Atlantic seaboard and accounts for about 40 deaths in the United States each year.[8] Signs and symptoms usually develop within 1 week of the tick bite and include headache, high fever, and loss of appetite. This may be followed with small pink spots that appear on the wrists and ankles. Eventually the rash spreads over the entire body, and the spots darken and enlarge and become petechial. In mild cases, recovery occurs within 20 days. The mortality rate, if untreated, is between 8% and 25%.[15]

Lyme Disease. **Lyme disease** is the most commonly reported tick-borne disease in the United States. The disease is caused by the bite of an *Ixodes* tick known to infect deer and dogs. The course of the disease follows several stages. Initially a red dot appears at the site of the tick bite that gradually expands into a reddened rash. During this stage, fever, lethargy, muscle pain, and general malaise may develop. This may be followed by a second stage that is manifested by cardiac abnormalities (including various atrioventricular [AV] blocks) and neurological effects such as cranial nerve palsies. Still later, a third stage may develop, with arthritis as the primary symptom. Unless the disease is diagnosed and treated, symptoms may continue for several years, gradually declining in severity.

Tick Paralysis. **Tick paralysis** results from a prolonged bite by a female wood tick. The disease occurs sporadically during the spring and summer months. The paralysis is caused by a neurotoxin secreted from the salivary glands of the tick after the tick attaches to the host. At first the patient is restless and complains of paresthesia in the hands and feet. Over the next 48 hours, a flaccid paralysis may develop with loss of deep tendon reflexes. The paralysis begins at the feet and travels upward, affecting both sides of the body. In severe cases, death may result from respiratory paralysis. Removal of the tick usually results in rapid improvement and complete resolution within several days.

BOX 34-12 Signs and Symptoms of Scorpion Envenomation

- Hyperesthesia at the site of bite
- Pain, tingling, and a burning sensation radiating along the nerves at the location of the bite
- SLUDGE: *s*alvation, *l*acrimation, *u*rination, *d*efecation, *g*astrointestinal upset, and *e*mesis
- Initial bradycardia followed by tachycardia
- Cardiac dysrhythmias
- Muscle twitching
- Convulsions
- Roving eye movements (cranial nerve dysfunction)

If undiagnosed, the disease may be fatal, especially in young and older patients.

CRITICAL THINKING

How can you distinguish tick paralysis from other conditions that cause progressive paralysis?

Management. The principal treatment of tick bites is proper removal of the tick. The paramedic should grasp the tick as close to the skin surface as possible with forceps, tweezers, or protected fingers and pull it out with steady pressure. Care should be taken not to crush or squeeze the body of the tick, which can transmit disease from infective tick fluid. Other methods of tick removal, such as applying fingernail polish, isopropanol, or a hot match head, should be avoided. These traditional methods are ineffective and may induce the tick to salivate or regurgitate into the wound. After removal, the bite should be disinfected with soap and water and should be covered with a sterile dressing.

Reptile Bites

The American Association of Poison Control Centers National Data Collection System listed a total 6343 bites from poisonous and nonpoisonous snakes in 2007.[3] Of these exposures, 3267 were known to be poisonous, and the rest were from unidentified snakes. According to these records, two deaths were reported. This reflects the high morbidity and low mortality associated with snake venom poisoning. Of the 115 species of snakes in the United States, only 19 are venomous. The two main families of venomous snakes indigenous to the United States are pit vipers and coral snakes.

PIT VIPERS

The pit viper family that inhabits the United States consists of rattlesnakes, the cottonmouth or water moccasin, the copperhead, the pigmy rattlesnake, and the Massasauga

rattlesnake. The vast majority of snakebites in the United States are caused by the rattlesnake family. The identifying features of pit vipers are vertical elliptical pupils and a triangular head that is distinct from the rest of the body. The rattlesnake is characterized further by interlocking horny segments (rattles) formed on the tail that sometimes vibrate in direct relation to environmental temperatures (Figure 34-5).

The venom apparatus of pit vipers is connected to one or more elongated hollow fangs on each side of the head. The venom is designed to immobilize, kill, and digest prey. Depending on the species and the amount of venom injected, the venom may be capable of producing various toxic effects on blood and other tissues, including hemolysis, intravascular coagulation, convulsions, and acute renal failure (Box 34-13). Bleeding caused by coagulation defects and massive swelling can lead to hypovolemic shock. On any given strike, the snake may release a quantity of venom varying from little or none to almost the entire contents of the glands.

FIGURE 34-5 Pit viper. (Courtesy Saint Louis Zoo, St Louis, Mo.)

BOX 34-13 Signs and Symptoms of Pit Viper Envenomation

Mild Envenomation
Presence of one or more fang marks
Local swelling and pain
Lack of systemic symptoms

Moderate Envenomation
Presence of one or more fang marks
Pain and edema beyond the site
Systemic signs and symptoms
Weakness
Diaphoresis
Nausea and vomiting
Paresthesias

Severe Envenomation
Presence of one or more fang marks
Massive edema
Subcutaneous ecchymosis
Severe systemic symptoms
Shock

CORAL SNAKES

Two members of the coral snake family are found in the United States: the Arizona coral snake and the Eastern coral snake. In contrast to the pit viper, the coral snake has round pupils and small, fixed fangs located near the anterior end of the maxilla. Most coral snakes have a three-color pattern with red, black, and yellow or white bands that completely encircle the body, along with a black snout (Figure 34-6). Many nonpoisonous snakes in the United States mimic the appearance of the coral snake. The coral snake is identified by the sequence of colors: red bands bordered by yellow indicate a venomous species. Thus there is a mnemonic: "red on yellow, kill a fellow; red on black, venom lack."

Most coral snakes are shy and docile and seldom bite unless threatened. The small mouth and fangs of the snake make it difficult to bite anything larger than a finger, toe, or fold of skin. The coral snake tends to hang on and chew rather than to strike and release like the pit viper. The venom of the coral snake mainly is neurotoxic. The bite generally produces little or no pain and no necrosis or edema. Early signs and symptoms of a coral snake bite are slurred speech, dilated pupils, and dysphagia (usually delayed several hours after the bite). If untreated, the venom produces flaccid paralysis and death within 24 hours. Death is caused by respiratory failure, following nervous system dysfunction.

MANAGEMENT OF SNAKE ENVENOMATION

Venom, like any drug or toxin, has absorption, distribution, and elimination phases. Tissue damage increases as venom spreads into the lymphatics and blood. Thus emergency care is directed at retarding the systemic spread of the venom. Prehospital management of snake bites includes the following:

1. Stay clear of the striking range of the snake (about the length of the snake), and move the patient to a safe area. If the snake has been killed before EMS arrival, it should

FIGURE 34-6 Coral snake. (Courtesy Saint Louis Zoo, St Louis, Mo.)

be transported in a closed container to the emergency department with the patient. EMS personnel should make no attempt to capture or kill the snake; doing so may result in a paramedic being bitten. Identification of the snake is not necessary to manage the patient appropriately.

2. Provide adequate airway, ventilatory, and circulatory support to the patient as needed. Continually monitor vital signs and the electrocardiogram. Also establish an intravenous line in an unaffected extremity with a volume-expanding fluid.
3. Medical direction may recommend that a bitten extremity be immobilized in a neutral position. Immobilization by splinting may delay systemic absorption and may diminish local tissue necrosis. Every effort should be made to keep the patient at rest. Applying a pressure immobilizaton bandage (as tightly as one would wrap an acute strain) along the entire length of the bitten extremity is an effective and safe way to slow dissemination of venom by slowing lymph flow Application of ice or chemical cold packs should be avoided. Their use may further damage tissue.[18]
4. Prepare the patient for immediate transport to a proper medical facility.
5. Methods to remove the venom (e.g., making an incision and performing suction) are potentially harmful and should not be used. In severe cases, administration of antivenin to neutralize the venom may be required. This is provided in the hospital after the patient has been tested for allergies to the antivenin.

CRITICAL THINKING

What strategies can you use to calm the emotional state of a patient who has sustained a snake bite?

Hazardous Aquatic Life

The marine animals most likely to be involved in human poisonings in U.S. coastal waters are the coelenterates, echinoderms, and stingrays. The specialized venom apparatuses of these animals are used for defense and for capturing prey. In addition to venom produced by the animal, aquatic life may contain other poisonous substances as a result of toxic ingestions. Exposures to hazardous aquatic life result from recreational, industrial, scientific, and military oceanic activities.

After stabilizing the patient with adequate airway, ventilatory, and circulatory support, the two primary goals of managing all envenomations from hazardous aquatic life are preventing further venom discharge and relieving pain by neutralizing the effects of the venom.[15,18]

COELENTERATES (JELLYFISH, SEA ANEMONES, FIRE CORAL)

Coelenterates are a group of species that may be encountered in the ocean (Figure 34-7). Some of these species carry venomous stinging cells (nematocysts). The nematocyst is venom-filled and contains a long, coiled, hollow, threadlike tube that serves as a tiny hypodermic needle. The severity of envenomation is related to the type and toxicity of the venom, the number of nematocysts discharged, and the physical condition of the victim.

Jellyfish occur throughout the Atlantic and Pacific oceans. The Portuguese man-of-war is the largest jellyfish. The nematocyst-bearing tentacles of this jellyfish may be up to 100 feet long, and a single envenomation may involve several hundred thousand nematocysts. A swimmer who comes in contact with these tentacles may suffer enough envenomation to produce systemic signs and symptoms. Nematocysts often remain embedded in the tissues of the

FIGURE 34-7 Coelenterates. **A,** Fire coral. **B,** Man-of-war. (From Uerbach JS: *A medical guide to hazardous marine life,* ed 2, St Louis, 1991, Mosby.)

victim. Detached tentacle fragments can retain their potency for months.

Sea anemones are colorful bottom dwellers; they are sometimes found in tidal pools. They have a flowerlike appearance and possess slender projections that are used to sting and paralyze passing fish. These nematocyst-type projections are capable of producing mild to moderate pain in human beings.

Fire corals are not true, stony corals, but rather ocean-bottom dwellers. They often are mistaken for seaweed because they commonly are attached to rocks, shells, and corals. These stinging corals may grow up to 2 meters high and have a razor-sharp exoskeleton with thousands of protruding nematocyst-bearing tentacles.

Management. Coelenterate envenomation ranges in severity from irritant dermatitis to excruciating pain, respiratory depression, anaphylaxis, and life-threatening cardiovascular collapse. Envenomation most often is mild and usually is characterized by a stinging sensation, paresthesias, pruritus, and reddish-brown linear wheals or "tentacle prints." If a potent venom or a large body surface area is involved, systemic symptoms may include nausea, vomiting, abdominal pain, headache, bronchospasm, pulmonary edema, hypotension, and respiratory arrest. Emergency care includes the following:

- Remove visible tentacle fragments with forceps. Avoid touching the tentacles.
  - Immediately wash the stings with liberal amounts of vinegar (4% to 6% acetic acid solution) or a baking soda slurry for at least 30 seconds. (Wet sand or freshwater usually causes the nematocysts to discharge their venom. Thus these are contraindicated.)
  - Instruct the patient to take a hot shower or immerse the affected body part in hot water when possible. The water should be as hot as can be tolerated without scalding, but no warmer than 45°C (113°F). The immersion should last for as long as pain persists. If hot water is not available, dry hot or cold packs may be helpful in decreasing pain.
  - Administer analgesics as needed.
- Transport the patient for physician evaluation.

ECHINODERMS (SEA URCHINS, STARFISH, SEA CUCUMBERS)

Echinoderms are marine animals with a water-vascular system. They usually have a hard, spiny skeleton and radial body (Figure 34-8).

Sea urchins have a globular, dome-shaped body and are found on rocky bottoms or burrowed in sand or crevices. These animals have tiny spines, some of which are venomous. Some also have small pincer-like organs that are thought to discharge a poisonous substance. The spines are dangerous to handle and may break off easily in the flesh, lodging deeply and making removal difficult.

Some starfish are covered with thorny spines that secrete toxins. As the spine enters the skin, it carries venom into the wound with immediate pain, copious bleeding, and mild edema. Multiple puncture wounds may result in acute systemic reactions.

Sea cucumbers are sausage-shaped animals found in shallow and deep water. They produce a liquid toxin in a tentacle-shaped organ. This organ can be projected and extended anally. Generally the liquid is secreted into the surrounding ocean. It usually produces only a minor dermatitis or conjunctivitis in swimmers and divers.

Management. Emergency management for echinoderm envenomation usually involves caring for puncture wounds caused by spines and inactivating the venom. The paramedic should remove embedded spines with forceps. Protective gloves should be worn to avoid self-contamination. Larger spines may require surgical removal by a physician.

Echinoderm toxins may cause immediate intense pain, swelling, redness, aching in the affected extremity, and nausea. Delayed toxic effects may include respiratory distress, paresthesia of the lips and face, and, in severe cases, respiratory paralysis and complete atonia. The paramedic must be prepared to deal with a variety of physical reactions.

Most marine venoms lose their toxicity when exposed to changes in temperature or humidity. The recommended management for stable patients is to immerse the affected area (usually the foot or hand) in hot water before and during transport.. As a safety precaution, it generally is recommended that both hands or feet not be immersed at the same time. This protects against thermal injury that may be unnoticed by the patient because of numbness or pain in the affected part.

STINGRAYS

Stingrays are responsible for about 1800 injuries each year in the United States.[15] These marine animals vary in size from 2 inches to 14 feet. They often are found half-buried in mud or sand in shallow water (Figure 34-9). The venom organ of stingrays consists of two to four venomous barbs on the dorsum of a whiplike tail. Envenomation generally occurs from stepping on the sand-buried ray. This causes the tail to thrust up and forward, driving the barb into the victim's leg or foot. The defensive barb produces a large, severe laceration that may be more than 15 to 20 cm long. In addition to injecting venom into the wound, the entire barb tip of the venom apparatus sometimes is detached and embedded in the tissue.

Stingray venom has local and systemic complications. Locally, the venom produces a traumatic injury that causes immediate, intense pain; edema; variable bleeding; and necrosis. Systemic manifestations include weakness, nausea, vomiting, diarrhea, vertigo, seizures, cardiac conduction abnormalities, paralysis, hypotension, and death. Prehospital care is directed to life support, alleviation of pain, inactivation of venom, and prevention of infection. The wound should be irrigated with normal saline or tap water.[15] If the venom apparatus is visible, it should be carefully removed. The affected part should be immersed in hot (but not scalding) water and remain there until pains subside or until the

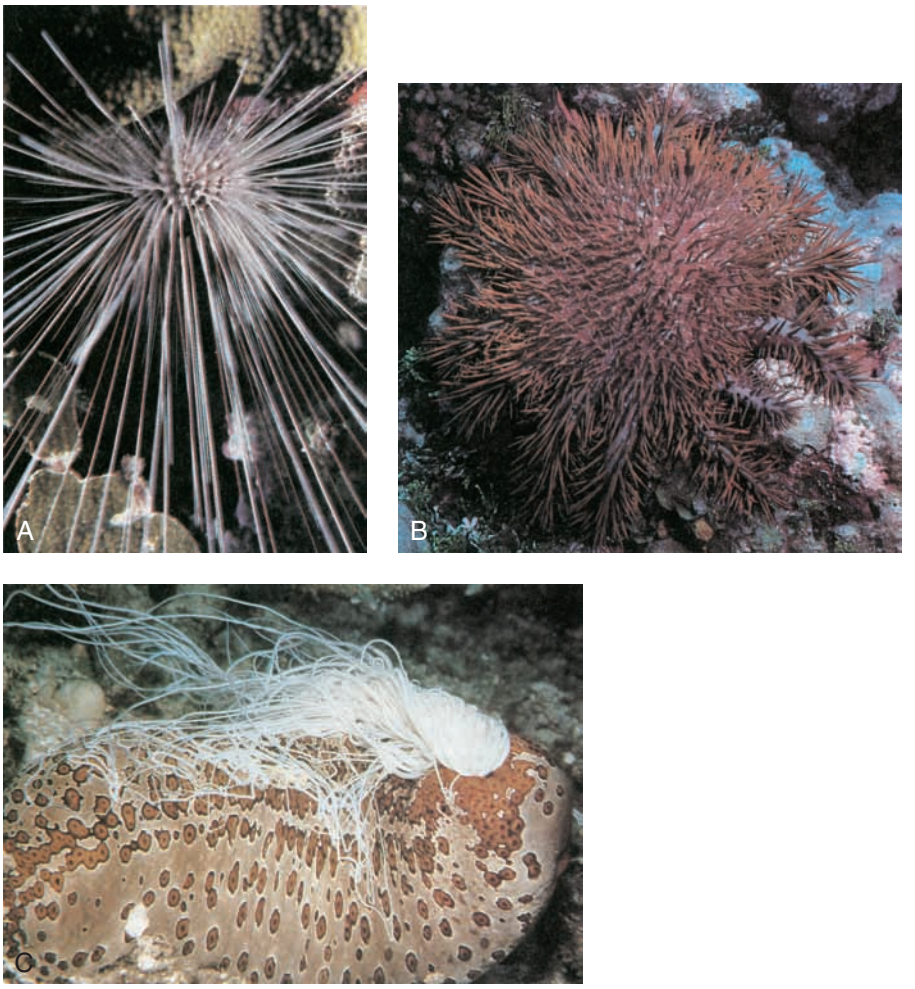

FIGURE 34-8 Echinoderms. **A,** Black sea urchin. **B,** Crown-of-thorns starfish. **C,** Sea cucumber with extended tentacles. (From Uerbach JS: *A medical guide to hazardous marine life*, ed 2, St Louis, 1991, Mosby.)

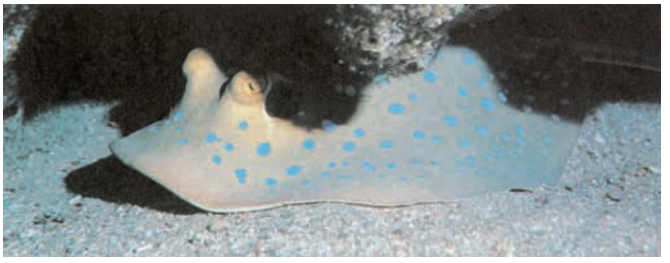

FIGURE 34-9 Stingray. (From Uerbach JS: *A medical guide to hazardous marine life*, ed 2, St Louis, 1991, Mosby.)

patient reaches the emergency department. Analgesics may be needed to manage pain.

POISONING BY ABSORPTION

Many poisons can be absorbed through the skin. Two compounds, organophosphates and carbamates, are responsible for a large number of skin-absorbed poisonings each year. Organophosphates and carbamates are commonly available for commercial and public use in the form of pet, home, and commercial insecticides. Organophosphates also are used in the development of military nerve agents such as sarin and soman (see Chapter 58). Because of the widespread availability of insecticides that contain organophosphate/carbamate compounds, paramedics must be aware of the nature of these chemicals, the necessary precautions for personal safety, and the immediate management that may be required before symptoms or signs of illness occur.

Organophosphates and carbamates are highly toxic. In addition, they are well absorbed by ingestion, inhalation, and dermal routes. Both classes have similar pharmacological actions, inhibiting the effects of acetylcholinesterase, an enzyme that degrades acetylcholine at nerve terminals. To review, acetylcholine is a cholinergic neurotransmitter for preganglionic autonomic fibers, somatic nerves to skeletal muscle, and many synapses in the CNS. When acetylcholinesterase is inhibited, acetylcholine accumulates at the synapses. This results in a cholinergic "overdrive." The signs and symptoms resulting from cholinergic overdrive are seen in organophosphate and carbamate poisoning.

Signs and Symptoms

Early signs and symptoms of organophosphate or carbamate poisoning may be nonspecific, including headache, dizziness, weakness, and nausea. As overstimulation and

disruption of transmission in the central and peripheral nervous systems occur, signs and symptoms begin to develop. These signs and symptoms result from a wide range of physiological and metabolic derangements (Box 34-14).

The rapidity and sequence in which these signs and symptoms develop depend on the particular compound and on the amount and route of exposure. The onset of symptoms is probably quickest after inhalation. Onset is slowest after a primary skin exposure and may be delayed for several hours. There are helpful mnemonics to recognize the signs of poisoning. One is *SLUDGE—s*alivation, *l*acrimation, *u*rination, *d*efecation, *g*astrointestinal upset, and *e*mesis. Another is *DUMBBELLS—d*iarrhea or *d*iaphoresis, *u*rination, *m*iosis or *m*uscle fasciculations, *b*ronchospasm, *b*radycardia, *e*mesis, *l*acrimation, *l*ethargy, and *s*alivation. Rapidly changing pupils with miosis are common with vapor exposure of organophosphates. Muscle twitching (fasciculations) can follow rapidly. Individual muscle twitching can result from liquid contact and local skin absorption at the site.

CRITICAL THINKING

Consider a person who does not suspect poisoning. What condition might that person think he or she is suffering from with this clinical presentation?

Management

Emergency care begins with scene safety, personal protection, and decontamination procedures. The scene should be secured by qualified personnel. Personal protective actions include wearing protective clothing and using respiratory protection. The patient should be removed safely from the contaminated area as soon as possible so that decontamination can begin (see Chapter 58). After these measures are completed, patient care can be initiated. The general principles of management for poisoning by absorption include respiratory support, drug administration, and electrocardiogram monitoring. Organophosphates and carbamates produce similar physiological effects. However, carbamates have a shorter duration of action. Thus they have a more rapid decrease in their effect.

RESPIRATORY SUPPORT

Respiratory tract symptoms usually are first to appear after exposure to organophosphates or carbamates. In addition, respiratory paralysis may occur suddenly without warning. The need for advanced airway management and ventilatory support should be anticipated. Copious bronchial secretions may require suctioning. Bronchoconstriction also may necessitate positive-pressure ventilation and positive end-expiratory pressure.

DRUG ADMINISTRATION

Drug therapy in organophosphate or carbamate poisoning is directed at blocking the effects of acetylcholine, separating cholinesterase from the chemical compound, and suppressing seizure activity if present. The drugs currently used as antidotes include ***atropine, pralidoxime chloride,*** and ***diazepam*** or ***lorazepam.***

BOX 34-14 Signs and Symptoms of Organophosphate or Carbamate Poisoning

Cardiovascular System
Bradycardia
Variable blood pressure (usually hypotensive)

Respiratory System
Bronchoconstriction
Dyspnea
Rhinorrhea
Wheezing

Gastrointestinal System
Blurred vision
Cramps
Defecation
Emesis
Increased bowel sounds

Central Nervous System
Anxiety
Coma
Convulsions
Dizziness
Respiratory depression

Musculoskeletal System
Fasciculations
Flaccid paralysis

Skin
Diaphoresis

Other Signs and Symptoms
Lacrimation
Miosis
Rapidly changing pupil size
Salivation
Urination

NOTE

Drug therapy should be initiated only if the patient has two or more signs or symptoms of poisoning and/or respiratory distress is present. Drug therapy should be initiated only after consulting with medical direction or a poison control center.

Atropine reverses the muscarinic effects (bradycardia, bronchoconstriction, increased respiratory secretions, and miosis) of moderate to severe organophosphate or carbamate poisoning. The drug competitively antagonizes the actions of acetylcholine. This results in a decrease in the

hyperactivity of smooth muscles and glands. The drug is indicated to dry the patient's secretions. It also helps to decrease pulmonary resistance to ventilation. Potentially hypoxic patients may require the administration of large doses of ***atropine*** (see the *Emergency Drug Index*). The electrocardiogram should be monitored for dysrhythmias (other than tachycardia). Supplemental oxygen should be given to minimize the risk of ventricular fibrillation. ***Atropine*** is the drug of choice for carbamate poisonings.

NOTE

As a rule, cholinergic poisoning causes the patient to be "wet." This is manifested by profuse sweating, lacrimation, salivation, vomiting, diarrhea, and incontinence. Anticholinergic poisoning generally causes the patient to be "dry." This is manifested by dry, flushed skin; elevated temperature; and urinary retention. Being cognizant of this "wet vs. dry" symptomatology can be lifesaving for the poisoned patient. The wet-appearing patient will require atropine.

Pralidoxime is the treatment of choice for organophosphate poisoning after the administration of ***atropine. Pralidoxime*** should be used for nearly all patients with significant exposures, particularly those with muscular twitching and weakness. ***Pralidoxime*** has the primary effect of reactivating acetylcholinesterase. The adult and pediatric doses for ***pralidoxime*** can be found in the *Emergency Drug Index.*

Diazepam or ***lorazepam*** may be indicated if seizures are present. The need for seizure control may arise before decontamination is complete. In this case, the drugs can be administered intramuscularly to control seizure activity (see the *Emergency Drug Index*). As a safety precaution, IV therapy usually is not initiated in a patient in a contaminated area. The paramedic should be alert to the risk for respiratory and CNS depression.

CRITICAL THINKING

Consider that you give diazepam or lorazepam for seizures in this case. Will that eliminate the need for atropine?

ELECTROCARDIOGRAM MONITORING

Electrocardiogram monitoring may reveal a variety of abnormalities, including idioventricular rhythms, multifocal premature ventricular contractions, ventricular tachycardia, torsades de pointes, ventricular fibrillation, complete heart block, and asystole These dysrhythmias usually occur in two phases. The first phase begins with a transient episode of intense sympathetic tone. This results in sinus tachycardia. This phase is followed by a period of extreme parasympathetic tone. It may manifest as sinus bradycardia, atrioventricular block, and ST segment and T wave abnormalities. As described in Chapter 22, slow ventricular dysrhythmias that do not respond to the usual therapy may need to be treated with overdrive pacing.

SECTION TWO
Drug Abuse

The term **drug abuse** refers to the use of prescription drugs for nonprescribed purposes. It also refers to the use of drugs that have no prescribed medical use (Box 34-15). Emergencies that result from drug abuse include adverse effects caused by the drug or impurities or contaminants mixed with the drug, life-threatening infections from intravenous or intradermal injection of drugs with unsterile equipment, injuries during intoxication, and drug dependence or withdrawal syndrome resulting from the habit-forming potential of many drugs (see Chapter 13).

Because of the widespread use and misuse of drugs (Box 34-16), the paramedic should maintain a high degree of suspicion and consider the possibility for a drug-related problem in *any patient* of *any age* who has seizures, behavioral changes, or decreased level of consciousness. In addition, consideration of the visibility, accessibility, and careful handling of all medications carried on an EMS vehicle should be a part of any EMS policy and procedure.

CRITICAL THINKING

Why might a patient (or their friends) delay calling for help in a situation involving drug overdose?

BOX 34-15 Drug Abuse Terminology

Drug abuse: Self-medication or self-administration of a drug in chronically excessive amounts, resulting in psychological and/or physical dependence, functional impairment, and deviation from approved social norms

Drug dependence: Condition marked by an overwhelming desire to continue taking a drug for its desired effect, usually an altered mental activity, attitude, or outlook

Physical dependence: An adaptive physiological state occurring after prolonged use of many drugs (Discontinuation causes withdrawal syndromes that are relieved by readministering the same drug or a pharmacologically related drug.)

Psychological dependence: Emotional reliance on a drug (manifestations range from a mild desire for a drug to craving and drug-seeking behavior to repeated compulsive use of a drug for its subjectively satisfying or pleasurable effects.)

Tolerance: A tendency to increase drug dosage to experience the same effect formerly produced by a smaller dose

Withdrawal syndrome: A predictable set of signs and symptoms that occurs after a decrease in the amount of the usual dose of a drug or its sudden cessation

BOX 34-16 Initiation of Substance Use (Incidence, or First-Time Use) Within the Past 12 Months: 2008 Data

- In 2008 an estimated 2.9 million persons ages 12 or older used an illicit drug for the first time within the past 12 months. This averages to almost 8000 initiates per day. A majority of these past year illicit drug initiates reported that their first drug was marijuana (56.6%). Nearly one third initiated with psychotherapeutics (29.6%), including 22.5% with pain relievers, 3.2% with tranquilizers, 3.0% with stimulants, and 0.8% with sedatives. A sizable proportion reported inhalants (9.7%) as their first illicit drug, and a small proportion used hallucinogens as their first drug (3.2%).
- In 2008 the illicit drug categories with the largest number of past year initiates among persons ages 12 or older were marijuana use (2.2 million) and nonmedical use of pain relievers (2.2 million).
- In 2008 there were 729,000 persons ages 12 or older who had used inhalants for the first time within the past 12 months; 70.4% were younger than age 18 when they first used.
- The number of past year initiates of methamphetamine among persons ages 12 or older was 95,000 in 2008.
- Between 2003 and 2008, the number of Ecstasy initiates increased from 642,000 to 894,000 and the number of LSD initiates increased from 200,000 to 394,000.
- Most (84.6%) of the 4.5 million past year alcohol initiates were younger than age 21 at the time of initiation.

From U.S. Department of Health and Human Services, Substance Abuse and Mental Health Services Administration, Office of Applied Studies: *2008 National Survey on Drug Use and Health: National Findings,* http://oas.samhsa.gov/nsduh/2k8nsduh/2k8Results.cfm#Ch5.

BOX 34-17 Common Agents Involved in Poisoning

Acetaminophen
Cardiac medications
Drugs abused for sexual purposes/sexual gratification
Hallucinogens
Lithium
Metals (iron, lead, and mercury)
Monoamine oxidase inhibitors
Nonprescription pain medicines
Opioids
Phencyclidine
Salicylates
Sedatives-hypnotics
Stimulants
Tricyclic antidepressants

TOXIC EFFECTS OF DRUGS

EMS personnel often encounter persons who are suffering from the toxic effects of drugs. Toxicity may be the result of an overdose, a potential suicide attempt, polydrug administration, or an accident (accidental ingestion, miscalculation, changes in drug strength). Box 34-17 lists the drugs discussed in this chapter.

Common drugs of abuse, along with their names and uses, vary widely in different geographical areas. Also, the drugs of abuse often change over time. Table 34-3 is a partial list of common drugs of abuse, their street names, and miscellaneous terminology relating to drug use.

DID YOU KNOW?

Dextromethorphan (DXM) is an ingredient found in more than 100 over-the-counter cough medicines and cold remedies, such as Robitussin. When consumed in excessive doses, the drug can cause euphoria and dysphoria. It also may cause cardiac irregularities, seizure, loss of consciousness, and brain damage.[19] In 2008 there were nearly 8000 emergency department visits in the United States from the abuse of cough medicines. This reflects a 73% rise from cases reported in 2004. Paramedics should consider the possibility of DXM abuse in any patient who appears to be "high."

General Management Principles

The following are general principles for managing drug abuse and the overdose that may result:

1. Ensure that the scene is safe. Be prepared for unpredictable behavior from the patient. Consider the need for help from law enforcement.
2. Ensure adequate airway, ventilatory, and circulatory support as needed.
3. Obtain a history of the event. This should include the self-administration of other drugs that may have been taken by another route. Obtain any significant medical or psychiatric history.
4. Identify the substance. Consult with medical direction or a poison control center.
5. Perform a full, focused physical examination. Continually monitor the patient's vital functions and electrocardiogram.
6. Start intravenous therapy. Draw a blood sample for laboratory analysis and administer the proper drug antidote, such as ***naloxone*** if an opioid overdose is suspected. Pay special attention to personal protection because many of these patients are at high risk of harboring infectious disease. The nasal administration of ***naloxone*** should be considered in these patient groups.
7. Administer ***activated charcoal*** (per protocol) for orally administered drugs taken within the previous hour.
8. Rapidly transport the patient for physician evaluation.

When examining any patient suspected of abusing drugs, the paramedic should always look for track marks. These may be in the antecubital space, under the tongue, or on top of the feet. The possibility of "body packing" (concealing packets of drugs in body cavities of the stomach, rectum, and vagina) and "body stuffing" (swallowing drugs to avoid arrest) should be considered when a person who abuses drugs appears ill for no apparent reason.

TABLE 34-3 Commonly Abused Drugs and Their Street Names*

Substances: Category and Name	Examples of Commercial and Street Names	DEA Schedule†/ How Administered‡	Intoxication Effects/Potential Health Consequences
Tobacco			
Nicotine	Found in cigarettes, cigars, bidis, and smokeless tobacco (snuff, spit tobacco, chew), drug patches	Not scheduled/ smoked, snorted, chewed	Increased blood pressure and heart rate/ chronic lung disease; cardiovascular disease; stroke; cancers of mouth, pharynx, larynx, esophagus, stomach, pancreas, cervix, kidney, bladder, and acute myeloid leukemia; adverse pregnancy outcomes; addiction
Alcohol			
Alcohol (ethyl alcohol)	Found in liquor, beer, and wine	Not scheduled/ swallowed	In low doses, euphoria, mild stimulation, relaxation, lowered inhibitions; in higher doses, drowsiness, slurred speech, nausea, emotional volatility, loss of coordination, visual distortions, impaired memory, sexual dysfunction, loss of consciousness/increased risk of injuries, violence, fetal damage (in pregnant women); depression; neurologic deficits; hypertension; liver and heart disease; addiction; fatal overdose
Cannabinoids			
Hashish	Boom, gangster, hash, hash oil, hemp	I/swallowed, smoked	Euphoria; relaxation; slowed reaction time; distorted sensory perception; impaired balance and coordination; increased heart rate and appetite; impaired learning, memory; anxiety; panic attacks; psychosis/ cough, frequent respiratory tract infections; possible mental health decline; addiction
Marijuana	Blunt, dope, ganja, grass, herb, joint, bud, Mary Jane, pot, reefer, green, trees, smoke, sinsemilla, skunk, weed	I/swallowed, smoked	
Opioids			
Heroin	Diacetylmorphine: smack, horse, brown sugar, dope, H, junk, skag, skunk, white horse, China white; cheese (with OTC cold medicine and antihistamine)	I/injected, smoked, snorted	Euphoria; drowsiness; impaired coordination; dizziness; confusion; nausea; sedation; feeling of heaviness in body; slowed or arrested breathing/constipation; endocarditis; hepatitis; HIV; addiction; fatal overdose
Opium	Laudanum, paregoric: big O, black stuff, block, gum, hop	II, III, V/swallowed, smoked	
Stimulants			
Cocaine	Cocaine hydrochloride: blow, bump, C, candy, Charlie, coke, crack, flake, rock, snow, toot	II/snorted, smoked, injected	Increased heart rate, blood pressure, body temperature, metabolism; feelings of exhilaration; increased energy, mental alertness; tremors; reduced appetite; irritability; anxiety; panic; paranoia; violent behavior; psychosis/weight loss, insomnia; cardiac or cardiovascular complications; stroke; seizures; addiction Also, for cocaine—nasal damage from snorting Also, for methamphetamine—severe dental problems
Amphetamine	Biphetamine, Dexedrine: bennies, black beauties, crosses, hearts, LA turnaround, speed, truck drivers, uppers	II/swallowed, snorted, smoked, injected	
Methamphetamine	Desoxyn: meth, ice, crank, chalk, crystal, fire, glass, go fast, speed	II/ swallowed, snorted, smoked, injected	
Club Drugs			
MDMA (methylenedioxy-methamphetamine)	Ecstasy, Adam, clarity, Eve, lover's speed, peace, uppers	I/swallowed, snorted, injected	**MDMA**—mild hallucinogenic effects; increased tactile sensitivity; empathic feelings; lowered inhibition; anxiety; chills; sweating; teeth clenching; muscle cramping/sleep disturbances; depression; impaired memory; hyperthermia; addiction **Flunitrazepam**—sedation; muscle relaxation; confusion; memory loss; dizziness; impaired coordination/addiction **GHB**—drowsiness; nausea; headache; disorientation; loss of coordination; memory loss/unconsciousness; seizures; coma
Flunitrazepam§	Rohypnol: forget-me pill, Mexican Valium, R2, roach, Roche, roofies, roofinol, rope, rophies	IV/swallowed, snorted	
GHB§	Gamma-hydroxybutyrate: G, Georgia home boy, grievous bodily harm, liquid Ecstasy, soap, scoop, goop, liquid X	I/swallowed	

Continued

TABLE 34-3—cont'd

Substances: Category and Name	Examples of Commercial and Street Names	DEA Schedule†/ How Administered‡	Intoxication Effects/Potential Health Consequences
Dissociative Drugs			
Ketamine	Ketalar SV: cat Valium, K, Special K, vitamin K	III/injected, snorted, smoked	Feelings of being separate from one's body and environment; impaired motor function/ anxiety; tremors; numbness; memory loss; nausea
PCP and analogs	Phencyclidine: angel dust, boat, hog, love boat, peace pill	I, II/swallowed, smoked, injected	Also, for ketamine—analgesia; impaired memory; delirium; respiratory depression and arrest; death
Salvia divinorum	Salvia, Shepherdess's Herb, Maria Pastora, magic mint, Sally-D	Not scheduled/ chewed, swallowed, smoked	Also, for PCP and analogs—analgesia; psychosis; aggression; violence; slurred speech; loss of coordination; hallucinations
Dextromethorphan (DXM)	Found in some cough and cold medications: Robotripping, Robo, Triple C	Not scheduled/ swallowed	**Also, for DXM**—euphoria; slurred speech; confusion; dizziness; distorted visual perceptions
Hallucinogens			
LSD	Lysergic acid diethylamide: acid, blotter, cubes, microdot, yellow sunshine, blue heaven	I/swallowed, absorbed through mouth tissues	Altered states of perception and feeling; hallucinations; nausea
Mescaline	Buttons, cactus, mesc, peyote	I/swallowed, smoked	**Also, LSD and mescaline**—increased body temperature, heart rate, blood pressure; loss of appetite; sweating; sleeplessness; numbness, dizziness, weakness, tremors; impulsive behavior; rapid shifts in emotion
Psilocybin	Magic mushrooms, purple passion, shrooms, little smoke	I/swallowed	**Also, for LSD**—flashbacks, hallucinogen persisting perception disorder
			Also for psilocybin—nervousness; paranoia; panic
Other Compounds			
Anabolic steroids	Anadrol, Oxandrin, Durabolin, Depo-Testosterone, Equipoise: roids, juice, gym candy, pumpers	III/injected, swallowed, applied to skin	Steroids—no intoxication effects/hypertension; blood clotting and cholesterol changes; liver cysts; hostility and aggression; acne; in adolescents—premature cessation of growth; in males—prostate cancer, reduced sperm production, shrunken testicles, breast enlargement; in females—menstrual irregularities, development of beard and other masculine characteristics
Inhalants	Solvents (paint thinners, gasoline, glues); gases (butane, propane, aerosol propellants, nitrous oxide); nitrites (isoamyl, isobutyl, cyclohexyl): laughing gas, poppers, snappers, whippets	Not scheduled/ inhaled through nose or mouth	Inhalants (varies by chemical)—stimulation; loss of inhibition; headache; nausea or vomiting; slurred speech; loss of motor coordination; wheezing/cramps; muscle weakness; depression; memory impairment; damage to cardiovascular and nervous systems; unconsciousness; sudden death

*For more information on prescription medications, please visit www.nida.nih.gov/DrugPages/PrescripDrugsChart.html

†Schedule I and II drugs have a high potential for abuse. They require greater storage security and have a quota on manufacturing, among other restrictions. Schedule I drugs are available for research only and have no approved medical use; Schedule II drugs are available only by prescription (unrefillable) and require a form for ordering. Schedule III and IV drugs are available by prescription, may have five refills in 6 months, and may be ordered orally. Some Schedule V drugs are available over the counter.

‡Some of the health risks are directly related to the route of drug administration. For example, injection drug use can increase the risk of infection through needle contamination with staphylococci, HIV, hepatitis, and other organisms.

§Associated with sexual assaults.

CRITICAL THINKING
For what illnesses is the patient who uses intravenous narcotics at risk?

Opioid Overdose

Heroin accounts for about 90% of the opioid abuse in the United States. Pure heroin is a bitter-tasting white powder. Heroin usually is adulterated or "cut" for street distribution. A typical "bag" is the single-dose unit of heroin and may weigh 100 mg. On average, heroin is only 20% to 30% pure and often is mixed with other drugs such as ***fentanyl***. Other opioid drugs include ***morphine,*** hydromorphone, methadone, ***meperidine,*** codeine, oxycodone, propoxyphene, hydrocodone, and "designer opioids" that have been chemically modified such as alpha-methylfentanyl ("China white").

NOTE
Vicodin (hydrocodone) is one of the most commonly prescribed and most commonly abused pain medications today. Vicodin and its related medications, Lorcet, Lortab, Percodan, and OxyContin, are opioid-based drugs. Vicodin is a derivative of opium, which is also used to manufacture heroin. Vicodin successfully diminishes pain, but it is highly addictive. The drug can be taken orally in pill form, chewed, or crushed and sniffed like cocaine. Physical effects from misusing these drugs include dizziness, blurred vision, constipation, fluctuations in heart rate, hallucinations, nausea, vomiting, sedation, and respiratory depression. Signs and symptoms of withdrawal from these drugs are similar to those of other opioids. Overdose is not uncommon, and higher doses of ***naloxone*** may be required to manage these patients.

Depending on the preparation, these drugs may be taken orally, injected intradermally ("skin popping") or intravenously ("mainlining"), taken intranasally ("snorted"), or smoked. All opioids are CNS depressants. They can cause life-threatening respiratory depression. In severe intoxication, hypotension, profound shock, and pulmonary edema may be present. Signs and symptoms of narcotic/opioid overdose include the following:

SHOW ME THE EVIDENCE
Researchers reviewed records retrospectively to see the clinical response to intranasal (IN) versus intramuscular (IM) naloxone administration. Patients whose respiratory rate increased or whose Glasgow Coma Scale score reached 6 were responders. Although the mean time from administration to response was longer in the IN group, the time from patient contact to response was not significantly different. Three patients who received IN naloxone were later given IM or IV naloxone. The authors concluded that IN naloxone may be a safer alternative for prehospital naloxone administration.

Robertson T, Hendey G, Stroh G, et al: Intranasal naloxone is a viable alternative to intravenous naloxone for prehospital narcotic overdose, *PEC* 13(4):512-515, 2009.

- Euphoria
- Arousable somnolence ("nodding")
- Nausea
- Pinpoint pupils (except with ***meperidine,*** under hypoxic conditions, or in combination with other types of drugs)
- Slow and shallow respirations
- Coma
- Seizures

ANTIDOTE THERAPY

As described in Chapter 13, ***naloxone*** is a pure opioid antagonist effective for virtually all opioid and opioid-like substances. The drug reverses the three major symptoms of opioid overdose: respiratory depression, coma, and miosis. Its use should be considered when opioid intoxication is suspected.[18] ***Naloxone*** also is indicated for use when a coma of unknown origin is present. The EMS crew should be prepared to restrain the patient. The patient's behavior may be unpredictable when the effects of the drug are reversed and the patient experiences withdrawal symptoms. Medical direction may recommend that the ***naloxone*** be given in small amounts. The amount should be enough to restore airway reflexes and adequate breathing, without fully awakening the patient. The patient should be ventilated with a bag mask before ***naloxone*** administration. If the patient does not respond to treatment with ***naloxone,*** intubation should be considered. (*Note:* In the absence of respiratory depression, the use of ***naloxone*** is controversial; seizure activity is a possible side effect of the drug.)

NOTE
Two other pure opioid antagonists are available. ***Naltrexone*** is an oral medication used in long-term programs for opioid addiction. ***Nalmefene*** appears to be as effective as ***naloxone*** in acute opioid intoxications. Moreover, ***nalmefene*** has a longer duration of action (4 to 8 hours) than ***naloxone***.

Some opioids (e.g., heroin) and some narcotics (e.g., methadone) have a longer duration than ***naloxone.*** Thus the patient must be monitored closely during antidote therapy. Repeated doses of ***naloxone*** may be needed as well. In communities where abuse of naloxone-resistant opioids or the use of China white is common, larger initial doses of ***naloxone*** may be needed. The desired signs of reversal of opioid intoxication are adequate airway reflexes and ventilations, not complete arousal.

Naloxone can cause a withdrawal syndrome in opioid-dependent patients. Slowly administer a smaller dose of the drug for these patients. Withdrawal usually can be managed by symptomatic and supportive care. Box 34-18 lists signs and symptoms of opioid withdrawal.

Sedative-Hypnotic Overdose

Sedative-hypnotic agents include benzodiazepines and barbiturates. These drugs usually are taken orally. Yet they may be diluted and injected intravenously. Taking these drugs

BOX 34-18 Signs and Symptoms of Opioid Withdrawal

Abdominal cramps
Anorexia
Cold sweats or chills
Diaphoresis
Diarrhea
Fever
General malaise
Gooseflesh
Insomnia
Irritability
Nausea and vomiting
Pulmonary edema
Severe agitation
Ventricular dysrhythmias
Tachycardia
Tremors

with alcohol greatly increases their effects. Sedative-hypnotic drugs commonly are known as *downers*.

Benzodiazepines are among the best-known and most widely prescribed drugs used to control symptoms of anxiety, stress, and insomnia. These drugs sometimes are used to manage alcohol withdrawal and to control seizure disorders as well. They promote sleep and relieve anxiety by depressing brain function. Often they are abused for their sedative effects. Individually, these drugs are somewhat nontoxic. They may accentuate the effects of other sedative-hypnotic agents. Common benzodiazepines are ***diazepam*** (Valium), alprazolam (Xanax), and ***lorazepam*** (Ativan).

Barbiturates are general CNS depressants that inhibit impulse conduction in the brainstem. These drugs once were widely used to treat anxiety and insomnia. Their addictive properties and potential for abuse have led to their replacement by benzodiazepines and other nonbarbiturate drugs. Barbiturates that commonly are abused include phenobarbital, amobarbital, and secobarbital.

Signs and symptoms of sedative-hypnotic overdose chiefly are related to the central nervous and cardiovascular systems. Adverse effects include excessive drowsiness, staggering gait, and, in some cases, paradoxical excitability. In cases of severe toxicity the patient may become comatose, with respiratory depression, hypotension, and shock. The pupils may be constricted. More often, though, they become fixed and dilated even in the absence of significant brain damage. Airway control and ventilatory management are the most important actions in managing significant sedative-hypnotic overdose. ***Flumazenil*** is a benzodiazepine antagonist that can be used to reverse the effects of benzodiazepines.[18] The drug, however, can produce seizure activity, dysrhythmias, and hypotension.[18] ***Flumazenil*** is contraindicated in patients who are prone to seizures and in those with tricyclic antidepressant overdose. It is generally only used to reverse benzodiazepine effects after procedural sedation.

BOX 34-19 Methamphetamine

Methamphetamine is a synthetically manufactured central nervous system stimulant. Methamphetamine is legally manufactured for medicinal purposes (Methedrine and Desoxyn). Yet illicit production of methamphetamine as a street drug in the United States is on the rise. Common names for methamphetamine include meth, speed, crank, crystal, water, or ice.

Illegal methamphetamine can be produced inexpensively in clandestine meth labs with common chemical methods (hydriodic acid, phenyl-2-propane, sodium ammonia, thionyl chloride). The drug then can be smoked, injected, snorted, or taken orally. Once methamphetamine enters the body, it can produce skeletal muscle tremors, sleeplessness, and euphoria that can last up to 10 days. During these drug-induced sleepless "binges," users may become hostile and paranoid. This is followed by a "crash" (an emotionally depressed state) that can last for several days.

In addition to ensuring personal safety when dealing with these patients, the paramedic crew should be keenly aware of potential hazards associated with clandestine labs. These hazards include the production of highly explosive toxic gases (e.g., phosphine) that can be absorbed readily through the skin in quantities that can be fatal; the presence of an oxygen-depleted environment; the use of toxic solvents that can lead to lab explosions; and exposure to other dangerous chemicals. Any time a meth lab is suspected, the emergency medical services crew should withdraw. Patients and bystanders should be evacuated. Law enforcement and specialized hazardous materials personnel should be summoned to the scene. Drug-making paraphernalia that should alert the paramedic to the presence of a meth lab include the following*:

- Amber stains on walls, furniture, and counters
- Equipment that has a red or amber color
- Two large, round-bottom flasks (with stoppers) connected by a hose
- Pyrex-type meatloaf container
- Various measuring and funnel devices
- A heat source

*From Goss J: Meth labs, *J Emerg Med Serv* 23:1, 1998.

Stimulant Overdose

Commonly abused stimulant drugs are those of the sympathomimetic family (e.g., amphetamine sulfate, dextroamphetamine, cocaine, methamphetamine) (Box 34-19).

Sympathomimetic drugs often are used to produce general mood elevation, improve task performance, suppress appetite, and prevent sleepiness. Structurally, the amphetamines are similar to the catecholamines epinephrine and norepinephrine. Yet they differ in their more pronounced effects on the CNS. Adverse effects include tachycardia, hypertension, tachypnea, agitation, dilated pupils, tremors, and disorganized behavior. In severe intoxication the patient may exhibit psychosis and paranoia and may experience hallucinations. Sudden withdrawal or cessation of amphetamine use may result in a "crash" stage. In this stage the patient becomes depressed, suicidal, incoherent, or nearly comatose. As a rule, these drugs are taken orally. They also may be smoked or injected for a more

rapid onset of action. Amphetamines commonly are known as *speed* or *uppers.*

COCAINE

Cocaine is one of the most popular illegal drugs in the United States. Cocaine is a fine, white crystalline powder. Like heroin, street forms of cocaine usually are adulterated. They vary in purity from 25% to 90%; doses vary from near 0 to 200 mg. This form of cocaine generally is taken intranasally by snorting a "line" containing 10 to 35 mg of the drug (depending on purity). After absorption through the mucous membranes, the effects of the drug begin within minutes. Peak effects occur 15 to 60 minutes after use, with a half-life of 1 to 2½ hours. Cocaine also is used by the subcutaneous, intramuscular, and intravenous routes; the intravenous route provides immediate absorption and intense stimulation. Taken IV, the peak occurs within 5 minutes and with a half-life of about 50 minutes. *Speedballing* refers to an injection of a cocaine-heroin combination.

Freebase or "crack" cocaine is a more potent formulation of the drug. Crack is prepared by mixing powdered street cocaine with an alkaline solution and then adding a solvent such as ether. The combination separates into two layers. The top layer contains the dissolved cocaine. Evaporation of the solvent results in pure cocaine crystals, which are smoked and absorbed via the pulmonary route. Cocaine in this form is called rock or crack because of the popping sound produced when the crystals are heated. Freebase cocaine generally is combined with marijuana or tobacco and is smoked in a pipe or a cigarette. The reactions are similar to those experienced in intravenous use, with equal intensity and effects.

NOTE

In recent years, a synthetic substitute for marijuana began to be distributed and sold throughout the United States. The product usually is packaged and marketed as an herbal product intended to be burned as incense. It is available under various names, including K2 and Spice. The active ingredient in the synthetic substitute is a cannabinoid, a class of drug that includes tetrahydrocannabinol (THC; the active ingredient in marijuana). As a result, the effects of the product are similar to those of marijuana when smoked or inhaled. Many local jurisdictions throughout the United States have banned the sale of these products. Synthetic THC also may be legally prescribed for medicinal use (Marinol). The "marijuana pill" has been found to relieve the nausea and vomiting associated with chemotherapy for cancer patients and to assist with loss of appetite with acquired immunodeficiency syndrome (AIDS) patients.

Bath salts are also being sold in the United States, that when snorted, inhaled, or injected, produce effects similar to methamphetamine. These powders are sold under names such as Ivory Wave, White Lightning, and Hurricane Charlie. They contain mephedrone and methylenedioxypyrovalerone (also known as MDPV), and can cause hallucinations, paranoia, tachycardia, and suicidal thoughts. Many U.S. states are banning the sale of these products.

Cocaine is a major CNS stimulant. It causes profound sympathetic discharge. The increased levels of circulating catecholamines result in excitement, euphoria, talkativeness, and agitation. The effects of the drug can cause significant cardiovascular and neurological complications such as cardiac dysrhythmias, myocardial infarction, seizures, intracranial hemorrhage, hyperthermia, and psychiatric disturbances. Cocaine overdose can occur with any form of the drug and any route of administration. The adult fatal dose is thought to be about 1200 mg (1.2 g), but fatalities from cocaine-induced cardiac dysrhythmias have been reported with single doses of as little as 25 to 30 mg.[8]

Prehospital management of the cocaine-intoxicated patient may be difficult. Cocaine toxicity may range from minor symptoms to life-threatening overdose. Emergency care may require a full spectrum of basic and advanced life-support measures, including aggressive airway management, ventilatory and circulatory support, drug therapy, and rapid transport to an appropriate medical facility. Benzodiazepines are the mainstay of treatment initially in cocaine toxicity. For cocaine-induced hypertension or chest discomfort, ***nitroglycerine*** and/or ***morphine*** can be beneficial.[18]

PHENCYCLIDINE OVERDOSE

Phencyclidine (PCP) is a dissociative analgesic originally used as a veterinary tranquilizer. The drug has sympathomimetic and CNS stimulant and depressant properties. Phencyclidine is a potent psychoactive drug illegally sold in liquid, tablet, or powder form to be taken orally, intranasally, intravenously/intramuscularly, or with other drugs to be smoked (a "Sherman"). Most tablets contain about 5 mg of PCP. As a rule, PCP in its powder form is purer (50% to 100% PCP). Chronic use can result in permanent memory impairment and loss of higher brain functions. The pharmacological effects are dose-related. They can be divided into low-dose and high-dose toxicity. Ketamine is a derivative of PCP and has identical actions.

Low-Dose Toxicity. In low doses that are less than 10 mg, PCP intoxication produces an unpredictable state that can resemble drunkenness. The user may have a sense of euphoria or confusion, disorientation, agitation, or sudden rage. An intoxicated patient often has a blank stare and a stumbling gait. The patient often is in a dissociative state. The patient's pupils generally are reactive. The patient may experience flushing, diaphoresis, facial grimacing, hypersalivation, and vomiting. **Nystagmus** with a burstlike quality is characteristic of low-dose PCP use. In this range of toxicity, death usually is related to behavioral disturbances resulting from spatial disorientation, drug-induced immobility, and insensitivity to pain. This insensitivity to pain leads to bold acts of strength. This is because the

CRITICAL THINKING

Why does this type of drug intoxication put the patient at a high risk for injury?

normal muscle activity limitation resulting from pain is inhibited.

In low-dose toxicity sensory stimulation should be avoided. Verbal and physical stimuli will likely make the clinical symptoms worse. Violent and combative patients require protection from self-injury. Safeguards also must be provided for the emergency crew and bystanders. The paramedic should monitor the patient's vital signs and level of consciousness closely. The patient should be observed for increasing motor activity and muscle rigidity as well. These may precede seizures.

High-Dose Toxicity. Patients with high-dose PCP intoxication from more than 10 mg may be in a coma that can last from hours to several days. These patients often are unresponsive to painful stimuli. Respiratory depression, hypertension, and tachycardia also may be present, depending on the dosage. In severe cases a hypertensive crisis causing cardiac failure, hypertensive encephalopathy, seizures, and intracerebral hemorrhage may result. Prehospital care is directed at managing respiratory and cardiac arrest, controlling status seizures, and rapidly transporting the patient for physician evaluation.

PHENCYCLIDINE PSYCHOSIS

Phencyclidine psychosis is a true psychiatric emergency that may mimic schizophrenia. The psychosis usually is of acute onset. It may not become apparent until several days after drug ingestion. Psychosis can occur after a single low-dose exposure to PCP. Psychosis also may last from several days to weeks. Signs and symptoms may range from a catatonic and unresponsive state to bizarre and violent behavior. The patient often appears agitated and suspicious, and may experience auditory hallucinations and paranoia. Appropriate management usually requires involuntary hospitalization, control of violent behavior, and administration of antipsychotic agents. When dealing with these patients in the prehospital setting, personal safety is of prime importance; law enforcement personnel should be called upon for assistance.

Hallucinogen Overdose

Hallucinogens are substances that cause perceptual distortions. The most common hallucinogen in use today is lysergic acid diethylamide (LSD). Other hallucinogens include mescaline, found in the buttons of peyote cactus, which can be used legally in some religious settings; psilocybin mushrooms, found in the United States and Mexico; marijuana, the active agent of the plant *Cannabis sativa;* morning glory plant; nutmeg; mace; and some amphetamines, such as methylenedioxymethamphetamine (Ecstasy) and 3,4-methylenedioxyamphetamine (MDEA Eve).

Depending on the agent, the effects of hallucinogens may range from minor visual to more serious complications associated with lysergic acid diethylamide use. The more serious effects include respiratory and CNS depression (rare). Prehospital management usually is limited to supportive care, minimal sensory stimulation, calming measures, and transportation to a medical facility. After arrival at the emergency department, these patients generally are placed in a quiet environment for observation.

Tricyclic Antidepressant Overdose

Tricyclic antidepressants often are prescribed to help manage depression and certain pain syndromes. These drugs work by blocking the uptake of norepinephrine and serotonin into the presynaptic neurons. They also alter the sensitivity of brain tissue to the actions of these chemicals. Serious tricyclic antidepressant toxicity results in sodium channel blockade in the myocardium. Other toxicities include potassium efflux blockade and blockade of blood vessels, anticholinergic effects, and seizures. Commonly prescribed antidepressant drugs include the tricyclic antidepressants amitriptyline, desipramine, imipramine, and nortriptyline. The newer *selective serotonin reuptake inhibitors* such as fluoxetine, sertraline, and paroxetine are chemically unrelated to tricyclic antidepressants. These are considered safe and effective compared with tricyclic antidepressants (Box 34-20).

Early symptoms of tricyclic antidepressant overdose are dry mouth, blurred vision, confusion, inability to concentrate, and occasionally visual hallucinations. More severe symptoms include delirium, depressed respirations,

BOX 34-20 Serotonin Syndrome

Serotonin syndrome is a potentially life-threatening drug reaction. The reaction most often occurs when two or more drugs that affect serotonin levels are taken together. The drugs then cause too much serotonin to be released or to remain within brain tissue. Drug combinations that are associated with serotonin syndrome include migraine medicines (triptans) together with selective serotonin reuptake inhibitors (SSRIs) and selective serotonin/norepinephrine reuptake inhibitors (SNRIs). Popular SSRIs include Celexa, Zoloft, Prozac, Paxil, and Lexapro. SNRIs include Cymbalta and Effexor. Brand names of triptans include Imitrex, Zomig, Frova, Maxalt, Axert, Amerge, and Relpax. Drugs of abuse, such as Ecstasy and LSD, have also been associated with serotonin syndrome. Symptoms occur within minutes to hours and may include[20]:

- Agitation or restlessness
- Diarrhea
- Tachycardia
- Hallucinations
- Increased body temperature
- Loss of coordination
- Nausea
- Overactive reflexes
- Rapid changes in blood pressure
- Vomiting

Patients with serotonin syndrome usually require hospitalization for close observation and supportive care. Treatment may include benzodiazepines to decrease agitation, seizure-like movements, and muscle stiffness; cyproheptadine (Periactin) to block serotonin production; IV fluids; and the withdrawal of medicines that caused the syndrome.

hypertension, hypotension, hyperthermia, hypothermia, seizures, and coma (Box 34-21). Cardiac effects may range from tachycardia to bradycardia and various dysrhythmias caused by atrioventricular block. A prolonged QRS complex, right bundle branch block, and a Glasgow Coma Scale score less than 8, are characteristic findings that should alert the paramedic to a major toxicity with potentially serious complications. Sudden death from a cardiac arrest may occur several days after an overdose.

Prehospital management for major toxicity of a tricyclic antidepressant overdose is basic supportive care for the patient and rapid transport. About 25% of patients who ultimately die as a result of the overdose are alert and awake, and 75% have normal sinus rhythm when EMS personnel arrive.[3] Tachycardia, especially with a wide QRS complex greater than 100 ms, is an early sign of toxicity. ***Sodium bicarbonate,*** per medical direction, may begin to reverse cardiac toxicity.[18] Any patient with a history of tricyclic antidepressant ingestion should receive airway, ventilatory, and circulatory support; intravenous access; electrocardiogram monitoring; and rapid transport for physician evaluation. Treatment for specific problems such as seizures and ventricular dysrhythmias is complex. These conditions may require a combination of alkalinization and anticonvulsant medications. Rapid transport to the emergency department is the most prudent course of action.

CRITICAL THINKING

How can you ensure rapid transport of these patients?

Lithium

Lithium is a mood-stabilizing drug that is sometimes prescribed for the management of bipolar disorders (see Chapter 35). The drug has a low toxic-to-therapeutic dose ratio. Thus lithium overdose is common. Patients who are prescribed lithium have frequent blood tests to monitor the level of lithium in the body.

Lithium helps to prevent mood swings. It does this by interfering with hormonal responses to cyclic adenosine monophosphate and by increasing the reuptake of norepinephrine. This produces an antiadrenergic effect. As a result of these actions, lithium has many effects on the body. These include muscle tremor, thirst, nausea, increased urination, abdominal cramping, and diarrhea. With toxic ingestion, signs and symptoms may include the following:

- Muscle weakness
- Slurred speech
- Severe trembling
- Blurred vision
- Confusion
- Seizure
- Apnea
- Coma

BOX 34-21 Five Signs of Major Tricyclic Antidepressant Toxicity

Cardiac dysrhythmias
Coma
Gastrointestinal disturbances
Hypotension or hypertension
Respiratory depression

Prehospital care for patients with suspected lithium overdose should focus on airway management, ventilatory and circulatory support, and the control of seizure activity if present. ***Activated charcoal*** does not effectively bind lithium and should not be administered. In-hospital care may include restoring intravascular volume, maintaining urine output, correcting hyponatremia, and sometimes undergoing dialysis.

Cardiac Medications

Cardiac drugs are a common cause of poisoning deaths in children and adults. The drugs responsible for the majority of these fatalities are ***digoxin,*** beta blockers, and calcium channel blockers (Box 34-22). As in all other cases of

BOX 34-22 Toxic Effects of Common Cardiac Drugs

Digoxin
Atrial fibrillation
Atrial tachycardia
Bigeminal and multifocal premature ventricular contractions
First- and second-degree atrioventricular block
Sinus bradycardia
Ventricular tachycardia/ventricular fibrillation

Beta Blockers
Bradycardia
Hypotension
Respiratory arrest
Seizure
Unconsciousness
Ventricular tachycardia/ventricular fibrillation (rare)

Calcium Channel Blockers
Acute respiratory distress syndrome
Asystole
Atrioventricular dissociation
Coma
Confusion
Hypotension
Lactic acidosis
Mild hyperglycemia/hyperkalemia
Pulmonary edema
Respiratory depression
Sinus arrest
Sinus bradycardia
Slurred speech

poisoning, patients with toxic ingestion of cardiac drugs require high-concentration oxygen administration, intravenous access, and careful monitoring of vital signs and electrocardiogram.

Digoxin exerts direct and indirect effects on sinoatrial and atrioventricular nodal fibers. At toxic levels the drug can halt impulses in the sinoatrial node, depress conduction through the atrioventricular node, and increase sensitivity of the sinoatrial and atrioventricular nodes to catecholamines.[8] ***Digoxin*** affects the Purkinje fibers as well. It decreases the resting potential and action potential duration of the heart and increases automaticity. This can cause an increase in premature ventricular contraction formation. Unlike most cardiovascular drugs, ***digoxin*** can produce almost any dysrhythmia or conduction block. In addition to dysrhythmias, common signs and symptoms of ***digoxin*** toxicity include nausea, anorexia, fatigue, visual disturbances, and a variety of disorders of the gastrointestinal, ophthalmological, and neurological systems. Oral overdoses sometimes are managed with ***activated charcoal*** and drugs to treat life-threatening dysrhythmias. Severe overdoses are managed with intravenous digoxin-specific Fab. This is a drug that decreases the morbidity and mortality associated with ***digoxin*** overdose.

CRITICAL THINKING

Why is it possible that this type of overdose would not be noticed immediately?

Beta blockers are absorbed rapidly after ingestion. Toxicity impairs sinoatrial and atrioventricular node function. This leads to bradycardias and atrioventricular blocks. The associated depression in ventricular conduction and sodium channel blockade may cause the QRS complex to widen. Occasionally, patients become susceptible to ventricular dysrhythmias. However, rarely will these patients exhibit ventricular tachycardia or ventricular fibrillation. Other signs and symptoms include CNS and respiratory depression, hypotension, and seizures. Treatment for patients with beta-blocker overdose may include administration of ***activated charcoal*** and drugs to manage hypotension and dysrhythmias. The in-hospital care may include infusions of ***glucagon,*** high-dose ***insulin,*** or IV calcium salts.[18] Hemodialysis may be necessary, depending on the particular agent involved.

Toxic ingestion of calcium channel blockers can lead to myocardial depression and peripheral vasodilation with negative inotropic, chronotropic, dromotropic, and vasotropic effects. Hypotension and bradycardia are early signs of toxicity. Overdose may result in serious dysrhythmias that include atrioventricular block of all degrees, sinus arrest, atrioventricular dissociation, junctional rhythm, and asystole. (Calcium channel blockers have little effect on ventricular conduction; ventricular dysrhythmias are uncommon.) Other signs and symptoms of calcium channel toxicity include nausea and vomiting, hypotension, and CNS and respiratory depression. In addition to airway, ventilatory, and circulatory support, emergency care may include the use of antidysrhythmics, vasopressors, high-dose ***insulin***, and ***calcium chloride*** (in shock refractory to other measures).[18]

Monoamine Oxidase Inhibitors

As described in Chapter 13, monoamine oxidase (MAO) inhibitors block the breakdown of monoamines (norepinephrine, dopamine, serotonin). These CNS transmitters are distributed throughout the body. The highest concentration is in the brain, liver, and kidneys. Monoamine oxidase inhibitors are prescribed as antidepressants, antineoplastics, antibiotics, and antihypertensives. Some monoamine oxidase inhibitors (e.g., the antidepressants phenelzine and tranylcypromine) have active metabolites. Signs of monoamine oxidase inhibitor toxicity usually are delayed, presenting 6 to 24 hours after ingestion. The duration of effects also may last for several days (Box 34-23). These effects include CNS depression and various neuromuscular and cardiovascular system manifestations.

LOOK AGAIN

See Chapter 13: Principles of Pharmacology and Emergency Medications, pp. 309-311.

The prehospital care is mainly supportive. Care includes airway, ventilatory, and circulatory support; cardiac medications as needed; and rapid transport for physician evaluation. ***Activated charcoal*** may be indicated.

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are a group of drugs that have an analgesic and antipyretic action. They also reduce inflammation of joints and soft tissues such as muscles and ligaments. They work by

BOX 34-23 Effects of Monoamine Oxidase Inhibitor Toxicity

Agitation
Bradysystolic rhythms
Cardiovascular system manifestations
Central nervous system depression
Hallucinations
Hyperreflexia
Hypertension
Hypotension with vascular collapse
Neuromuscular system manifestations
Nystagmus
Rigidity
Seizure
Sinus tachycardia

blocking the production of prostaglandins, which are chemicals that cause inflammation and trigger transmission of pain signals to the brain. Nonsteroidal antiinflammatory drugs are used widely to relieve symptoms caused by types of arthritis (rheumatoid arthritis, osteoarthritis, gout) and to treat back pain, menstrual pain, headaches, minor postoperative pain, and soft tissue injuries. Common nonsteroidal antiinflammatory drugs include diflunisal, fenoprofen, ibuprofen, and naproxen. Ibuprofen and naproxen are available over the counter.

IBUPROFEN OVERDOSE

Ibuprofen is one of the most commonly ingested nonsteroidal antiinflammatory drugs in overdose. The effects usually are reversible and are seldom life threatening. However, significant toxicity may result in coma, seizure, hypotension, and acute renal failure. Chronic and acute ingestion is usually more than 300 mg/kg. In such an ingestion, common symptoms include mild gastrointestinal and CNS disturbances. These usually resolve within 24 hours after ingestion. Other less common effects include mild metabolic acidosis, muscle fasciculations, chills, hyperventilation, hypotension, and asymptomatic bradycardia. Emergency care for patients who have ingested toxic amounts of ibuprofen may consist of gastric decontamination. These patients require careful monitoring for secondary complications such as hypotension and dysrhythmias.

SALICYLATE OVERDOSE

Salicylates are widely available in prescription and over-the-counter products such as acetylsalicylic acid (***aspirin***), many cold preparations, and oil of wintergreen (methyl salicylate) and in combination with some analgesics such as propoxyphene and oxycodone. Table 34-4 contains general guidelines for salicylate toxicity.

NOTE

At one time, the ingestion of colorful and tasty children's aspirin was the most common cause of pediatric poisoning. In response to this problem, the number of tablets now is limited to 36 per container. Because of the association of aspirin with Reye's syndrome, aspirin is not recommended for children younger than 16 years of age who have viral symptoms.

The process of toxicity with salicylate poisoning is complex. Toxicity includes direct CNS stimulation, interference with cellular glucose uptake, and inhibition of Krebs cycle enzymes that affect energy production and amino acid metabolism. The volume of distribution is dose-dependent and usually small. With toxic ingestion, however, redistribution of the drug into the CNS occurs. This prolongs elimination of the drug from the body. Complications that may result from chronic or acute ingestion of salicylates include CNS stimulation, gastrointestinal irritation, inhibition of glucose metabolism, fluid and electrolyte imbalance, neurological symptoms, and coagulation defects. Confusion, lethargy, convulsions, respiratory arrest, coma, and brain death can occur in severe salicylate poisoning.

TABLE 34-4 Toxicity Guidelines to Salicylate

Toxicity	Amount Ingested
Mild	<150 mg/kg
Moderate to severe	150-300 mg/kg
Severe	>300 mg/kg
Fatal	>500 mg/kg

From Clark J: *Pharmacological basis of nursing*, ed 10, St Louis, 2001, Mosby.

In addition to general supportive measures, prehospital care for salicylate poisoning may include the administration of ***activated charcoal*** for decontamination of the gastrointestinal tract. Treatment also may include intravenously administered glucose to manage hypoglycemia. Salicylates are weak acids that can be excreted by the kidney. Thus medical direction may recommend the administration of ***sodium bicarbonate*** in an effort to produce alkaline urine. Definitive care includes in-hospital intensive care observation, continued support of vital functions, and perhaps hemodialysis.

CRITICAL THINKING

Would you predict tachypnea or bradypnea in these patients? Why?

ACETAMINOPHEN OVERDOSE

Acetaminophen is a commonly prescribed analgesic and antipyretic agent. Acetaminophen is available in many prescription and nonprescription preparations (e.g., Tylenol and Panadol). The widespread availability of acetaminophen accounts for its high incidence in unintentional and intentional poisoning. Acetaminophen is 1 of the 10 most commonly used drugs for intentional self-poisoning and is associated with significant morbidity and mortality.[8] Acetaminophen overdose can cause life-threatening liver damage from toxic metabolites if it is not managed within 16 to 24 hours of ingestion. As few as 30 standard-size (325-mg) acetaminophen tablets are toxic in an average adult. Acetaminophen also is present in many drug combinations including Darvocet-N, Excedrin, and Sinutab.

Acute acetaminophen ingestion includes doses of 140 mg/kg or greater. The toxic effects of such an ingestion can be classified in four stages (Box 34-24). The course of toxicity begins with mild symptoms that may be overlooked or masked by more dramatic effects of other agents followed by temporary clinical improvement and finally peak liver

BOX 34-24 Stages of Acetaminophen Poisoning

Stage I: Gastrointestinal Irritability (0 to 24 hours)
Anorexia
Diaphoresis
General malaise
Nausea
Pallor
Vomiting

Stage II: Abnormal Laboratory Findings (24 to 48 hours)
Possible abdominal pain and tenderness in the right abdominal quadrant
Resolution of stage I symptoms

Stage III: Hepatic Damage (72 to 96 hours)
Dysrhythmias
Hepatotoxicity with significant increase in hepatic enzymes
Hypoglycemia
Jaundice
Lethargy
Vomiting

Stage IV: Recovery (4 to 14 days) or Progressive Hepatic Failure*
Resolution of hepatic dysfunction
Lack of permanent effects in patients who recover

**NOTE:* The percentage of patients who recover in stage IV depends on the amount of acetaminophen ingested and whether effective therapy (activated charcoal, acetylcysteine, or both) was given. Patients with serum levels in the hepatotoxic range have mortality rates up to 25% if untreated.

damage. (If acetaminophen was the only drug taken and a dangerously high dose was ingested, the first two stages may be asymptomatic.) If antidote management is started within 8 hours of ingestion, full recovery should occur.

CRITICAL THINKING
Do you think most laypersons realize that acetaminophen overdose can be fatal?

Emergency care includes respiratory, cardiac, and hemodynamic support in critically ill patients. If ingestion is within 1 hour and the patient is alert, medical direction may recommend the administration of ***activated charcoal.*** Patients with progressive acetaminophen toxicity require in-hospital administration of its antidote, *N*-acetylcysteine.

Drugs Abused for Sexual Purposes/ Sexual Gratification

Some drugs are abused for sexual purposes or for sexual gratification. These drugs commonly are classified by users as "uppers," "downers," and "all-arounders" (those that have more than one primary effect). Box 34-25 gives a sampling of these drugs. These drugs generally are taken alone or in combination to produce one or more of the following effects:

- A sense of euphoria
- Excitation ("rush")
- Relaxation ("blissed out")
- A loss of inhibition

Each of these drugs has different chemical structures, mechanisms of action, and side effects. So the problems associated with their use can vary greatly. Signs and symptoms of use of these drugs can range from mild nausea and vomiting to life-threatening respiratory depression, hypotension, **methemoglobinemia** (elevated serum hemoglobin level), coma, and death. The emergency care for these patients mainly is supportive. Care includes airway, ventilatory, and circulatory support, and rapid transport for physician evaluation. As with all other cases of patients who use mood-altering agents, personal safety is of primary importance.

BOX 34-25 Uppers, Downers, and All-Arounders

Uppers
Anabolic steroids
Coke/crack
Ecstasy
Speed/meth/crystal

Downers
Alcohol
Benzodiazepines (diazepam, temazepam, Rohypnol)
Gamma-hydroxybutyrate (GHB)
Heroin

All-Arounders
Cannabis/skunk
Ketamine
Lysergic acid diethylamide (LSD)
Poppers (alkyl nitrates)

SECTION THREE Alcoholism

Alcohol and related illness continue to be a major problem in the United States. In 2008, 51.6% of Americans age 12 years and older reported current use of alcohol; 23.3% of the population admitted to binge drinking (5 or more drinks within 2 hours); and 23.3% of the population reported drinking 5 or more drinks per occasion on 5 or more days per month.[21] In addition, the most recent statistics report that alcohol is a key factor in 41% of vehicle fatalities, 68% of manslaughters, 62% of assaults, 54% of murder attempts, and 48% of robberies. The economic cost

of alcohol and other drug-related crime is $61.8 billion annually.[2]

CRITICAL THINKING
How many calls have you been on that involved patients intoxicated with alcohol? What kinds of calls were they?

ALCOHOL DEPENDENCE

Alcohol dependence is a disorder characterized by chronic, excessive consumption of alcohol that results in injury to health or in inadequate social function and the development of withdrawal symptoms when the patient stops drinking suddenly. An estimated 5 million alcohol-dependent persons (1 in 50) live in the United States. Another 10 million have a difficult time controlling their consumption of the drug.[22]Alcohol dependence should be considered a chronic, progressive, potentially fatal disease characterized by remissions, relapses, and cures.

The development of alcohol dependence can be divided into four main stages.[23] These stages merge imperceptibly. The time frame of these stages may range from 5 to 25 years, but the average is about 10 years. In the first stage, tolerance of the drug develops in the heavy social drinker. This allows a person to consume larger quantities of alcohol before experiencing its ill effects. On entering the second stage, the drinker experiences memory lapses relating to events occurring during the drinking episodes. The third stage is characterized by loss or lack of control over alcohol; the drinker can no longer be certain of discontinuing alcohol consumption at will. The final stage begins with prolonged binges of intoxication. This is associated with mental and physical complications. Some drinkers halt their consumption for a brief time or permanently during one of the first three stages. The active ingredient in all alcoholic beverages is ethanol, a colorless, flammable liquid produced from the fermentation of carbohydrates by yeast.

Metabolism

About 80% to 90% of ingested alcohol is absorbed within 30 minutes. (Twenty percent is absorbed in the stomach, the rest in the small intestine.) Once absorbed, the drug is distributed rapidly throughout the vascular space. Alcohol reaches virtually every organ system. About 3% to 5% of alcohol is excreted unchanged via the lungs and kidneys; the rest is metabolized in the liver to carbon dioxide and water. The actual rate at which alcohol is metabolized depends on individual variation (e.g., physical and mental state, body weight, and size). Metabolism also depends on whether the drinker is alcohol-dependent.

Blood Alcohol Content

The alcohol content of blood is measured in terms of mass (milligrams) of alcohol per given volume of blood (deciliter). Blood alcohol content is used widely to evaluate the CNS status of an intoxicated person. In most states the legal limit of intoxication is 80 mg/dL. (This is equivalent to 0.08%.) Some states have laws that allow paramedics to assist in conducting breathalyzer or blood tests to detect alcohol or drug intoxication. EMS personnel should be well versed in the laws of their state before assisting with these tests and follow established protocols carefully.

CRITICAL THINKING
Can you use an alcohol prep to prepare the site before drawing a blood alcohol specimen? Why?

MEDICAL CONSEQUENCES OF CHRONIC ALCOHOL INGESTION

Alcohol affects nearly every organ system of the body. Thus persons who consume large amounts of alcohol are at risk for a number of physical and mental disorders. These include neurological disorders, nutritional deficiencies, fluid and electrolyte imbalances, gastrointestinal disorders, cardiac and skeletal muscle myopathy, and immune suppression. In addition, alcohol may affect a patient's ability to tolerate traumatic injury.

Neurological Disorders

Alcohol is a potent CNS depressant. When consumed in moderate amounts, the drug reduces anxiety and tension. Alcohol gives most drinkers a feeling of relaxation and confidence. Initial feelings of well-being develop into impaired judgment and discrimination, prolonged reflexes, and incoordination and drowsiness. This ultimately may progress to stupor and coma. The long-term neurological effects of chronic alcohol abuse are similar to those of the aging process. They include short-term memory deficit, problems with coordination, and difficulty with concentration and abstraction.

Nutritional Deficiencies

Alcohol can satisfy the caloric requirements of the body for a brief time. Yet alcohol does not have essential vitamins, proteins, or fats. Thus alcohol-dependent persons may have a decreased dietary intake and malabsorption. This leads to multiple vitamin and mineral deficiencies that can cause altered immunity, poor wound healing, anorexia, cardiac dysrhythmias, and seizures.

WERNICKE-KORSAKOFF SYNDROME

Alcohol-dependent persons are at particular risk of developing **Wernicke-Korsakoff syndrome.** This results from a reduction in intestinal absorption and metabolism of thiamine caused by alcohol. The disease affects the brain and nervous system. The syndrome disrupts central and peripheral nerve function. The disease may consist of two stages: Wernicke's encephalopathy and Korsakoff's psychosis, or a combination of the two.

Wernicke's encephalopathy usually develops suddenly with the clinical manifestations of ataxia, nystagmus, disturbances of speech and gait, signs of neuropathy (paresthesias, impaired reflexes), stupor, and (rarely) coma.[24] Because the body needs thiamine to metabolize glucose, the syndrome may be caused by the intravenous administration of glucose or glucose-containing fluids in the malnourished patient. Coma may be the sole manifestation of Wernicke's encephalopathy. Therefore medical direction may recommend the intravenous administration of ***thiamine*** before giving IV glucose in patients with altered mental status or coma of unknown origin.

CRITICAL THINKING

Why do you think recognizing this syndrome is delayed in alcoholic patients?

Many chronic alcoholic patients also display signs of **Korsakoff's psychosis**. This is a mental disorder often found with Wernicke's encephalopathy. Signs include apathy, poor retentive memory, retrograde amnesia, confabulation (invention of stories to make up for gaps in memory), and dementia. Korsakoff's psychosis usually is considered irreversible. It leaves the patient permanently handicapped by memory loss, requiring continual supervision.

Fluid and Electrolyte Imbalances

Urinary output increases after ingesting alcohol, over and above that expected from the amount of fluid ingested. This diuresis results because alcohol blocks the secretion of antidiuretic hormone. This can lead to dehydration and electrolyte imbalances.

Gastrointestinal Disorders

The effects of alcohol on the gastrointestinal system can produce several types of alcohol-related illnesses and diseases. The alcohol-related gastrointestinal disorders most likely to initiate an EMS response include gastrointestinal hemorrhage, cirrhosis, and acute or chronic pancreatitis.

GASTROINTESTINAL HEMORRHAGE

Four primary causes of gastrointestinal hemorrhage in patients who drink alcohol are gastritis, ulcer formation, esophageal tear (Mallory-Weiss syndrome), and variceal hemorrhage (see Chapter 39).

Gastritis results from the toxic effects of ethanol on the gastric mucosa. This leads to diffuse or localized areas of erosion. In the chronic form of gastritis, blood may ooze continually from the mucosal lining, and ulcers may develop.

Esophageal tears of the gastroesophageal junction, stomach, or esophagus usually follow severe or protracted vomiting or retching. The injury results when gastric contents are forced against an unrelaxed gastroesophageal junction. This produces a sudden increase in pressure and a mucosal tear with subsequent bleeding. The bleeding can be worsened by clotting abnormalities. Such abnormalities are common in patients with alcoholic liver disease.

Varices are a result of portal hypertension caused by cirrhosis. Any of these thin-walled, blood-engorged veins are subject to rupture and hemorrhage. But the most common site is the varices of the esophagus. Bleeding esophagogastric varices remain one of the most difficult conditions to manage. Severe blood loss through vomiting requires aggressive supportive care with large-bore intravenous lines and fluid resuscitation. Like other forms of GI bleeding described in Chapter 29, permissive hypotension to maintain a systolic blood pressure of 80 to 90 mm Hg may be prudent.[25] The paramedic should consult with medical direction or follow established protocol.

LOOK AGAIN

See Chapter 29: Abdominal and Gastrointestinal Disorders, pp. 894-895.

CIRRHOSIS

Cirrhosis of the liver is caused by chronic damage to liver cells and eventual necrosis. In the disease process, bands of fibrous scar tissue develop and disturb the normal structure of the liver. The distortion and fibrosis of the liver lead to portal hypertension. This results in complications such as ascites, splenomegaly, and bleeding esophageal and gastric varices. In addition, cirrhosis may lead to **hepatic encephalopathy.** This is caused by the accumulation of toxic metabolic waste products that normally would be detoxified by a healthy liver. Cirrhosis is the twelfth leading cause of death by disease, accounting for 27,000 deaths each year.[26]

ACUTE OR CHRONIC PANCREATITIS

Alcohol is the most common cause of acute and chronic pancreatitis. Chronic pancreatitis usually produces the same symptoms as the acute form (described in Chapter 29). The pain, however, may last from several hours to several days. The attacks also become more frequent as the condition progresses. The effects of chronic pancreatitis include malabsorption and electrolyte imbalances. Diabetes mellitus also may develop from insufficient insulin production. Complications of pancreatitis are hemorrhagic pancreatitis, sepsis, and pancreatic abscess. These complications are associated with high mortality.

Cardiac and Skeletal Muscle Myopathy

Cardiac and skeletal muscle damage related to alcohol abuse is thought to result from a direct toxic effect of alcohol or its metabolites. In heart muscle, these toxic effects can result in a decreased force of contraction, dysrhythmias, and a tendency to develop congestive heart failure. In skeletal muscle the major symptoms are weakness and muscle wasting.

Immune Suppression

Long-term alcohol abuse renders the immune system less effective. Alcohol abuse suppresses bone marrow production of white blood cells. In addition, production of red blood cells and platelets is often decreased. Alcohol has direct, specific effects on lung tissue. These effects may impair macrophage mobilization and protective ciliary function. As a result, the ability of the body to fight pulmonary infection is lowered. This makes the alcoholic more susceptible to viral and bacterial pneumonia.

CRITICAL THINKING

For what other pulmonary disease is the immune-suppressed alcoholic patient at risk?

Trauma

Alcohol suppresses clotting factors that are produced in the liver. This blood-clotting deficiency makes alcoholics prone to bruising and internal hemorrhage. The deficiency also adds to the frequency of subdural bleeding, even after relatively minor head trauma[27] (see Chapter 40).

ALCOHOL EMERGENCIES

Several other conditions caused by consumption or abstinence from alcohol may require emergency care. These include acute alcohol intoxication, alcohol withdrawal syndromes, and disulfiram-ethanol reaction. Alcohol-induced ketoacidosis and hypoglycemia were discussed in Chapter 26.

LOOK AGAIN

See Chapter 26: Endocrine, pp. 813-814.

Acute Alcohol Intoxication

The ingestion of alcohol may cause acute poisoning if consumed in large amounts over a short period. At toxic levels, hypoventilation (including respiratory arrest), hypotension, and hypothermia may develop. The patient who has signs and symptoms of acute alcohol intoxication should be evaluated for hidden trauma and coexisting medical conditions. These conditions include hypoglycemia, cardiac myopathy and dysrhythmias, gastrointestinal bleeding, polydrug abuse, and ethylene glycol or methanol ingestion. Because the patient is prone to injury and usually has other medical problems, the paramedic should never assume that an intoxicated patient is merely inebriated.

MANAGEMENT

A patient who is mildly intoxicated may need to be transported for physician evaluation. In most cases, management requires patient observation in the emergency department only until the patient is sober. The paramedic should monitor the patient's vital signs and level of consciousness carefully en route. A thorough physical examination is warranted to rule out illness or injury masked by alcohol ingestion.

Care of the acutely intoxicated patient is aimed at protecting the patient from further injury and maintaining vital functions. If the patient is conscious and agitated, restraints may be necessary. If physical restraint becomes necessary, the police should be summoned. After scene safety has been established, the primary survey and resuscitation should include the following:

1. Rapidly evaluate airway patency with spinal precautions. Assess the patient's ventilatory and hemodynamic status while obtaining a history. The patient's account of the event may be unreliable because of the alcohol ingestion.
2. Initiate intravenous therapy. Draw blood samples for laboratory analysis. If hypoglycemia is confirmed, administer ***thiamine, dextrose 50%*** (per protocol). Give ***naloxone*** if opioid overdose is suspected.
3. Continually monitor the patient's airway and provide adequate ventilatory and circulatory support as needed. Be prepared to provide suction and aggressive airway management.
4. Monitor the electrocardiogram for dysrhythmias.
5. Rapidly transport the patient for physician evaluation.

Alcohol Withdrawal Syndromes

A period of relative or full abstinence from alcohol may cause withdrawal in an alcoholic. Alcohol withdrawal syndromes are mediated by several mechanisms that result in CNS hyperexcitability. Biochemical changes such as respiratory alkalosis and hypomagnesemia may also play a role. Alcohol withdrawal syndromes can be divided into four general categories: minor reactions, hallucinations, alcohol withdrawal seizures, and delirium tremens.[28]

SHOW ME THE EVIDENCE

These researchers sought to identify factors that predicted mortality in patients with delirium tremens (DT). They investigated 36 deaths related to DT that occurred between 2000 and 2006. Hyperthermia and the use of restraints were associated with an increased risk of death.

Khan A, Levy P, DeHorn S, et al: Predictors of mortality in patients with delirium tremens, *Acad Emerg Med* 15(8):788-790, 2008.

MINOR REACTIONS

Minor reactions begin about 6 to 12 hours after cessation or reduction of alcohol intake. These symptoms peak within 24 to 36 hours. They may persist for 10 to 14 days. When alcohol withdrawal is confined to minor reactions, the prognosis for full recovery is excellent with the proper management. Minor reactions include facial flushing, diaphoresis, nausea and vomiting, slight disorientation, and generalized tremor made worse by agitation. Mild tachycardia, hypertension, and hyperreflexia also may be present.

CRITICAL THINKING

What kinds of feelings do you think the patient and the patient's family may be having during withdrawal reactions?

HALLUCINATIONS

Hallucinations usually occur 12 to 24 hours after the patient stops drinking alcohol. Disorders of perception are common. They may vary from auditory and visual illusions to frank hallucinations. The latter can produce agitation, fear, and panic. During this period, the patient may show signs of suicidal and homicidal tendencies, and minor reactions may be more pronounced. The prognosis for hallucinations is the same as that for minor reactions with appropriate care.

ALCOHOL WITHDRAWAL SEIZURES

Alcohol withdrawal seizures (or "rum fits") usually occur 24 to 48 hours after ethanol cessation. They most often are grand mal of short duration; status seizures are rare.[8] This category of withdrawal may be self-limiting or may progress to delirium tremens with or without a lucid interval. Because of the high drug tolerance level of the alcoholic patient, seizure activity may require intravenous administration of large doses of ***diazepam*** or ***lorazepam.*** These drugs may synergistically interact with any ethanol still in the patient's system. Thus vital signs, respirations, and mental status should be monitored closely.

DELIRIUM TREMENS

Delirium tremens is the most dramatic and serious form of alcohol withdrawal. It affects about 5% of all alcoholics hospitalized for withdrawal.[29] Delirium tremens usually occurs 48 to 72 hours after cessation of alcohol. Yet it may be delayed up to 14 days. The syndrome is characterized by psychomotor, speech, and autonomic hyperactivity; profound confusion; disorientation; delusion; vivid hallucinations; tremor; agitation; and insomnia. A single episode may last 1 to 3 days and, with multiple recurrences, may last up to 1 month. Delirium tremens is a true medical emergency. It has a mortality rate that approaches 15%.[30] Associated alcohol-related illnesses such as pneumonia, pancreatitis, and hepatitis are frequent contributing causes of death.

MANAGEMENT

The care for patients with alcohol withdrawal syndromes mainly is supportive. After scene safety is ensured, the paramedic should carefully monitor the patient's airway, ventilatory, and circulatory status. Intravenous therapy should be initiated with a saline solution for rehydration. Pharmacological therapy may be indicated for an altered level of consciousness, dysrhythmias, or seizure activity. In addition, these patients need calm reassurance and frequent reorientation. All patients with signs and symptoms of alcohol withdrawal syndrome require physician evaluation. Benzodiazepines (e.g., oxazepam, ***lorazepam,*** and ***diazepam***) are often prescribed at regular intervals to help control the withdrawal symptoms.

Disulfiram-Ethanol Reaction

Disulfiram (tetraethylthiuram disulfide [Antabuse]) is a medication prescribed to some alcoholic patients to help them abstain. The drug works by inhibiting ethanol metabolism and by allowing the accumulation of the metabolite acetaldehyde. Acetaldehyde produces ill effects on the gastrointestinal, cardiovascular, and autonomic nervous systems. Acetaldehyde is the metabolic product that is thought to be responsible for the common "hangover." Patients who take disulfiram and then drink alcohol experience an unpleasant and potentially life-threatening physiological response.

The **disulfiram-ethanol reaction** begins 15 to 30 minutes after the ingestion of two to five alcoholic drinks. The reaction continues for 1 to 2 hours. It causes the patient to experience vertigo, headache, vomiting, and flushing, which may give the skin a "lobster-red" appearance. Other effects include dyspnea, diaphoresis, abdominal pain, and sometimes chest pain. More serious reactions include hypotension, shock, and dysrhythmias. Sudden death, myocardial and cerebral infarction, and cerebral hemorrhage also have been reported after as little as one drink of ethanol in patients taking high doses of disulfiram.[31] Acute overdose of disulfiram is now uncommon with current dosing regimens.[8]

MANAGEMENT

Prehospital care for a disulfiram-ethanol reaction involves airway, ventilatory, and circulatory support; administration of intravenous fluids to manage hypotension; pharmacological therapy as needed to manage dysrhythmias; and rapid transport for physician evaluation. Most patients recover from these episodes. Supportive care and in-hospital observation are usually all that are required.

SECTION FOUR
Management of Toxic Syndromes

GENERAL MANAGEMENT PRINCIPLES FOR TOXIC SYNDROMES

As stated before, most poisoned patients require only supportive therapy to recover, regardless of the toxic agent (Box 34-26). However, grouping toxic agents and physical findings into toxic syndromes, or **toxidromes,** can give the paramedic important clues to what type of poison or toxin is involved. This will aid the paramedic in remembering assessment and management strategies as well (Table 34-5). The five toxic syndromes presented in this chapter are the following[3]:

1. Cholinergic
2. Anticholinergic
3. Hallucinogenic
4. Opioid
5. Sympathomimetic

NOTE

Toxic syndrome classification does not consider how or why the toxin was introduced into the body. Thus the paramedic should consider route of entry in addition to specific treatments.

Cholinergics

Exposure to cholinergics is uncommon. However, it is important to recognize cholinergic poisoning so that lifesaving care can be initiated. Causative agents include pesticides (organophosphates, carbamates) and nerve agents (e.g., sarin and soman). Assessment findings include headache, dizziness, weakness, bradycardia, nausea, and a "wet" presentation manifested by profound *s*alivation, *l*acrimation, *u*rination, *d*efecation, *g*astrointestinal upset, and *e*mesis (SLUDGE). In severe cases, coma and convulsions may be present. In addition to airway, ventilatory, and circulatory support and decontamination, drug therapy may include administration of ***atropine, pralidoxime, diazepam*** or ***lorazepam,*** and ***activated charcoal.***

Anticholinergics

Exposure to anticholinergics is fairly common because so many medications and plants have anticholinergic properties. Examples include drugs such as antihistamines, antipsychotics, antispasmodics, and tricyclic antidepressants; and plants such as jimson weed, night blooming jessamine, panther mushroom, and angel's trumpet. The signs and symptoms include tachycardia; dry, flushed skin; dilated pupils; and facial flushing. This "dry" patient presentation usually is managed with airway, ventilatory, and circulatory support. Physostigmine may be given as an antidote in rare cases, in the absence of tricyclic antidepressant overdose.[7]

TABLE 34-5 Toxicological Syndromes

Common Signs	Causative Agents	Specific Treatment
Cholinergic ("Wet" Patient Presentation)		
Confusion, CNS depression, weakness, SLUDGE (*s*alivation, *l*acrimation, *u*rination, *d*efecation, *g*astrointestinal upset, *e*mesis), bradycardia, wheezing, bronchoconstriction, miosis, coma, convulsions, diaphoresis, seizures	Organophosphate and carbamate insecticides, nerve agents, some mushrooms	***Atropine, pralidoxime*** (2-PAM chloride), ***diazepam*** or lorazepam, ***activated charcoal***
Anticholinergic ("Dry" Patient Presentation)		
Delirium, tachycardia, dry and flushed skin, dilated pupils, seizures, and dysrhythmias (in severe cases)	Antihistamines, antiparkinson medications, atropine, antipsychotic agents, antidepressants, skeletal muscle relaxants, many plants (e.g., Jimson weed and *Amanita muscaria*)	***Diazepam*** or lorazepam, activated charcoal, rarely physostigmine (Antilirium)
Hallucinogens		
Visual illusions, delusions, bizarre behavior, flashbacks, respiratory and CNS depression	LSD, PCP, mescaline, some mushrooms, marijuana, Jimson weed, nutmeg, mace, some amphetamines	Minimal sensory stimulation, calming measures, ***diazepam*** or lorazepam if necessary
Opioids		
Euphoria, hypotension, respiratory depression/arrest, nausea, pinpoint pupils, seizures, coma	Heroin, ***morphine,*** codeine, ***meperidine*** (Demerol), propoxyphene, fentanyl	***Naloxone*** (Narcan), ***nalmefene*** (Revex)
Sympathomimetics		
Delusions, paranoia, tachycardia or bradycardia, hypertension, diaphoresis; seizures, hypotension, and dysrhythmias in severe cases	Cocaine, amphetamine, methamphetamine, over-the-counter decongestants	Minimal sensory stimulation, calming measures, ***diazepam*** or lorazepam if necessary; manage dysrhythmias

LSD, Lysergic acid diethylamide; *PCP,* phencyclidine.

BOX 34-26 General Management Guidelines for the Poisoned Patient

1. Ensure scene and personal safety.
2. Provide adequate airway, ventilation, and circulation.
3. Obtain a thorough history, and perform a focused physical examination.
4. Consider hypoglycemia in a patient who is unconscious, convulsing, drowsy, or combative..
5. Administer naloxone or nalmefene to a patient with respiratory depression and suspected opioid ingestion.
6. If overdose is suspected, obtain an overdose history from the patient, family, or friends.
7. Consult with medical direction or a poison control center for specific treatment to prevent further absorption of the toxin (or antidote therapy).
8. Frequently monitor vital signs and electrocardiogram.
9. Safely obtain any substance or substance container of a suspected poison. Transport it with the patient.
10. Transport the patient for physician evaluation.

Hallucinogens

Common hallucinogens include lysergic acid diethylamide (LSD), PCP, peyote, mushrooms, and mescaline. Depending on the agent and dose, signs and symptoms may include CNS stimulation and/or depression, behavioral disturbances, delusions, hypertension, chest pain, tachycardia, seizures, and respiratory and cardiac arrest. Prehospital care for these patients is focused on ensuring personal safety and providing airway, ventilatory, and circulatory support.

Opioids

The opioid syndrome carries a hallmark triad of depressed level of consciousness, respiratory depression, and pinpoint pupils. Common causative agents include heroin, ***morphine,*** codeine, ***meperidine,*** oxycodone, hydrocodone, and ***fentanyl.*** Drugs in this class often are mixed with alcohol or other drugs (e.g., benzodiazepines). This leads to increased respiratory depression, hypotension, and bradycardia. Other signs and symptoms may include euphoria, nausea, pinpoint pupils, and seizures. In addition to ensuring airway, ventilatory, and circulatory support, drug therapy may include the administration of ***naloxone*** or another opioid-specific antidote agent.

Sympathomimetics

The sympathomimetic syndrome usually results from acute overdose of amphetamines or cocaine. Signs and symptoms include elevated blood pressure, tachycardia, dilated pupils, and altered mental status, including paranoid delusions. In severe cases, cardiovascular collapse can occur. Management consists of ensuring personal safety and providing airway, ventilatory, and circulatory support.

CRITICAL THINKING

Why is it important to be able to identify these toxic syndromes?

SUMMARY

- A poison is any substance that produces harmful physiological or psychological effects.
- The toxic effects of ingested poisons may be immediate or delayed. This depends on the substance that is ingested. The main goal is to identify effects on the three vital organ systems most likely to produce immediate morbidity and mortality. These are the respiratory system, the cardiovascular system, and the central nervous system. In some cases, serious poisonings by ingestion are managed by preventing the toxic substance from reaching the small intestine. This limits its absorption.
- Strong acids and alkalis may cause burns to the mouth, pharynx, esophagus, and sometimes the upper respiratory and GI tracts. Prehospital care is usually limited to airway and ventilatory support, IV fluid replacement, and rapid transport to the appropriate medical facility.
- The most important physical characteristic in the potential toxicity of ingested hydrocarbons is its viscosity. The lower the viscosity, the higher the risk of aspiration and associated complications. Hydrocarbon ingestion may involve the patient's respiratory, gastrointestinal, and neurological systems. The clinical features may be immediate or delayed in onset.
- Methanol is a poisonous alcohol. It is found in a number of products. Methanol itself is no more toxic than ethanol. Yet its metabolites (formaldehyde and formic acid) are very toxic. Ingestion can affect the central nervous system, the gastrointestinal tract, and the eyes. It also can cause the development of metabolic acidosis.
- Ethylene glycol toxicity is caused by the buildup of toxic metabolites, especially glycolic and oxalic acids after metabolism. This occurs mainly in the liver and kidneys. This toxicity may affect the central nervous system and cardiopulmonary and renal systems. It may result in hypocalcemia as well.
- The majority of isopropanol (isopropyl alcohol) is metabolized to acetone after ingestion. Isopropanol poisoning affects several body systems, including the central nervous, gastrointestinal, and renal systems.
- Infants and children are high-risk groups for accidental iron, lead, and mercury poisoning. This is due to their immature immune systems or increased absorption as a function of age. Ingested iron is corrosive to

Continued

gastrointestinal tract mucosa. It may produce lethal GI hemorrhage, bloody vomitus, painless bloody diarrhea, and dark stools.

- Food poisoning is a term used for any illness of sudden onset (usually associated with stomach pain, vomiting, and diarrhea) suspected of being caused by food eaten within the previous 48 hours. Food poisoning can be classified as infectious. This results from a bacterium or virus. It also can be classified as noninfectious. This results from toxins and pollutants.
- The toxic effects of major poisonous plant ingestions are predictable. They are categorized by the chemical and physical properties of the plant. Most responses are consistent with the type of major toxic chemical component in the plant.
- The concentration of a chemical in the air helps to predict the severity of an inhalation injury. The duration of exposure helps to determine this as well. Solubility also influences the extent of an inhalation injury. Highly reactive chemicals cause more severe and rapid injury than less reactive chemicals. Properties that determine chemical reactivity are chemical pH; direct-acting potential of chemicals; indirect-acting potential of chemicals; and allergic potential of chemicals.
- Cyanide refers to any of a number of highly toxic substances that contain the cyanogen chemical group. Regardless of the route of entry, cyanide is a rapidly acting poison. It combines and reacts with ferric ions of the respiratory enzyme cytochrome oxidase. This inhibits cellular oxygenation. This can produce a rapid progression from dyspnea to paralysis, unconsciousness, and death.
- Ammonia is a toxic irritant. It causes local pulmonary complications after inhalation. In severe cases, bronchospasm and pulmonary edema may develop.
- Hydrocarbon inhalation may cause aspiration pneumonitis. It also has the potential for systemic effects such as CNS depression and liver, kidney, or bone marrow toxicity.
- Simple asphyxiants cause toxicity by lowering ambient oxygen concentration. Chemical asphyxiants possess intrinsic systemic toxicity. This toxicity occurs after absorption into the circulation. Irritants or corrosives cause cellular destruction and inflammation as they come into contact with moisture in the respiratory tract.
- The general principles of managing inhaled poisons are the same as those for any other hazardous materials incident.
- Hymenoptera and Arachnida cause the highest incidence of need for emergency care. Arthropod venoms are complex and diverse in their chemistry and pharmacology. They may produce major toxic reactions in sensitized persons. Such reactions include anaphylaxis and upper airway obstruction.
- The two main families of venomous snakes indigenous to the United States are pit vipers and coral snakes. Pit viper venom can produce various toxic effects on blood and other tissues. These effects include hemolysis, intravascular coagulation, convulsions, and acute renal failure. The venom of the coral snake is mainly neurotoxic. Signs and symptoms range from slurred speech, dilated pupils, and dysphagia to flaccid paralysis and death.
- The marine animals most likely to be involved in human poisonings in U.S. coastal waters are coelenterates, echinoderms, and stingrays. Coelenterate envenomation ranges in severity from irritant dermatitis to excruciating pain, respiratory depression, and life-threatening cardiovascular collapse. Echinoderm toxins may cause immediate intense pain, swelling, redness, aching in the affected extremity, and nausea. Delayed effects may include respiratory distress, paresthesia of the lips and face, and, in severe cases, respiratory paralysis and complete atonia. Locally, stingray venom produces a painful traumatic injury. It may cause bleeding and necrosis. Systemic manifestations range from weakness and nausea to seizures, paralysis, hypotension, and death.
- Organophosphates and carbamates inhibit the effects of acetylcholinesterase. A mnemonic that may help the paramedic to recognize this type of poisoning is SLUDGE. (This stands for *s*alivation, *l*acrimation, *u*rination, *d*efecation, *g*astrointestinal upset, and *e*mesis.) The most specific findings, however, are miosis, rapidly changing pupils, and muscle fasciculation.
- General principles for managing drug abuse and overdose include providing scene safety; ensuring adequate airway, breathing, and circulation; obtaining a history; identifying the substance; performing a focused physical exam; initiating an IV; administering an antidote if needed; preventing further absorption; and providing rapid patient transport.
- Narcotics are CNS depressants. They can cause life-threatening respiratory depression. In severe intoxication, hypotension, profound shock, and pulmonary edema may be present. Naloxone is a pure narcotic antagonist effective for virtually all narcotic and narcotic-like substances.
- Sedative-hypnotic agents include benzodiazepines and barbiturates. Signs and symptoms of sedative-hypnotic overdose are chiefly related to the central nervous and cardiovascular systems. Flumazenil (Romazicon) is a benzodiazepine antagonist. It is useful in reversing the effects of these agents if they were given in a clinical setting.
- Commonly used stimulant drugs are those of the amphetamine family. Adverse effects include tachycardia, hypertension, tachypnea, agitation, dilated pupils, tremors, and disorganized behavior. With sudden with-

drawal, the patient becomes depressed, suicidal, incoherent, or nearly comatose.

- Phencyclidine (PCP) is a dissociative analgesic with sympathomimetic and CNS stimulant and depressant effects. In low doses, PCP intoxication produces an unpredictable state that can resemble drunkenness (and rage). High-dose intoxication may cause coma. This may last from several hours to days. Respiratory depression, hypertension, and tachycardia may be present. PCP psychosis is a psychiatric emergency. It may mimic schizophrenia.
- Hallucinogens are substances that cause distortions of perceptions. Depending on the agent, overdose may range from visual hallucinations and anticholinergic syndromes to more serious complications, including psychosis, flashbacks, and respiratory and CNS depression.
- Tricyclic antidepressant (TCA) toxicity is thought to result from central and peripheral, atropine-like anticholinergic effects and direct depressant effects on myocardial function. A prolonged QRS complex, a GCS score less than 8, or both, should alert the paramedic to a major TCA toxicity.
- Lithium is a mood-stabilizing drug. Toxic ingestion can include CNS effects that can range from blurred vision and confusion to seizure and coma.
- Cardiac drugs are a common cause of poisoning deaths in children and adults. The drugs responsible for the majority of these fatalities are digitalis, beta blockers, and calcium channel blockers.
- MAO inhibitors block or diminish the activity of the monoamines (norepinephrine, dopamine, serotonin). Toxic effects include CNS depression and various neuromuscular and cardiovascular system manifestations.
- Nonsteroidal antiinflammatory drugs (NSAIDs) work by blocking the production of prostaglandins. The effects of overdose of ibuprofen are usually reversible, are seldom life threatening, and include mild GI and CNS effects. Salicylate poisoning may cause CNS stimulation, GI irritation, inhibition of glucose metabolism, fluid and electrolyte imbalance, and coagulation defects.
- Acetaminophen overdose may cause life-threatening liver damage. This results from formation of a hepatotoxic intermediate metabolite if it is not managed within 16 to 24 hours of ingestion.
- Some drugs are abused for sexual purposes or for sexual gratification. These are commonly classified by users as "uppers," "downers," and those that have more than one primary effect ("all-arounders"). Problems associated with their use vary widely.
- Alcohol dependence is a disorder characterized by chronic, excessive consumption of alcohol that results in injury to health or in inadequate social function and the development of withdrawal symptoms when the patient stops drinking suddenly. Alcohol causes multiple systemic effects. These include neurological disorders, nutritional deficiencies, fluid and electrolyte imbalances, gastrointestinal disorders, cardiac and skeletal muscle myopathy, and immune suppression. Several conditions caused by consumption or abstinence from alcohol that may require emergency care are acute alcohol intoxication, alcohol withdrawal syndromes, and disulfiram-ethanol reaction.
- The most common toxic syndromes are cholinergic, anticholinergic, hallucinogenic, opioid, and sympathomimetic. Using these classifications allows the paramedic to group similar toxic agents together. It allows the paramedic to more easily remember how to assess and treat the poisoned patient.

CHAPTER

35 Behavioral and Psychiatric Disorders

OBJECTIVES

Upon completion of this chapter, the paramedic student will be able to:

1. Define what constitutes a behavioral emergency.
2. Identify potential causes for behavioral and psychiatric illnesses.
3. List three critical principles that should be considered in the prehospital care of any patient with a behavioral emergency.
4. Outline key elements in the prehospital patient examination during a behavioral emergency.
5. Describe effective techniques for interviewing a patient during a behavioral emergency.
6. Distinguish between key symptoms and management techniques for selected behavioral and psychiatric disorders.
7. Identify factors that must be considered when assessing suicide risk.
8. Formulate appropriate interview questions to determine suicidal intent.
9. Explain prehospital management techniques for the patient who has attempted suicide.
10. Describe assessment of the potentially violent patient.
11. Outline measures that may be used in an attempt to safely diffuse a potentially violent patient situation.
12. List situations when patient restraints can be used.
13. Discuss key principles in patient restraint.
14. Describe safety measures taken when patient violence is anticipated.
15. Explain variations in approach to behavioral emergencies in children.

KEY TERMS

acute psychosis A condition that refers to a patient who presents with one or more of the following criteria: a sudden onset of delusions that rapidly change; hallucinations; bizarre behavior and posture; or disorganized speech.

affect An outward manifestation of a person's feelings or emotions.

agitated delirium Describes a person with delirium who has (1) acute onset and fluctuating course, (2) reduced clarity of awareness of the environment, (3) perceptual disturbance, disorientation, or memory disturbance, and (4) underlying general medical condition.

anhedonia The inability to enjoy what is usually pleasurable.

anorexia nervosa A disorder characterized by a prolonged refusal to eat, resulting in emaciation, amenorrhea, emotional disturbance concerning body image, and an abnormal fear of becoming obese.

anxiety A state or feeling of apprehension, uneasiness, agitation, uncertainty, and fear resulting from the anticipation of some threat or danger.

autism spectrum disorder A range of neurodevelopmental disorders characterized by three sets of behavioral features: (1) impairment in social interaction, (2) communication deficits (both verbal and nonverbal), and (3) restricted, repetitive behaviors, including decreased imaginative play, stereotyped behaviors, and inflexible adherence to routines.

behavioral emergency A change in mood or behavior that cannot be tolerated by the involved person or others and that requires immediate attention.

biological disturbances Mental disorders that result from a physical rather than a purely psychological cause.

bipolar disorder A disorder marked by alternating periods of mania and depression; also known as manic-depressive disorder.

bulimia nervosa A disorder characterized by an insatiable craving for food, often resulting in episodes of binge eating followed by purging (through self-induced vomiting or use of laxatives), depression, and self-deprivation.

chemical restraint The use of drugs to control behavior.

clinical depression A disabling condition that adversely affects a person's family, work or school life, sleeping and eating habits, and general health; also known as *major depression*.

cognitive disorder A disorder that results in a disturbance of cognitive functioning.

conversion disorder A mental illness in which painful emotions are repressed and unconsciously converted into physical symptoms.

delirium An abrupt disorientation for time and place, usually with delusions and hallucinations.

delusions Persistent beliefs or perceptions held by a person despite evidence that refutes them (i.e., false beliefs).

dementia A slow, progressive loss of awareness of time and place. It usually involves an inability to learn new things or recall recent events.

depression A mood disturbance characterized by feelings of sadness, despair, and discouragement.

dissociative disorders A group of psychological illnesses. In these illnesses, a particular mental function is separated (dissociated) from the mind as a whole.

dyskinesia An impairment of the ability to execute voluntary movements; often an adverse effect of prolonged use of antipsychotic medications.

dysthymia A form of depression that is chronic in nature, lasting as long as 2 years or more.

factitious disorders A group of disorders in which symptoms mimic a true illness. However, the symptoms have actually been invented.

hallucinations The apparent perception of sights, sounds, and other sensory phenomena that are not actually present.

impulse control disorders A group of psychiatric conditions characterized by the inability to resist an impulse or a temptation to perform some act that is unlawful, socially unacceptable, or self-harmful.

mania A mood disorder characterized by extreme excitement, hyperactivity, agitation, and sometimes violent and self-destructive behavior.

mental status examination An evaluation tool that includes an assessment of appearance and behavior, speech and language, emotional stability, and cognitive abilities.

mood disorder Refers to changes in emotions that a person experiences in life (e.g., happiness, depression, fear, and anxiety).

Munchausen syndrome A factitious disorder in which the patient makes routine pleas for treatment and hospitalization for a symptomatic, but imaginary, acute illness.

Munchausen syndrome by proxy A factitious disorder in which a person injures or induces illness in others (usually children) in order to gain sympathy.

obsessive-compulsive disorder A psychiatric disorder in which a person feels stress or anxiety about thoughts or rituals over which the individual has little control.

panic disorder An anxiety disorder characterized by unexpected and repeated episodes of intense fear accompanied by physical symptoms that may include chest pain, heart palpitations, shortness of breath, dizziness, or abdominal distress.

paranoia A condition characterized by an elaborate, overly suspicious system of thinking.

personality disorder A large group of conditions distinguished by a failure to learn from experience or to adapt appropriately to changes; results in personal distress and impairment of social functioning.

phobia An anxiety disorder characterized by an obsessive, irrational, and intense fear of a specific object or activity.

posttraumatic stress disorder An anxiety reaction to a severe psychosocial event; also known as *posttraumatic syndrome*.

psychosis Maladaptive behavior involving major distortions of reality.

schizophrenia A group of disorders characterized by recurrent episodes of psychotic behavior.

somatization disorder A condition in which an individual has complaints (lasting several years) of various physical problems for which no physical cause can be found.

somatoform disorder Any of a group of neurotic disorders characterized by symptoms suggesting physical illness or disease, for which there are no organic or physiological causes.

suicide The act of a human being intentionally causing his or her own death.

Caring for a patient with a behavioral or psychiatric emergency can be challenging, even for the most experienced practitioner. These emergencies call for strong diagnostic skills and a good understanding of pharmacology and toxicology. They also require thorough assessment skills to identify organic illness that can masquerade as a psychiatric condition. Behavioral and psychiatric emergencies demand excellent communication skills, a compassionate and caring approach, and supportive measures to prevent a crisis from escalating.

UNDERSTANDING BEHAVIORAL EMERGENCIES

An estimated 26.2% of Americans age 18 and older (1 in 4 adults) suffer from a diagnosable mental disorder in a given year. This number translates to about 57.7 million people.[1]

The National Institute of Mental Health has estimated that one in seven individuals will need treatment at some point in life for an emotional disturbance. Mental health problems are the leading cause of disability in the United States and Canada for people 15 to 44 years of age.

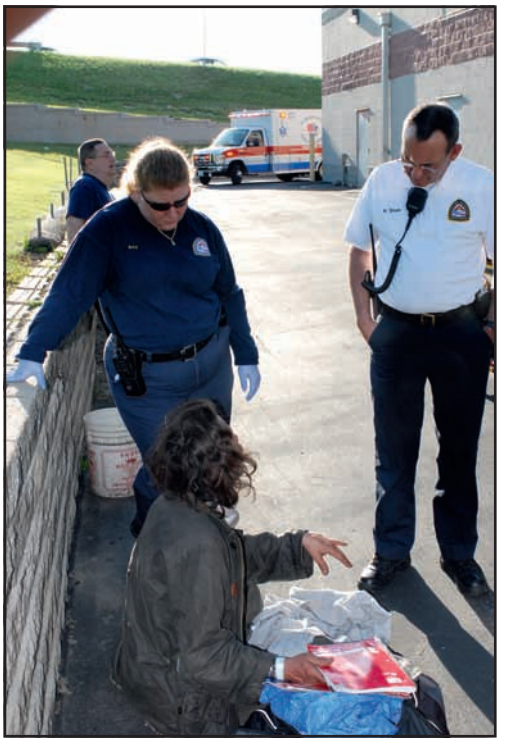
There is no clear agreement or ideal model for "normal" behavior. It generally is considered to be adaptive behavior that is accepted by society. (This can vary by culture and ethnic group.) The concept of "abnormal" (maladaptive) behavior also is defined by society when behavior:

- Deviates from society's norms and expectations
- Interferes with well-being and ability to function
- Harms the individual or group

CRITICAL THINKING

Can you think of a time in your life when you, a family member, or a close friend had a behavior that fit the definition of abnormal behavior? How did it make you feel?

A **behavioral emergency** can be defined as a change in mood or behavior that cannot be tolerated by the involved person or others and that requires immediate attention. Behavioral emergencies may range from a brief inability to cope with stress or anxiety to more intense situations in which patients may be dangerous to themselves and others. However, most people with mental illness function well on a daily basis. Common conditions such as depression, anxiety disorders, and mild personality disorders often are effectively managed with medication and counseling in outpatient mental health centers. Most behavioral emergencies have a biological/organic, psychosocial, or sociocultural cause. Mental illness also may be the result of more than one of these factors (Figure 35-1). Ten common myths about mental illness are listed in Box 35-1.



(Courtesy Ray Kemp, St. Charles, Mo.)

Biological Causes

Physical or biochemical disturbances in the brain can result in significant changes in behavior. In mental health care, **biological disturbances** are mental disorders that result from a physical rather than a purely psychological cause. Examples of biological causes include genetic factors, prenatal and postnatal factors (including infection, and endocrine, metabolic, and vascular disorders), an imbalance in brain chemistry (which may have a heritable component), and alterations in neurotransmission. An example of a biological mental illness is schizophrenia, described later in this chapter. In this illness, specific genes have been identified that may influence the balance of chemicals in the brain. As described in Chapter 13: Principles of Pharmacology and Emergency Medications, neurotransmitters are responsible for communication among the brain cells. To review, the predominant neurotransmitters in the brain include glutamate, γ-aminobutyric acid (GABA), **serotonin,** dopamine, and norepinephrine. Most scientists believe that mental illnesses result from problems with communication between these neurotransmitters and the neurons in the brain.

See Chapter 13: Principles of Pharmacology and Emergency Medications, pp. 308-310.

FIGURE 35-1 Common causes of behavioral emergencies.

Organic causes of behavioral emergencies that are discussed throughout this text include substance abuse, trauma, illness (e.g., diabetes, electrolyte imbalance), infections, tumors, and dementia (Box 35-2). It is important that the paramedic consider the possibility of these medical conditions as part of a differential diagnosis in all behavioral emergencies.

Psychosocial Causes

Psychosocial mental illness often is related to an individual's personality type. It also may be related to the person's ability to resolve situational conflict in life. For example, psychosocial mental illness may result from childhood trauma, child abuse or neglect, or a dysfunctional family structure that affects relationships with parents and siblings. Biological disorders may contribute to psychosocial causes of mental illness.

Sociocultural Causes

Sociocultural causes of mental illness are related to the way a person balances emotions, thoughts, and interactions in society. When this balance shifts rapidly, a person may experience emotional turmoil that results in crisis. Factors that may be related to sociocultural causes of behavioral emergencies include personal relationships, family stability, economic status, social cohesion, work environment, and personal belief systems and values. Changes in behavior caused by personal or situational stress often are linked to a specific event (e.g., the death of a loved one) or a series of events. Examples include environmental violence related to society (e.g., war, terrorism, riots), personal violence (e.g., rape, assault), ongoing discrimination or prejudice, and economic and employment problems.

ASSESSMENT AND MANAGEMENT OF BEHAVIORAL EMERGENCIES

The initial assessment and management of a patient with a behavioral emergency are similar to those used in any other EMS response. These steps include ensuring scene safety, containing the crisis, providing proper emergency medical care, and transporting the patient to an appropriate health care facility. In addition, most EMS services have protocols that call for law enforcement personnnel to evaluate the scene for possible danger and to control any acts of aggression by the patient.

Assessment

Paramedics should begin the assessment by creating a rapport with the patient. They can do this while gathering information needed for immediate management of life-threatening conditions. On arrival, paramedics should survey the scene for any relevant details. These may include

BOX 35-1 Top 10 Myths About Mental Illness

Myth: *1:* Psychiatric disorders are not true medical illnesses like heart disease and diabetes. People who have a mental illness are just "crazy."

Fact: Brain disorders, like heart disease and diabetes, are true medical illnesses. Research shows that psychiatric disorders have genetic and biological causes. Also, these diseases can be treated effectively.

Myth: *2:* People with a severe mental illness, such as schizophrenia, are usually dangerous and violent.

Fact: Statistics show that the incidence of violence among people who have a brain disorder is not much higher than it is in the general population. Individuals suffering from a psychosis such as schizophrenia are more often frightened, confused, and despairing than violent.

Myth: *3:* Mental illness is the result of bad parenting.

Fact: Most experts agree that genetic factors, along with other risk factors, lead to psychiatric disorders. In other words, mental illnesses have a physical cause.

Myth: *4:* Depression results from a personality weakness or character flaw. People who are depressed could just snap out of it if they tried hard enough.

Fact: Depression has nothing to do with being lazy or weak. It results from changes in brain chemistry or brain function. Medication and/or psychotherapy often help people to recover.

Myth: *5:* Schizophrenia means that the person has a split personality, and there is no way to control it.

Fact: Schizophrenia is often confused with multiple personality disorder. Actually, schizophrenia is a brain disorder that robs people of their ability to think clearly and logically. An estimated 2.5 million Americans have schizophrenia. Their symptoms range from social withdrawal to hallucinations and delusions. Medication has helped many of these people to lead fulfilling, productive lives.

Myth: *6:* Depression is a normal part of the aging process.

Fact: It is not normal for older adults to be depressed. Signs of depression in older people include a loss of interest in activities, sleep disturbance, and lethargy. Depression in the elderly is often undiagnosed. Older adults and their family members need to recognize the problem and seek professional help.

Myth: *7:* Depression and other illnesses, such as anxiety disorders, do not affect children or adolescents. Any problems they have are just a part of growing up.

Fact: Children and adolescents can develop severe mental illnesses. In the United States, 1 in 10 children and adolescents has a mental disorder severe enough to cause impairment. Yet only about 20% of these children receive treatment. Left untreated, these problems can worsen. *Anyone who talks about suicide should be taken very seriously.*

Myth: *8:* If you have a mental illness, you can will it away. Being treated for a psychiatric disorder means an individual has in some way "failed" or is weak.

Fact: A serious mental illness cannot be willed away. Ignoring the problem does not make it go away, either. It takes courage to seek professional help.

Myth: *9:* Addiction is a lifestyle choice and shows a lack of willpower. People with a substance abuse problem are morally weak or "bad."

Fact: Addiction is a disease that generally results from changes in brain chemistry. It has nothing to do with being a "bad" person.

Myth: *10:* Electroconvulsive therapy (ECT), formerly known as "shock treatment," is painful and barbaric.

Fact: ECT has given a new lease on life to many people who suffer from severe and debilitating depression. It is used when other treatments such as psychotherapy or medication fail or cannot be used. Patients who receive ECT are asleep and under anesthesia; therefore they do not feel anything.

National Alliance for Research on Schizophrenia and Depression: *Top 10 myths about mental illness based on a nationwide survey,* Great Neck, NY, 2003.

evidence of substance abuse, a suicide attempt, or other clues that may shed light on the patient's state. The patient should be observed for emotional response, such as fear, anger, confusion, or hostility. While providing patient care, the paramedic should focus the evaluation on the patient's level of cognitive functioning. This includes alertness, orientation, speech patterns, **affect,** and the way in which the patient interacts with friends, loved ones, and family members. When possible, the number of people around the patient should be limited. This helps to control the scene. Anyone who interferes with the scene or the patient assessment or who adversely affects the patient's condition should be removed from the area.

Other information can be volunteered by the patient, obtained from the patient interview, or provided by family members, bystanders, and first responders. The patient's family or caregiver should be interviewed about the patient's usual level of functioning, about recent stress in the patient's life, and about approaches that may help the paramedic to gain the patient's trust and cooperation. Information that should be obtained for a full background and history of the event include significant medical history, medications the patient has taken (Table 35-1), past psychiatric problems, and any precipitating factors that may have contributed to the behavioral emergency.

Interview Techniques

After managing any life-threatening illness or injury, the patient should be interviewed if possible. The paramedic should not ask for more details than are needed. A limited

BOX 35-2 Common Medical Conditions That Manifest as Behavioral Disorders

Metabolic Disorders
Glucose, sodium, calcium, or magnesium imbalance
Acid-base imbalance
Acute hypoxia
Renal failure
Hepatic failure

Endocrine Disorders
Thyroid disease
Parathyroid disease
Adrenal hormone imbalance

Infectious Diseases
Encephalitis
Meningitis
Brain abscess
Severe systemic infection

Trauma
Concussion
Intracranial hematoma (especially subdural hematoma)

Cardiovascular Disorders
Cardiac dysrhythmia
Hypotension
Transient ischemic attack
Cerebrovascular accident (or stroke)
Hypertensive encephalopathy

Neoplastic Diseases
Central nervous system tumors or metastases

Degenerative Diseases
Dementia of the Alzheimer's type
Other dementias

Drug Abuse
Alcohol
Barbiturates
Narcotics
Sedative-hypnotics
Amphetamines and other stimulants
Hallucinogens

Drug Reactions
Beta-adrenergic blockers
Antihypertensives
Cardiac drugs
Bronchodilators
Beta-adrenergic agonists
Anticonvulsants

and supportive interview strengthens the paramedic's rapport with the patient. It also can help to establish and maintain a relationship during the provision of patient care. As described in Chapter 17 and Chapter 18, effective interview techniques include active listening, showing

DID YOU KNOW?

Unemployment: Link to Mental Illness[2]

The U.S. recession that began in 2007 resulted in a national unemployment rate of nearly 10%. Following are key findings of a survey done by the National Alliance on Mental Illness:

- 13% of unemployed individuals report that they have thought of harming themselves, which is four times more than reported by persons with full-time work.
- People who are unemployed are approximately six times as likely to have difficulty paying household expenses—22% report great difficulty paying their utilities and almost 50% have significant difficulty in obtaining health care, further compounding their situation.
- People who are unemployed are also twice as likely to report concern with their mental health or use of alcohol or drugs within the last 6 months than individuals working full time.
- Of those who have not spoken to a health professional about these concerns, 42% cited cost or lack of insurance coverage as the main reason.
- Nearly 20% of the sample reported that they had experienced a forced change (e.g., pay cuts, reduced hours) in their employment during the last year.
- Although most of these individuals are employed, individuals with a forced change in employment are twice as likely to report symptoms consistent with severe mental illness than would be expected. They are also five times more likely to report feeling hopeless most or all of the time than individuals who had not experienced a forced change.

support and empathy, preventing interruptions, and respecting the patient's personal space by limiting physical touch (Box 35-3).

MENTAL STATUS EXAMINATION

A **mental status examination** (MSE) is an evaluation tool that can help the paramedic during the patient assessment. Although many variations of an MSE are available (Box 35-4), most include an assessment of appearance and behavior, speech and language, cognitive abilities, and emotional stability.[3] The following factors should be assessed in each of these areas.

Appearance and Behavior
- How does the patient look? Is the person neatly dressed and well groomed?
- Is the patient pleasant and cooperative or agitated?
- Is the patient's behavior appropriate for the particular situation?
- What is the patient's body language?
- Do body movements or posture suggest tension, anxiety, hostility, or aggression?
- Does the patient maintain eye contact during the patient interview?

Speech and Language
- Is the patient's speech intelligible and normal in tone, volume, and rate?

TABLE 35-1 Examples of Drugs Used to Treat Psychiatric Disorders

Trade Name(s)	Generic Name	Drug Class
Abilify	Aripiprazole	Antipsychotic
Adderall	(amphetamine/dextroamphetamine)	ADHD
Akineton	Biperiden	Antiparkinson agent
Anafranil	Clomipramine	Antidepressant
Asendin	Amoxapine	Antidepressant
Ativan	Lorazepam	Antianxiety
Aventyl	Nortriptyline	Antidepressant
Thorazine, Largactil, Chlorpromanyl, Novo-Chlorpromazine	Chlorpromazine	Antipsychotic
Celexa	Citalopram	SSRI
Clozaril	Clozapine	Antipsychotic
Cogentin, Apo-Benztropine, PMS Benztropine	Benztropine mesylate	Antiparkinson agent
Cymbalta	Duloxetine	Antidepressant
Desyrel	Trazodone	Antidepressant
Effexor	Venlafaxine	Antidepressant
Elavil, Levate, Apo-Amitriptyline, Novo-Triptyn, PMS Amitriptyline	Amitriptyline	Antidepressant
Eldepryl, SD Deprenyl	Selegiline	Antiparkinson agent
Fluanxol	Flupenthixol dihydrochloride	Antipsychotic
Geodon	Ziprasidone	Antipsychotic
Lexapro	Escitalopram	SSRI antidepressant
Modecate, Apo-Fluphenazine, Permitil, Moditen	Fluphenazine	Antipsychotic
Haldol, Apo-Haloperidol, Novo-Peridol, Peridol, PMS Haloperidol	Haloperidol	Antipsychotic
Kemadrin, PMS Procyclidine, Procyclid	Procyclidine	Antiparkinson agent
Lithium, Lithane, Carbolith, Duralith, Lithizine	Lithium carbonate	Antipsychotic
Luvox	Fluvoxamine maleate	Antidepressant
Marplan	Isocarboxazid	Antidepressant
Mellaril, Apo-Thioridazine, Novo-Ridazine, PMS Thioridazine	Thioridazine	Antipsychotic
Nardil	Phenelzine	Antidepressant
Neuleptil	Pericyazine	Antipsychotic
Norpramin, Pertofrane	Desipramine	Antidepressant
Nozinan	Methotrimeprazine	Antipsychotic
Orap	Pimozide	Antipsychotic
Parnate	Tranylcypromine	Antidepressant
Parsitan, Profenamine	Ethopropazine	Antiparkinson agent
Paxil	Paroxetine	SSRI
Piportil L4	Pipotiazine	Antipsychotic
Promazine	Promazine	Antipsychotic
Prozac	Fluoxetine	Antidepressant
Remeron	Mirtazapine	Antidepressant
Ritalin	Methylphenidate	Cerebral stimulant
Risperdal	Risperidone	Antipsychotic
Seroquel	Quetiapine	Antipsychotic
Serentil	Mesoridazine	Antipsychotic
Serzone	Nefazodone	Antidepressant
Sinequan, Novo-Doxepin, Triadapin	Doxepin	Antidepressant
Stelazine, Apo-Trifluoperazine, PMS Trifluoperazine, Terfluzine, Novo-Flurazine, Solazine	Trifluoperazine	Antipsychotic
Stemetil, Prorazin, PMS Prochlorperazine	Prochlorperazine	Antipsychotic
Surmontil, Apo-Trimip, Novo-Trimpramine, Rhotrimine	Trimipramine	Antidepressant
Tegretol, Apo-Carbamazepine, Mazepine, Novo-Carbamaz PMS	Carbamazepine	Antipsychotic
Tofranil, Apo-Imipramine, Impril, Novopramine, PMS Imipramine	Imipramine	Antidepressant
Trilafon, Apo-Perphenazine, PMS Perphenazine	Perphenazine	Antipsychotic
Triptil	Protriptyline	Antidepressant
Valium, Apo-Diazepam, Diazemuls, Novodipam, PMS Diazepam, Vivol	Diazepam	Antianxiety
Wellbutrin	Bupropion	Antidepressant
Xanax, Apo-Alpraz, Novo-Alprazol, Nu-Alpraz	Alprazolam	Antianxiety
Zoloft	Sertraline	SSRI Antidepressant
Zyprexa	Olanzapine	Antipsychotic

ADHD, Attention-deficit/hyperactivity disorder; SSRI, selective serotonin reuptake inhibitor.

BOX 35-3
Ten Useful Interviewing Skills for Behavioral Emergencies

1. Listen to the patient in a caring, concerned, and receptive manner. Be aware of nonverbal cues. Examples of such are eye contact, facial expression, and posture. These can reassure the patient that you are responding with empathy.
2. Elicit feelings as well as facts to help develop a more accurate impression of the patient. If the patient is anxious, encourage the person to share details relevant to that feeling.
3. Respond to the patient's feelings by acknowledging and labeling them. (For example, you might say, "You seem angry.") This may help validate and legitimize the patient's intense and sometimes overwhelming feelings.
4. Correct cognitive misconceptions or distortions. If a distorted sense of reality is producing fear or anxiety, offer a simple and correct explanation.
5. Explain to the patient the care the person can expect to receive upon arrival at the hospital.
6. Offer honest and realistic reassurance and support. Providing this support helps calm the patient and establishes rapport.
7. Ask effective questions. Ask closed-ended questions if you are seeking immediate information. For example, "Are you thinking of hurting yourself?" and "What medicines did you take?" Open-ended questions are appropriate after you have identified problems that require immediate attention. Such questions allow the patient to develop answers that usually help the paramedic more fully understand the problem.
8. Avoid questions that may lead the person to say things he or she did not intend.
9. Structure the interview to develop a pattern rather than allowing a natural flow of details. Histories or sequences of events in chronological order usually allow for a fuller understanding of the patient's problem. (This is particularly true for causal relationships.) This order also helps the patient to organize thoughts. Keep the patient's responses focused. This can be done by using comments such as "What happened next?" and "Was that before or after what you were just telling me about?"
10. Conclude the interview. After getting the relevant information, encourage the patient to describe other important events or feelings.

Modified from Bassuk EL: *Behavioral emergencies: a field guide for EMTs and paramedics,* Boston, 1983, Little, Brown.

- Does the tone of the patient's voice change?
- Is speech spontaneous, with ease of expression?
- Do the patient's words and sentences proceed in an orderly fashion?

Cognitive Abilities

- Is the patient oriented to person, time, and place?
- Does the patient know who and where he or she is?
- Does the patient know who you are?
- Can the patient remain focused on your questions and conversation?
- What is the patient's attention span?

BOX 35-4 COASTMAP

A memory aid that may help direct components of the mental status exam is COASTMAP[4]:

C: Consciousness
O: Orientation
A: Activity
S: Speech
T: Thought
M: Memory
A: Affect and mood
P: Perception

- Can the patient follow a series of short commands?
- Does the patient respond to directions appropriately?
- Are the patient's comments logical and presented in an organized fashion?

Emotional Stability

- Is the patient aware of his or her environment?
- Can the patient describe or rate his or her mood using a scale of 1 to 10?
- Does the patient appear happy, sad, depressed, or angry?
- Is the patient's mood appropriate for the specific situation?
- Does the patient show mood swings or behaviors that indicate anxiety, depression, anger, or hostility?
- Does the patient stay focused during the interview or stray quickly to related topics?
- Is the patient experiencing perceptual distortions or hallucinations?

CRITICAL THINKING

Think about interviewing techniques that you have seen EMS crews use when caring for patients with behavioral emergencies. Were the techniques effective? Could the paramedics have improved their patient care by using any of the techniques listed in Box 35-3?

DIFFICULT PATIENT INTERVIEWS

Some patients with behavioral or psychiatric disorders are difficult to interview. For example, a patient may refuse to talk to the paramedic. (This may be the case especially if the family requested EMS assistance without the patient's consent.) A patient may be extremely talkative and have disorganized speech. In addition, a patient may be confrontational. If a patient refuses to be interviewed, paramedics should speak to the patient in a quiet voice. They should avoid questions that the patient may see as an "interrogation." Also, paramedics should allow the patient extra time to respond. Patients who are too talkative need to have their attention focused on the interview. To do this, the paramedic can raise a hand or call the person's name. With a confrontational patient, additional help may be required to ensure scene safety.

Other Patient Care Measures

After the initial assessment and history taking, the remainder of the examination is determined by the patient's overall condition and the nature of the psychiatric problem. The benefits of a thorough physical examination must be weighed against the risks of a patient who might construe the exam as a physical violation. If there is reason to suspect an organic cause for the patient's condition, a physical examination should be performed. Otherwise, patient care for a person with a behavioral emergency may be limited to maintaining an effective rapport with the patient during transfer to the hospital.

SPECIFIC BEHAVIORAL AND PSYCHIATRIC DISORDERS

More than 250 psychiatric conditions have been identified by mental health professionals. In addition, some patients may have symptoms that are associated with more than one condition. The following are common classifications of mental disorders discussed in this chapter[4]:

- Cognitive disorders
- Schizophrenia
- Anxiety disorders
- Mood disorders
- Substance-related disorders
- Somatoform disorders
- Factitious disorders
- Dissociative disorders
- Eating disorders
- Impulse-control disorders
- Personality disorders

NOTE

The American Psychiatric Association (APA) also has identified major classes of psychiatric disorders. These are known as *DSM-IV-TR* groups.[5] (*DSM-IV-TR* refers to the APA's *Diagnostic and Statistical Manual of Mental Disorders,* edition 4, text revision, which was published in 2000.) Many mental health professionals use these classifications for diagnostic purposes. In addition to the disorders listed in the text, other *DSM-IV* classes of psychiatric disorders include the following:

Disorders First Diagnosed in Infancy, Childhood, and Adolescence

- Delirium, dementia, amnesia, and other cognitive disorders
- Psychotic disorders other than schizophrenia
- Mental disorders caused by a general medical condition
- Sexual and gender identity disorders
- Sleep disorders
- Adjustment disorders
- Other conditions that may be the focus of clinical attention

Patient care for most behavioral emergencies is mainly supportive. It usually involves providing emotional support, assessing and managing coexisting emergency medical problems, and transporting the patient for evaluation by a physician. In some cases paramedics may need to take measures to protect the patient and others from harm. This includes the possible use of physical and chemical restraint (described later in this chapter).

Cognitive Disorders

Cognitive disorders may have an organic cause (e.g., a disease process). They also may be a result of physical or chemical injury, such as trauma or drug abuse. All cognitive disorders result in a disturbance of cognitive functioning. This may manifest as delirium or dementia (previously described in Chapter 25) or autism spectrum disorder.

DELIRIUM

Delirium is an abrupt disorientation of time and place. It usually involves delusions and hallucinations. **Delusions** are false beliefs. **Hallucinations** are the perception of sights, sounds, and other sensory phenomena that are not actually present. The symptoms vary according to an individual's personality, the environment, and the severity of the illness. Common signs and symptoms of delirium include inattention, memory impairment, disorientation, clouding of consciousness, and vivid visual hallucinations. Treatment of delirium is aimed at correcting the underlying physical disorder to reduce anxiety (Box 35-5). Sedatives may be required to manage the patient. The exact occurrence rate of delirium is unknown. However, some groups of people are more susceptible to delirium than others. These groups include the following:

- Older adults
- Children

BOX 35-5 Agitated Delirium

Agitated delirium or excited delirium describes a person with delirium who has (1) acute onset and fluctuating course, (2) reduced clarity of awareness of the environment, (3) perceptual disturbance, disorientation, or memory disturbance, and (4) an underlying general medical condition. Agitated delirium is not currently recognized as a medical or psychiatric condition by the America Psychiatric Association or the World Health Organization. It is a label assigned to the state of acute behavioral disinhibition manifested in a cluster of behaviors that may include bizarreness, aggressiveness, agitation, ranting, hyperactivity, paranoia, panic, violence, public disturbance, surprising physical strength, profuse sweating attributable to hyperthermia, respiratory arrest, and death.[6] Excited delirium has been reported to result from substance intoxication, psychiatric illness, alcohol withdrawal, head trauma, or a combination of these factors. The condition has gained public notice because it often is blamed for the deaths of persons being restrained by law enforcement personnel or who have died while in custody.[7]

- Burn patients
- Patients who have had major heart surgery
- Patients who have had a previous brain injury (e.g., stroke)
- Patients with acquired immunodeficiency syndrome (AIDS)

DEMENTIA

Dementia is a clinical state characterized by loss of function in multiple cognitive domains. It is a slow, progressive loss of awareness of time and place. It usually involves an inability to learn new things or to remember recent events. About 75 types of dementia have been identified (Box 35-6). However, most cases result from cerebrovascular disease (including stroke) and Alzheimer's disease (described in Chapter 25). Dementia is a major health problem in the United States because of Americans' long life spans. The disorder affects about 10% of those over age 65 and nearly 50% of those over age 85.[8] The personal habits of patients with dementia often deteriorate. Speech may become incoherent. Also, many of these patients revert to a "second childhood." These patients need total care for feeding, toileting, and physical activities. Treatment of certain illnesses may help to slow the mental decline associated with this disease.

Delirium and dementia may be difficult to differentiate. This is because both may cause disorientation and impaired memory, thinking, and judgment. Dementia usually occurs in people without diminished alertness, appears slowly, and worsens over time. Sleeping and waking problems occur less often in people with dementia than in those with delirium. People with dementia may have difficulty with short- and long-term memory, as well as impairment of judgment and abstract thinking. Delirium sometimes may occur at the same time as dementia. This is especially the case in older adults or people with chronic illnesses.

CRITICAL THINKING

Besides auditory hallucinations, think of other sensory hallucinations that can occur in these patients.

AUTISM SPECTRUM DISORDER

Autism spectrum disorder (ASD) is a range of neurodevelopmental disorders that include *autistic disorder* (classic autism), *Asperger's syndrome*, and *Pervasive Developmental Disorder-Not Otherwise Specified* (PDD-NOS, or atypical autism) (Box 35-7). Each of these disorders is characterized by three sets of behavioral features: (1) impairment in social interaction, (2) communication deficits (both verbal and nonverbal), and (3) restricted, repetitive behaviors, including decreased imaginative play, stereotyped behaviors, and inflexible adherence to routines. The degree to which these behaviors are manifested may vary between the disorders as well as between each individual. The symptoms of ASD can usually be observed in infants by 18 months of age, but often are unnoticed and therefore undiagnosed (Box 35-8). Autism spectrum disorders are more common in boys; in siblings of those with autism; and in people with certain developmental disorders (e.g., inherited mental retardation).

Children and adults with autism may engage in self-injurious behaviors such as hitting themselves, head

BOX 35-6 Some Causes of Dementia

Degenerative Diseases
Huntington's disease
Parkinson's disease (not in all cases)
Cerebellar degenerations
Amyotrophic lateral sclerosis (not in all cases)
Rare genetic and metabolic diseases

Vascular Dementia
Multiinfarct dementia
Microinfarct dementia
Large infarct dementia
Cerebral embolic disease

Anoxic Dementia
Cardiac arrest
Cardiac failure (severe)
Carbon monoxide poisoning

Traumatic Dementia
Dementia pugilistica (boxer's dementia)
Head injury (open or closed)

Infectious Dementia
Acquired immunodeficiency syndrome (AIDS) dementia
Opportunistic infection
Postencephalitic dementia
Herpes dementia
Fungal meningitis or encephalitis
Bacterial meningitis or encephalitis
Parasitic encephalitis
Brain abscess
Neurosyphilis (general paresis)

Space-Occupying Lesions
Chronic or acute subdural hematoma
Primary brain tumor
Metastatic tumor

Autoimmune Disorders
Disseminated lupus erythematosus
Vasculitis

Toxic Dementia
Alcohol
Metals (e.g., lead, mercury, arsenic)
Organic poisons (e.g., solvents, some insecticides)

BOX 35-7 Forms of Autism

Autistic disorder: Generally classified by impairment in social interactions and communication and includes some restrictive or repetitive behaviors.

Asperger's syndrome: A syndrome characterized by impairments in social interactions and the presence of restricted interests and activities, with no clinically significant general delay in language, and testing in the range of average to above average intelligence.

Pervasive Developmental Disorder-Not Otherwise Specified: A general category of disorders characterized by severe and pervasive impairment in several areas of development, including having communication and social deficits.

BOX 35-8 Possible Red Flags for Autism[11]

- The child does not respond to his/her name.
- The child cannot explain what he/she wants.
- The child's language skills are slow to develop or speech is delayed.
- The child does not follow directions.
- At times, the child seems to be deaf.
- The child seems to hear sometimes, but not other times.
- The child does not point or wave "bye-bye."
- The child used to say a few words or babble, but now he/she does not.
- The child throws intense or violent tantrums.
- The child has odd movement patterns.
- The child is overly active, uncooperative, or resistant.
- The child does not know how to play with toys.
- The child does not smile back when you smile at him/her.
- The child has poor eye contact.
- The child gets "stuck" doing the same things over and over and cannot move on to other things.
- The child seems to prefer to play alone.
- The child gets things for himself/herself only.
- The child is very independent for his/her age.
- The child does things "early" compared to other children.
- The child seems to be in his/her "own world."
- The child seems to tune people out.
- The child is not interested in other children.
- The child walks on his/her toes.
- The child shows unusual attachments to toys, objects, or schedules (e.g., always holding a string or having to put socks on before pants).
- The child spends a lot of time lining things up or putting things in a certain order.

banging, biting or scratching themselves, and picking at skin or sores. In addition, a person with autism may not respond in a normal fashion to pain. This, combined with an impaired ability to communicate, can present the paramedic with challenges in assessment and patient care. Paramedics should employ the therapeutic communications techniques described in Chapter 27. They should also be prepared to provide gentle restraint to ensure personal safety, and the safety of the patient and others.

NOTE

Recent studies estimate that 1 in every 110 children is diagnosed with autism (about 36,500 children each year).[9] An estimated 1.5 million people in the United States and tens of millions worldwide are affected by the disorder. Government statistics suggest the prevalence rate of autism is increasing 10% to 17% annually. This rise may be due to changes in diagnostic criteria (resulting in an increase in diagnosis), rather than an increase in actual illness.[10] The cause of the vast majority of cases is unknown. Possible causes include genetics, exposure to chemicals or infectious agents, immune system regulation, and inflammation of the central nervous system, among others.

There is no cure for ASD. Therapies and early behavioral interventions to manage specific symptoms can result in substantial improvement in some patients. There are many different types of treatments available for ASD. These treatments may include auditory training, discrete trial training, and vitamin therapy. Other treatments may include facilitated communication, music therapy, occupational therapy, physical therapy, sensory integration, and applied behavioral analysis. The different types of treatments can generally be broken down into the following categories[9]:

- Behavior and communication approaches
- Dietary approaches
- Medication
- Complementary and alternative medicine

Schizophrenia

Schizophrenia is a group of disorders characterized by recurrent episodes of **psychotic behavior.** Psychotic behavior can be defined as an inability or unwillingness to recognize and acknowledge reality and to relate with others (Box 35-9). Although the exact cause of the disease has not yet been identified, it may result from a combination of genetics (a family history of schizophrenia often exists), chemical and hormonal changes, autoimmune illness, viral infection, and other stress factors.[12] Schizophrenia usually becomes apparent during adolescence or early adulthood (Box 35-10).[13] Signs and symptoms of the illness appear slowly over time. They become more pronounced and bizarre as the disease progresses. These patients often develop abnormalities of thought processing, thought content, perception, and judgment. Hallmarks of the disease are **paranoia** (intense and irrational feelings of mistrust or suspicions), delusions, and auditory hallucinations (e.g., hearing voices that insult or make demands) (Box 35-11).

Many patients with schizophrenia function quite well with drug therapy. Others function poorly between frank psychotic episodes. These episodes often are the result of failure to comply with drug therapy. Most patients require lifelong therapy with antipsychotic drugs and medications that block the action of dopamine. Compliance with drug therapy often controls symptoms of the disease. (Noncompliance with medications is common in these patients.)

BOX 35-9 Acute Psychosis

The term acute psychosis refers to a patient who presents with one or more of the following criteria: a sudden onset of delusions that rapidly change; hallucinations; bizarre behavior and posture; or disorganized speech.[5] Acute psychosis may be related to mental illness, or it may have a biological cause (*organic psychosis*). The acute psychotic episode may be brief, lasting 1 day to 1 month, or of longer duration. The incidence of the disorder is not common. It is more likely to affect women than men, and is most common in people who are in their third and fourth decades of life.[14]

BOX 35-10 Facts About Schizophrenia

- More than 2.4 million adult Americans are affected by schizophrenia.
- In men, schizophrenia usually appears in the late teens or early twenties.
- In women, schizophrenia usually appears in the twenties to early thirties.
- Schizophrenia affects men and women with equal frequency.
- Most people with schizophrenia suffer chronically throughout their lives.
- One in 10 people with schizophrenia eventually commits suicide.
- Schizophrenia costs the United States more than $48 billion annually.

However, the drugs may produce side effects, especially **dyskinesia** (abnormal muscular movements) and tremor.

Anxiety Disorders

A certain amount of anxiety is useful and necessary for adapting constructively to stress (see Chapter 2: Well-Being of the Paramedic). However, a patient who suffers from an anxiety disorder has a persistent, fearful feeling that cannot be consciously related to reality (Box 35-12).[13] This type of illness can be disabling. The patient may withdraw from daily activities. This is usually an unsuccessful attempt to avoid the episodes of intense activity. Severe anxiety disorders may manifest in a **panic disorder** ("panic attack"). As compared to anxiety disorders that may result from acute grief or various phobias, for example, panic disorders often have no precipitating cause of the attack. Signs and symptoms of panic disorders include (Box 35-13)[13]:

- Hyperventilation
- Feeling of breathlessness or smothering
- Blurred vision
- Perioral and hand and foot paresthesias
- Fear of losing control
- Fear of dying

BOX 35-11 Responding to Paranoia, Delusions, and Hallucinations

1. First, assess whether the problem is troublesome or frightening to the person experiencing it. If not, ignoring it may be the best approach.
2. If a person seems to be hallucinating, leave the individual alone or approach slowly so as not to frighten the person. Respond with caution.
3. Do not try to argue or rationalize. Realize that hallucinations and delusions seem very real to the person who is experiencing them. Arguing does not build trust.
4. Offer reassurance and validation. You might say, "I know this is troubling for you. Let me see if I can help."
5. Check out the reality of the situation; maybe what the person sees or thinks is true.
6. Sometimes things in the environment may be misinterpreted (i.e., a glare or shadow in the window, a noisy furnace). These may be frightening. Explain the potential or actual misinterpretation (e.g., that the noise is the furnace turning on).
7. Modify the environment if necessary. (A mirror may become distracting or confusing; adding more lights may be helpful at night.)
8. Assess whether the person is having problems with hearing or vision. Resolving such problems can reduce the degree of disability.
9. Recall that whispering or laughing around the person may be misinterpreted.
10. Do not take any accusations personally.
11. Use distraction to try to pull the person's focus from the delusion or hallucination.
12. If the person asks you directly whether you see or hear something, be honest. However, do not struggle to convince or reason with the individual about what is real.
13. Try to respond to what the person may be feeling: insecurity, fear, and confusion.
14. Rule out any illnesses or the use of any medicines that could be contributing to the problem.
15. Use tact and firmness in persuading a patient to be transported to the hospital.

Modified from the Alzheimer's Association handout: *Hallucinations and delusions and understanding difficult behaviors,* Anne Robinson, Beth Spencer, Laurie White, Geriatric Education of Michigan University, Ypsilanti, Mich, 1991.

BOX 35-12 Facts About Anxiety Disorders

- About 40 million adults 18 years and older in the United States suffer from anxiety disorders.
- Most people have their first episode by 21.5 years of age.
- Anxiety disorders often are complicated by depression, eating disorders, or substance abuse.
- Anxiety disorders cost the nation more than $46 billion each year.

BOX 35-13 Facts About Panic Disorders

- Panic disorders affect about 6 million people in the United States each year.
- Panic disorders usually strike in young adulthood; about half of those affected develop the condition before age 24.
- Women are twice as likely as men to develop a panic disorder.
- People with a panic disorder also may suffer from depression and substance abuse. About 30% of people with panic disorder abuse alcohol; 17% abuse other drugs (e.g., cocaine, marijuana).
- About one third of those with a panic disorder develop agoraphobia.

- Somatic complaints
- Chest discomfort
- Palpitations or tachycardia
- Dyspnea
- Choking
- Faintness
- Syncope
- Vertigo
- Trembling and sweating
- Urinary frequency and diarrhea

Patient management is mainly supportive. The paramedic should assure these patients that although they may feel as if they are dying, they are not. Also, the paramedic should assure them that effective treatment is available. Panic attacks may mimic a number of medical emergencies, including myocardial infarction. Therefore any patient who shows the signs and symptoms described in the preceding list should be fully assessed at the scene and transported for evaluation by a physician. Sedation may be required. Patients with anxiety disorders should not be left alone.

PHOBIA

A **phobia** is a type of anxiety disorder. A person with a phobia has transferred anxiety onto a situation or an object in the form of an irrational, intense fear, such as a fear of heights, closed spaces, water, or other people. As the object or situation comes closer, the person's anxiety increases. If the crisis is allowed to continue, the patient's anxiety may escalate into a panic attack. These patients usually recognize that their fear is unreasonable. However, they cannot overcome the phobia. In some cases the phobia does not initiate the EMS response but becomes a secondary complication in emergency care. An example is a person who is phobic of water being trapped in a submerged vehicle.

CRITICAL THINKING

Do you know someone with an intense fear of a situation or object? How does this person behave when subjected to the object of the phobia?

BOX 35-14 Facts About Obsessive-Compulsive Disorder

- About 2.2 million American adults have obsessive-compulsive disorder (OCD) in a given year.
- First symptoms often begin in childhood and adolescence; median age of onset is 19.
- OCD affects men and women with equal frequency.
- The nation's social and economic losses caused by OCD total more than $8 billion each year.

When caring for patients with a phobia, the paramedic should take care to explain each step of an emergency or rescue procedure. The key is a careful rehearsal with the patient, in which the paramedic explains exactly what care will be given and how it will be performed. In addition, the EMS crew should show patience and understanding of the phobia. They should assure the patient that no forceful steps will be taken to place the person in an unwilling position.

OBSESSIVE-COMPULSIVE DISORDER

Obsessive-compulsive disorder (OCD) is a psychiatric disorder in which a person feels stress or anxiety about thoughts or rituals over which the individual has little control (Box 35-14).[13] The disorder can take many forms. These include excessive hand washing or showering, or upsetting thoughts (e.g., violence, vulgarities, harm to oneself or others). Obsessions also may involve special numbers, colors, single words or phrases, and sometimes melodies.

Although most adults realize to some degree that these obsessions and compulsions are without merit, they have great difficulty stopping them. Children with OCD may not realize that their behavior is unusual. OCD affects men and women equally, can start at any age, and may have a heritable component. People with OCD often cleverly hide their condition from family, friends, and co-workers. Medications and behavior therapy are often effective in controlling the symptoms of this disorder.

POSTTRAUMATIC SYNDROME

Posttraumatic stress disorder (PTSD) (*posttraumatic syndrome*) is an anxiety reaction to severe psychosocial events (Box 35-15).[13] These events often are life threatening. Examples include events associated with military service, natural and man-made disasters, and rape. The events often result in repetitive, intrusive memories. Manifestations of this illness may include depression, sleep disturbances, nightmares, and survivor guilt. The syndrome often is complicated by substance abuse.[14]

EMS personnel and other emergency responders may be subject to this syndrome as a result of their work. Examples include responding to major incidents with a large number of injured people, the death of a co-worker, a sudden infant

BOX 35-15 Facts About Posttraumatic Syndrome

- About 7.7 million people in the United States have posttraumatic syndrome during the course of a given year.
- Posttraumatic syndrome can develop at any age, including childhood; median age of onset is 23 years.
- Posttraumatic syndrome is more common in women than men.
- About 30% of men and women who have spent time in a war zone experience this disorder.
- Posttraumatic syndrome often occurs after violent personal assaults, such as rape, mugging, or domestic violence; terrorism; natural or human-caused disasters; and accidents.
- Depression, alcohol or other substance abuse, or another anxiety disorder often accompanies posttraumatic syndrome.

DID YOU KNOW?

PTSD

In the annual meeting of the American Public Health Association (APHA) in 2007, it was estimated that PTSD in veterans returning from Iraq and Afghanistan ranged from 12% to 20%. Other studies have reported as many as 10% of Gulf War veterans and as many as 30% of Vietnam veterans also suffer from PTSD.[15] The APHA meeting also estimated a minimum of 300,000 psychiatric casualties, and a lifetime cost of treatment in excess of $660 billion for veterans returning from Iraq and Afghanistan. The official 17 symptoms of PTSD associated with these veterans can be placed into 3 broad groups[16]:

- Reexperiencing: intrusive memories, nightmares, flashbacks, triggered distress
- Avoidance: isolation, withdrawal, emotional numbing, detachment, memory gaps
- Hyperarousal: insomnia, irritability, anger outbursts, poor concentration, hypervigilance, exaggerated startle response

death syndrome (SIDS) death, and the stress associated with responding to emergency calls (see Chapter 2: Well-Being of the Paramedic).

Mood Disorders

The term **mood disorder** is used to describe changes in emotions that a person experiences in life. (For example, these may include happiness, depression, fear, and anxiety.) Two conditions commonly associated with mood disorders are depression and bipolar disorder, both of which are associated with an increased risk of suicide.[4]

DEPRESSION

Depression is a mood disturbance characterized by feelings of sadness, despair, and discouragement. It is one of the most prevalent major psychiatric conditions, affecting 10% to 15% of the general population (Box 35-16).[13] Depression is usually episodic (episodes usually last longer than 1 month) with periods of remission. It is known to have

BOX 35-16 Facts About Depression

- More than 14.8 million adult Americans suffer from depression each year. Many are unnecessarily unable to function normally for weeks or months because their illness remains untreated.
- Almost twice as many women (12%) as men (7%) are affected by depressive illness each year.
- Depression is a frequent and serious complication of heart attack, stroke, diabetes, and cancer.
- Depression increases the risk of heart attack.
- Depression costs the nation more than $30 billion a year in direct and indirect costs.
- Major depression is the leading cause of disability in the United States.

either a gradual or a rapid onset, and at times a clustering of episodes. The depressed patient may show feelings of hopelessness, extreme isolation, tenseness, and irritability. In severe cases the depression may be followed by **anhedonia,** which is the inability to feel pleasure or happiness from experiences that ordinarily are pleasurable. Other effects of severe depression include insomnia or hypersomnia, weight loss from diminished appetite, weight gain from overeating, decreased libido, and deep feelings of worthlessness and guilt. The mnemonic *IN SAD CAGES* identifies the major features of depression.[17]

Interest
Sleep
Appetite
Depressed mood
Concentration
Activity
Guilt
Energy
Suicide

NOTE

Depression can be classified as dysthymia or clinical (major) depression. **Dysthymia** is a less severe form of depression that is chronic in nature, lasting as long as 2 years or more. In contrast to major depression (**clinical depression**), the symptoms of dysthymia may not always result in clinically significant distress. They are not always associated with impairment in social, occupational, academic, or other major areas of functioning (as is more common with clinical depression). Both forms of depression share similar symptoms, including depressed mood, disturbed sleep, low energy, and poor concentration. Parallel symptoms include poor appetite, low self-esteem, and hopelessness in dysthymia. The more severe symptoms of weight change, excessive guilt, and thoughts of death or suicide are associated with major depression. Dysthymia can often be treated effectively with counseling. Clinical depression usually requires medication therapy.

Depression is common in the elderly. It also is associated with an increased risk of suicide for all age groups (described

DID YOU KNOW?

Electroconvulsive Therapy (ECT)

ECT is provided to an anesthetized patient by passing a small electric current through the brain, producing a seizure. The current is supplied for 1 second or less while monitoring the patient's seizure activity (by electroencephalogram [EEG]) and cardiac rhythm (by electrocardiogram [ECG]). During the procedure, there may be brief hypotension and tachycardia, followed by a rise in blood pressure. The duration of a clinically effective seizure is 30 seconds to 1 minute or longer. ECT is usually given 3 times per week for a total of 3 to 15 treatments. Following the treatment, most patients regain consciousness within 10 to 15 minutes. They often will experience a brief period of confusion, headache, and muscle stiffness.

ECT is particularly useful for patients who cannot take antidepressants or for whom antidepressants are ineffective; for suicidal patients; and for pregnant women who suffer from mania or severe depression. It also can be effective in treating some forms of schizophrenia and other affective disorders. ECT has been reported to have a higher success rate for depression than any other form of treatment.[18]

later in this chapter). Care for depressed patients is directed at quietly talking to the patient about things that appear to be of interest and trying to gain responsiveness. Depression may be treated with antidepressant drug therapy, counseling, psychotherapy, and, in a small number of cases, **electroconvulsive therapy** (ECT).

BIPOLAR DISORDER

Bipolar disorder is a biphasic emotional disorder in which depressive and manic episodes alternate (Figure 35-2). **Mania** is characterized by excessive elation, talkativeness, flight of ideas, motor activity, irritability, accelerated speech, and, often, delusions that center around personal grandeur. Bipolar disorders sometimes develop slowly over time. However, they may occur abruptly and may be instigated by a single event. The manic phase can be very brief or can last weeks to months. Compared with depression, mania is rare.[14] The most frequent age for initial episodes is 20 to 35 years, with initial bouts of depression occurring about 10 years later (Box 35-17).[13] Many patients with bipolar disorder are treated with lithium. As described in Chapter 13: Principles of Pharmacology and Emergency Medications, lithium has a narrow therapeutic index; a common illness, such as influenza with diarrhea and/or vomiting, can result in lithium toxicity.

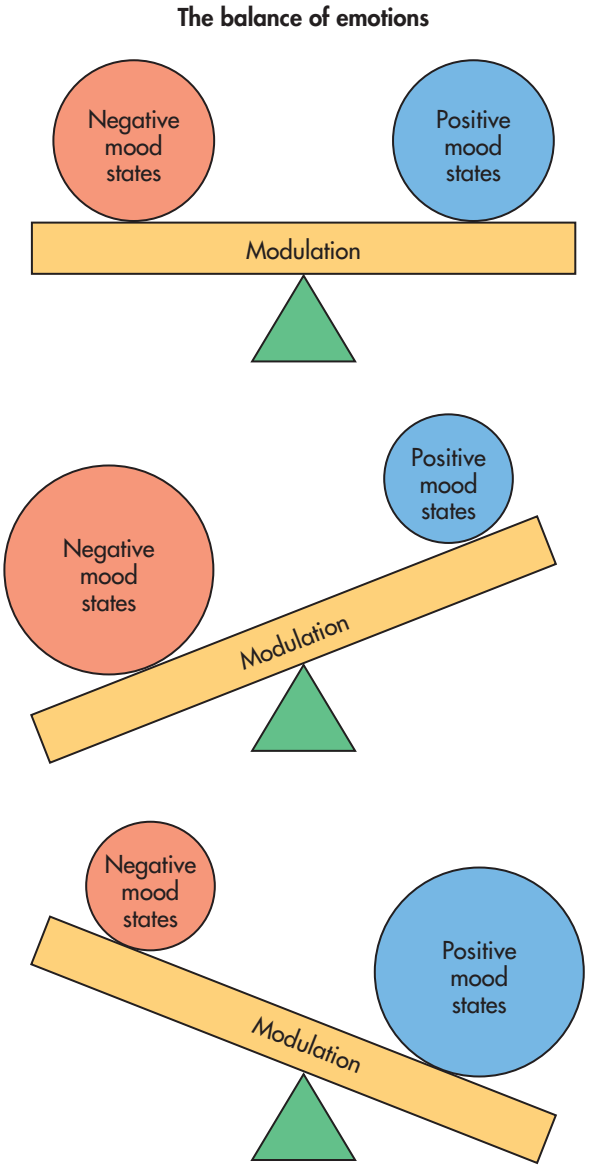

FIGURE 35-2 Bipolar disorder.

Emergency care should consist of calm, firm emotional support. It also should include transport for evaluation by a physician. If this is the patient's first manic episode, the paramedic should consider the possibility of drug abuse as a differential diagnosis. Stimulation should be kept to a minimum. If the patient's condition allows, EMS transport should proceed without using emergency lights and audible warning devices.

BOX 35-17 Facts About Bipolar Disorder

- More than 5.7 million Americans age 18 or older suffer from bipolar disorder in a given year. (This is about 2.6% of the U.S. population.)
- As many as 20% of people with bipolar disorder die by suicide.
- Men and women are equally likely to develop bipolar disorder.

CRITICAL THINKING

Do you think patients would be at higher risk for suicide during the depressive or the manic phase of bipolar disorder? Why?

SUICIDE AND SUICIDE THREATS

A threat of **suicide** is an indication that a patient has a serious crisis that calls for immediate intervention. In many cases suicide attempts are a cry for help. They also may be a form of direct or indirect communication. (The patient may be saying, "I don't want to live" or "I am angry with you.") Other suicide attempts are an effort by the patient to manipulate relationships so that the patient is surrounded by people who are ready and willing to provide advice and support (Box 35-18). In assessing the risk of suicide, the paramedic should consider these seven facts[19]:

1. In 2006 suicide was the eleventh leading cause of death for people of all ages; the seventh leading cause of death in males; and the sixteenth leading cause of death in females. More than 30,000 suicides occurred in the United States (91 suicides per day; 1 suicide every 16 minutes).
2. In the United States, Caucasian men older than age 75 have the highest suicide rate.
3. Women *attempt* suicide two to three times the rate at which men do.
4. Men *commit* suicide four times the rate at which women do (79% of all U.S. suicides).
5. Firearms are the most commonly used method for suicide in men. Poisoning is the most common method for suicide in women.
6. Among young adults 15 to 24 years of age, there are about 100 to 200 attempts for every completed suicide. Among adults older than 65 years of age, there are about 4 suicide attempts for every completed suicide.
7. The more specific and detailed the suicide plan, the greater the suicide potential.

Other factors associated with suicide threats include the recent death of a loved one or loss of a significant relationship, a financial setback or job loss, chronic or debilitating illness, social isolation, alcohol or other drug abuse, depression, and schizophrenia. If a suicide attempt is suspected, the paramedic should discuss these intentions with the patient. Questions such as the following are appropriate:

BOX 35-18 Myths About Suicide

Myth: People who talk about killing themselves rarely commit suicide.
Fact: Most people who commit suicide have given some clue or warning of their intent. *Suicidal threats and attempts should always be treated seriously.*
Myth: The tendency to commit suicide is inherited. It is passed from generation to generation.
Fact: Suicide does tend to run in families. However, the tendency does not appear to be transmitted genetically.
Myth: All suicidal people are deeply depressed.
Fact: Depression is often associated with suicidal feelings. However, not all people who kill themselves are obviously depressed. In fact, some suicidal people appear to be happier than they have been in quite a while because they have decided to "resolve" all their problems at the same time.
Myth: There is a very low correlation between alcoholism and suicide.
Fact: Alcoholism and suicide often go hand in hand. Alcoholics are prone to suicide. Even people who do not normally drink often ingest alcohol shortly before killing themselves.
Myth: Suicidal people are mentally ill.
Fact: Many suicidal people are depressed and distraught. However, most of them would not be diagnosed as mentally ill.
Myth: If a person attempts suicide, that individual will always entertain thoughts of suicide.
Fact: Most people who are suicidal are that way for only a brief period in their lives. An attempter who receives the proper assistance and support probably will never be suicidal again. Only about 10% of attempters later complete the act.
Myth: Asking a person about his or her suicidal intentions encourages the individual to act.
Fact: Actually, the opposite is true. Asking a person directly about suicidal intent often lowers the individual's anxiety level. In fact, it often acts as a deterrent to suicidal emotions.
Myth: Suicide is more common among the lower classes.
Fact: Suicide occurs in all socioeconomic groups. No one class is more susceptible to it than another.
Myth: Suicidal people rarely seek medical attention.
Fact: Research has consistently shown that about 75% of suicidal people visit a physician within 3 months of killing themselves.
Myth: Suicide is basically a problem limited to young people.
Fact: The suicide rate rises with age and reaches a peak among older Caucasian men.
Myth: Professional people do not kill themselves.
Fact: Physicians, lawyers, dentists, and pharmacists have high suicide rates.
Myth: When a person's depression lifts, the danger of suicide disappears.
Fact: The greatest danger of suicide exists during the first 3 months after a person recovers from a deep depression.
Myth: Suicide is a spontaneous activity that occurs without warning.
Fact: Most people plan their self-destruction. Then they give clues that they have become suicidal.
Myth: Because it includes the Christmas season, December has a high suicide rate.
Fact: No rash of suicides occurs at Christmas. In fact, December has the lowest rate of any month.

From Suicide Prevention Allied Regional Effort (SPARE): *The mythology of suicide,* Denver, www.mhaem.org/myths.htm, accessed 9-12-10.

"Do you have thoughts about killing yourself or others?" "Have you ever tried to kill yourself?" Many depressed patients are willing to discuss their suicidal (or homicidal) thoughts. During the patient interview, the paramedic should try to determine three important factors: (1) whether the patient has a plan (how and when the suicide will be done); (2) whether the plan is intended to be successful; and (3) whether the patient has the means or method to follow through with the plan.

CRITICAL THINKING

How would you feel about asking a patient, "Have you ever thought about killing yourself?"

When responding to a suicide attempt, paramedics should request police protection before approaching the scene. (Armed patients must be considered homicidal as well as suicidal.) After scene safety has been ensured and paramedics have gained access to the patient, the scene should be surveyed for the presence of dangerous objects (see Chapter 56).

The first priority in patient management is medical care. Unconscious patients should be managed with airway, ventilatory, and circulatory support and rapid transport. If the patient is conscious, creating rapport as soon as possible is essential. The paramedic should conduct a brief interview to assess the situation and determine the need for and direction of further action. To help reduce the potential for suicide, paramedics can take the following six steps:

1. Provide support and honest assurance about the patient's well-being.
2. Provide for physical safety as well as emotional security. Establish protective limits and measures. This helps to prevent injury to the patient or others. It also conveys to these patients that the paramedic will help them control their behavior until they can gain self-control.
3. Listen to the person, even if the speech seems bizarre, inappropriate, or unrealistic. Do not feel that every statement must be answered or that advice or opinions must be given. During the interview, acknowledge the patient's feelings; do not argue with the patient's wish to die. Explain alternatives to suicide that the patient may not have considered (e.g., counseling, support groups, pastoral care).
4. Determine the patient's support system or significant others when possible. Others may be better able to communicate with and calm the patient.
5. Encourage and reassure the patient during the crisis.
6. Transport the patient to the proper facility for emergency intervention.

Substance-Related Disorders

Some patients with a behavioral emergency may also be using alcohol or illegal drugs. This may cause difficulties during the physical examination. (Substance-related disorders are described in Chapter 34.) Often these patients are trying to "self-medicate" to improve their mood or lessen the anxiety associated with mental illness. Other patients self-medicate before receiving a diagnosis for their illness or before seeking professional help. Signs that may indicate alcohol or illicit drug use include a breath odor of alcohol, the presence of drug paraphernalia, and needle tracks on the extremities.

BOX 35-19 Facts About Dual Diagnosis

- About 50% of people with severe mental disorder are affected by substance abuse.
- About 37% of alcohol abusers and 53% of drug abusers also have at least one serious mental illness.
- Of all people diagnosed as mentally ill, 29% abuse either alcohol or other drugs.
- A patient with schizophrenia has a 10% higher than average risk of being an alcoholic or a drug abuser.

PATIENTS WITH A DUAL DIAGNOSIS

Some people struggle both with serious mental illness and with substance abuse. This *dual diagnosis* may be difficult to identify, because one disorder may mimic the symptoms of the other (Box 35-19).[20] It therefore is easy to attribute the patient's symptoms to only one of the two afflictions. It is estimated that as many as 50% of mentally ill individuals have a substance abuse problem. The drug most often used is alcohol. The next most commonly used drugs are marijuana and cocaine. Prescription drugs such as tranquilizers and sleeping medicines may also be abused. Factors associated with a dual diagnosis include the following:

- Recreational use of alcohol or other drugs
- Misguided attempts to self-medicate to relieve anxiety or depression
- Susceptibility to mental illness *and* substance abuse
- Environmental and social influences

Patients who have a dual diagnosis may alternate between requesting EMS assistance for mental illness and for substance abuse. Most psychiatric and drug counseling organizations agree that the two disorders must be treated at the same time.[20]

Somatoform Disorders
